PATHOPHYSIOLOGY

THE BIOLOGIC BASIS FOR DISEASE IN ADULTS AND CHILDREN

ABOUT THE COVER IMAGE

The cover image represents a stylized interface between genetics and epigenetics. Technological advances have changed our understanding of the genome and the role of transcriptional programs in the determination of cell fate and the response to environmental factors. We are beginning to understand how epigenetic modifications affect gene expression and alter cellular states without changing genomic DNA sequences. One analogy compares genetics to computer hardware with epigenetics as the software, software that may determine how the hardware behaves. Just as software can be tinkered with and erased, epigenetic marks may also be erasable, giving hope that we can intervene to change the landscape of the epigenome and prevent or cure disease. There is much to be learned and, over time, translated into clinical practice.

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

Pathophysiology incorporates basic, translational, and clinical research to advance understandings of disease and dysfunction. The study of pathophysiology involves many biomedical sciences and a wide range of research activities. Multiple aspects of cellular physiology are progressing rapidly, generating vast amounts of data to understand. The information expansion involves a greater understanding of the behavior of individual cells, of their neighboring microenvironment, and of the molecules that not only make up those cells but also communicate with their surroundings. Importantly, the forward movement of biomedical sciences occurs within the context of social, economic, and political processes that determine how disease is defined, experienced, and treated.

Interdisciplinary research has led to significant advancements in genetics, epigenetics, cell signaling and communication, control of cell behavior, metabolism, and cell fate. Knowledge about normal cell structures and signaling pathways is at the forefront of translational science. Advancements in tools to observe cells have provided new understanding of cellular processes including migration of tumor cells, responses of the immune system, and influences of the microenvironment. Investigators are studying if or how early life events affect health and disease into adulthood and across generations. A wide range of research is centered on microbial mechanisms of pathogenesis, immune responses, epidemiology, and drug efficacy and resistance.

Although these advancements have created an ever-increasing state of excitement, they have also created the problem of how students, teachers, and clinicians can cope with the expanding new information. Compressing these data into simplified discussions for students and clinicians is challenging. Our approach in this book has been to present an organized, logical sequence of content based on current literature and research reports with understandable explanations and accompanied by illustrations and summary tables. The primary focus is on pathophysiology, and there is less emphasis on the evaluation and treatment that is found in clinical management textbooks. As in previous editions, the following is a list of our specific goals for the textbook:

- Draw attention to differences in etiology, epidemiology, pathophysiology, clinical manifestations, and treatment according to gender and age.
- Pay careful attention to presentations of emerging new data on controversial topics.
- Integrate health promotion and disease prevention by updating risk factors, explaining certain relationships between nutrition and disease, and referencing screening recommendations and other therapeutic approaches.

ORGANIZATION AND CONTENT: WHAT'S NEW IN THE SEVENTH EDITION

The book is organized into two parts. Part One presents the cellular and tissue responses common to disease. The pathophysiology of disease, organized by body systems, is presented in Part Two. All content has been reviewed and updated with extensive new references and two new chapters.

Part One: Central Concepts of Pathophysiology: Cells and Tissues

Part One begins with an in-depth study of the cell and progresses to cover the underlying processes of disease. Concepts covered include cell signaling and cell communication processes; genes and common genetic diseases; epigenetics and disease; fluid, electrolyte, and acid-base balance; inflammation, cytokines and their biologic functions, and normal and altered immunity; infection, stress, coping, and immunity; tumor biology, epidemiology of cancer, and cancer in children. Particularly important revisions and additions to Part One include the following:

- Updated content on cellular organelles, the plasma membrane, cell signaling, and communication (Chapter 1)
- Updated content on agents of cell injury, oxidative stress, apoptosis, autophagy, and aging (Chapter 2)
- A new chapter on epigenetics and disease (Chapter 6)
- Updated content on normal innate and adaptive immunity (Chapters 7 and 8)
- Updated content on alterations of immunity and inflammation (Chapter 9)
- Updated content on infection (Chapter 10)
- Reorganization and updated content on stress and disease (Chapter 11)
- Extensive revisions and reorganization of tumor biology and invasion and metastases (Chapter 12)
- Extensive revisions and reorganization of epidemiology of cancer (Chapter 13)

Part Two: Pathophysiologic Alterations: Organs and Systems

Part Two is a systematic survey of diseases within body systems. Each unit focuses on a specific body system and begins with an anatomy and physiology chapter to provide a basis of comparison for understanding the alterations created by disease. A brief summary of normal aging is included at the end of the section on anatomy and physiology. The discussion of each disease in the alterations' chapters is developed in a logical manner that begins with an introductory paragraph on etiology and epidemiology, followed by pathophysiology, clinical manifestations, and evaluation and treatment. Separate chapters are dedicated to pediatric pathophysiology, and sensitivity is paid to gender and age. Especially significant revisions and additions to Part Two include the following:

- Updated information on chronic pain syndromes and classification of sleep disorders (Chapter 16)
- Updated content on concepts of alterations in consciousness, memory, delirium syndromes, and dementia. New information related to motor neuron and movement disorders

including Parkinson disease and amyotrophic lateral sclerosis (Chapter 17)
- Updated information on traumatic brain and spinal cord injury, degenerative disorders of the spine, stroke and headache syndromes, and multiple sclerosis (Chapter 18)
- Updated content on schizophrenia, mood disorders, and anxiety (Chapter 19)
- Updates on childhood cerebrovascular disease, seizure disorders, and brain tumors (Chapter 20)
- Extensive updates on diabetes mellitus, insulin resistance, and thyroid and adrenal gland disorders (Chapter 22)
- Extensively rewritten material on female reproductive disorders including cancer, benign breast diseases, and breast cancer (Chapter 24)
- A separate chapter on male reproductive disorders and cancer with extensive updating and reorganization (Chapter 25)
- Extensive updating of sexually transmitted infections (Chapter 26)
- Updated content on normal blood cells, hemostasis, platelet function, and coagulation (Chapter 27)
- Revised and updated content on alterations of leukocyte, lymphoid, and hemostatic function (Chapter 29)
- Extensively rewritten chapter on the anatomy and physiology of the cardiovascular and lymphatic systems (Chapter 31)
- Extensively updated coverage of atherosclerosis, endothelial injury and dysfunction, coronary artery disease, myocardial infarction, and heart failure (Chapter 32)
- Major revisions to the immune mechanisms of asthma, chronic lung disease; and updates for respiratory tract infection, pulmonary hypertension, pulmonary embolism, and lung cancers (Chapters 35)
- Major updates for childhood asthma, respiratory distress syndrome, cystic fibrosis, lung infections, and sudden infant death syndrome (Chapter 36)
- Updates on kidney stones, urinary tract infection, glomerulopathies, chronic renal failure, and bladder and kidney tumors (Chapter 38)
- New information for urinary tract infection, glomerulonephritis, and renal failure in children (Chapter 39)
- Updates on gastroesophageal reflux disease, peptic ulcer disease, irritable bowel syndrome, inflammatory bowel disease, intestinal obstruction, obesity, colon cancer, and liver disease (Chapter 41)
- New information on gluten-sensitive enteropathy, necrotizing enterocolitis, bowel obstruction, infections of the intestine, and liver disease in children (Chapter 42)
- Updated content on alterations of the musculoskeletal system (Chapter 44)
- Updated content on pressure ulcers, dermatitis and psoriasis, vesicular disorder, scleroderma, and skin cancer (Chapter 46)
- Updated content on childhood atopic dermatitis, skin infections, and immune drug reactions (Chapter 47)
- Extensive updating and reorganization of content on septic shock, multiple organ dysfunction syndrome, and burns for adults and children (Chapters 48 and 49)

FEATURES TO PROMOTE LEARNING

Ease of learning has been enhanced by designing a number of features that guide and support understanding, including:

- Each chapter opener notes the corresponding module in the Online Review Course. The course is available as a separate purchase. Details of the course can be reviewed at www.us.elsevierhealth.com.
- *Chapter Outlines* for each chapter
- *Special Headings* to underscore the consistent treatment of each disease—Pathophysiology, Clinical Manifestations, and Evaluation and Treatment
- More than 85 *What's New?* boxes review the most current research and clinical developments; a list of these is included on the inside front cover
- *Nutrition & Disease* boxes to emphasize nutrition as a health promotion strategy that may alter disease risk or pathogenesis
- End-of-chapter *Summary Review* sections summarize the content in each chapter and serve as built-in content review guides
- Boldface *Key Terms* with end-of-chapter term lists and page numbers for rapid access
- A comprehensive *Glossary* with approximately 1000 terms helps students with the often-difficult terminology related to pathophysiology

ART PROGRAM

The art program was carefully crafted. It received as much attention as the narrative. Nearly 200 new or revised full-color illustrations were created and strategically placed throughout the textbook. Also included are many new high-quality, full-color photographs of clinical manifestations, pathologic specimens, and clinical imaging techniques. The combination of illustrations, algorithms, and photographs and the use of color for tables and boxes allow clarification for complex concepts and the emergence of easily recognized essential information.

ANCILLARIES

For Students

On **Evolve**, at http://evolve.elsevier.com/McCance/, students can access 550 review questions, 100 animations to help students master the text content, 28 case studies with questions and answers, and downloadable chapter Key Point documents for each chapter.

The newly rewritten **Study Guide** includes many different question types, aiming to help all different types of student learners. Question types include the following:

- Choose the Correct Words
- Complete These Sentences
- Categorize These Clinical Examples
- Explain the Pictures
- Teach These People about Pathophysiology
- Plus many more…

Answers are found in the back of the Study Guide for easy reference for students.

For Instructors

The **Evolve Instructor Resources** for this textbook provide the following teaching aids:

- Teach for Nurses instructor manual, broken down by chapter, detailing the resources available to instructors for their lesson planning, and including unique case studies and class activities they can share with students
- Test Bank in ExamView with approximately 1900 questions (in multiple choice, multiple response, and matching formats) with answers, rationales, and textbook page references
- Image Collection with all of the approximately 1200 figures from the text
- PowerPoint lecture slides for each chapter (approximately 3400 slides and 420 images total), including integrated Audience Response Questions in each chapter (218 total), and integrated case studies at the end of each unit (15 total)

Evolve is an Internet-based learning environment that works in coordination with the text. This resource enables you to publish your class syllabus, outline, and lecture notes; set up "virtual office hours" and e-mail communication; share important dates and information through the online class calendar; and encourage student participation through chat rooms and discussion boards. Free with qualified adoption. Contact your sales representative or visit http://evolve.elsevier.com for more information about integrating **Evolve** into your curriculum.

ACKNOWLEDGMENTS

The enormous task of keeping this book current and readable greatly depends on our contributors; several new writers have joined our team for this edition. We thank them for their knowledge and tremendous labor of reviewing relevant literature, synthesizing it, and writing and revising chapters to make them highly readable for others. This edition includes a new chapter on epigenetics and disease and separate chapters for female and male alterations of reproduction. Several chapters were completely rewritten for this edition. We have a special appreciation for Neal Rote and Tina Brashers, section editors, for their tireless editing, writing, and development of new art. Neal managed the immunity, infection, and hematology chapters. For this edition, he completely updated the tumor biology chapter. Neal also fully updated the glossary. Tina managed the endocrine, pulmonary, and cardiovascular alterations chapters. Both Neal and Tina have exceptional ability to integrate, simplify, and illustrate the complex content of pathophysiology. Always motivated to *really* help students and clinicians, we thank you both. In addition, Tina Brashers, Samantha Greed, Lori Kelly, Kathleen Whalen, Diane Young, and Linda Turchin developed modules for the Online Review Course. There were also many faculty and clinicians who provided reviews for content revision and we are grateful for their insight and recommendations.

We extend gratitude to those who contributed to the book supplements. Linda Felver has created an all new inventive and resourceful Study Guide. Thank you Linda for very astute edits. For the Student Evolve website, Blaine Winters and Gaye Ray wrote the review questions. For the Instructor Evolve website, Linda Turchin updated and revised the Test Bank. Joanna Cain and Stacy June Breedlove Shaffer created unique case studies for the Teach for Nurses Instructor's Manual and PowerPoints. Kim Webb fully updated the PowerPoint presentations and supplemental audience response questions. Former Content Development Specialist on our book, Charlene Ketchum, created the Teach for Nurses Instructor's Manual. Also thank you to freelancer Allison Smith, who aided in the update of the glossary. We would also like to acknowledge Nancy Blasdell, Diane Young, Margaret Clayton, Susan Frazier, and Linda Turchin for their previous contributions to the Evolve resources. Thank you all for your help.

The process of completing this book is dependent on the "behind the scenes work" of numerous people. Manuscript management and final word processing is a huge and complex effort and was completed by our "rock" Sue Meeks, who has worked with us for more than 30 years. Her extraordinary talent, unwavering dedication to excellence, and detail kept us sane and on track. Every edition is monumental work—and she retypes and recounts endlessly—and unruffled. As always, our deepest appreciation for your continuing skill and patience.

Our Senior Content Development Editor at Elsevier is Karen Turner. This job is key. Karen monitored closely with an eagle eye! Karen was especially helpful with illustrations and exacting surveillance necessary for staying consistent and clear. Her questions were thoughtful and critically timed. She is very organized and practical and kept this project on target. Thank you Karen. Senior Content Strategist Sandra Clark helped with the overall structure of the book and all the business needed for contributors, designers, artists, and other editors. This is a big job and Sandra made sure that we had all resources necessary to complete this book. Thank you, Sandra. Senior Content Coordinator Brooke Kannady, a delight to work with, coordinated all reviewer projects, was quick to respond to any of the production needs, and is very conscientious. Thank you, Brooke. To Sally Schrefer, endless thanks for constant inspiration over 24 years.

The project manager for a book of this size and complexity of content has an enormous responsibility. The Senior Project Manager was Jeanne Genz. From copy edit to final page proofs, she is exacting and a gem to work with. Thank you, Jeanne, especially for your early morning consultations. Our book designer was Amy Buxton and she did an outstanding job guiding the design of the interior portion of the book—we are especially pleased with the layout, dynamic colors, and presentation of pedagogy. She also coordinated the work that went into creating the striking cover design. Thank you, Amy.

The newly drawn and revised artwork for this edition was completed by George Barile of Accurate Art Inc. The art is key and challenging and our drawings are often pathetic, but George was persistent to get it right and creative. Thank you so much George for the conceptual arrangements, labels, and beautiful colors.

We thank Ramón Andrade Candelario at 3Dciencia for allowing us to use the beautiful cover image. We also thank the Department of Dermatology at the University of Utah School of Medicine, which provided numerous photos of skin lesions. Thanks to Dr. Arthur R. Brothman, University of Utah School of Medicine, for the *N-myc* gene amplification slides used to illustrate the discussion of neuroblastoma, and to Dr. John Hoffman for the PET scan images of non–small cell lung cancer.

We are grateful to the many colleagues and friends at the University of Utah Health Sciences Center for their assistance with references and consultation on content. Thanks for the outstanding extra help—Ruth Weinberg, your experience and editorial skill are exceptional.

Special thanks are given to students, particularly nursing and other health science students, for the e-mails and phone calls we receive. Your questions and suggestions are inspiring and guide us in our efforts to prepare a clear and up-to-date manuscript with much visual input.

Sincerely and with great affection we thank our families, especially John, Mae, and Dorothy. Although disentangling certain data is inconvenient at times, we thank those committed to "getting it right"—increasing patient-centered quality care, safety, and satisfaction.

INTRODUCTION TO PATHOPHYSIOLOGY

The word root "patho" is derived from the Greek word *pathos,* which means suffering. The Greek word root "logos" means discourse or, more commonly, system of formal study, and "physio" pertains to functions of organisms. Generally, pathophysiology is the systematic study of the functional changes in cells, tissues, and organs altered by disease and/or injury. Important, however, is the inextricable component of suffering.

Knowledge of cellular biology as well as anatomy and physiology and the various organ systems of the body is an essential foundation for the study of pathophysiology. To understand pathophysiology the student must also use principles, concepts, and basic knowledge from other fields of study, including biology, genetics, immunology, pathology, and epidemiology. A number of terms are used to focus the discussion of pathophysiology; they may be used interchangeably at times, but that does not necessarily indicate that they have the same meaning. These terms are reviewed in Table I-1.

Pathophysiology is one of the most important bridging sciences between preclinical and clinical courses for students in the health sciences and it requires in-depth study at an early stage in the curriculum. The definitions or conceptual models of pathophysiology that we carry in our minds influence what we do with our observations and the rationale that we provide for our actions. Therefore, the clinician must understand that although pathophysiology is a science, it also designates suffering in people; the clinician should never lose sight of this aspect of its definition.

As students study clinically-related sciences, they learn to recognize and categorize disease. From the formulation of a differential diagnosis one understands the different *clinical manifestations,* the signs, and the symptoms of certain pathologies. These understandings structure further investigations, treatment plans, and evaluation. The interaction of these activities determines clinical outcomes and treatment success. Still, the concept of disease can be inherently ambiguous and elusive; many pathologies remain hidden and resist easy classification. One should appreciate that the naming and diagnosing of diseases involve evaluative judgments as well as scientific fact, and that the process is as much a social endeavor as it is a scientific one. Some diseases, such as tuberculosis, identify a highly specific causative or etiologic agent or process. Others, such as Alzheimer disease or arthritis, indicate pathologic changes of unclear cause. There is considerable need for more research to validate mental health diagnoses. In addition, syndromes and functional disorders simply describe multiple symptoms and signs that frequently occur together. Does commonality exist in all of these labels? The answer is "yes" and "no" and depends on our conception of health and disease. In the strictest sense, objective scientific facts help us know if an individual is healthy or suffering from disease. Critical to attaining health in the United States are nine domains particularly worrisome and include adverse birth outcomes, injuries and homicides, adolescent pregnancy and sexually transmitted infections, HIV and AIDS, drug-related mortality, obesity and diabetes, heart disease, chronic lung disease, and disability.[1]

An individual's conception of disease is based on personal beliefs and histories, professional and lay healers who interact with that individual, and society at large. Each idea or construct has the power to influence other ideas and constructs, and each relationship has the ability to shape the way disease is understood and experienced.[2] In short, defining and understanding disease are tremendously ambiguous. Although a discerning mind is key, perhaps an important trait for the new student of pathophysiology is an open and tolerant mind. To believe that science alone can overcome ignorance and that clinical training and technology can overcome ineptitude only encourages arrogance and undermines the scientific purpose.

Pathophysiology has had great success in explaining the mechanisms and clinical manifestations associated with infectious diseases. Syndromes of unclear etiology, such as headache and fibromyalgia, have proven to be troublesome. Even more difficult are multifactorial conditions, such as atherosclerosis or type 2 diabetes mellitus, in which several interacting factors contribute to the etiology. Learning how interacting factors relate to one another to increase morbidity or actually cause disease contributes to an appreciation of how emerging

TABLE I-1 TERMS AND DEFINITIONS RELATED TO PATHOPHYSIOLOGY

Pathology	Study of structural alterations in cells, tissues, and organs that help to identify the cause of disease
Pathogenesis	Pattern of tissue changes associated with the development of disease
Etiology	Study of the cause(s) of disease and/or injury
Idiopathic	Diseases with no identifiable cause
Iatrogenic	Diseases and/or injury as a result of medical intervention
Clinical manifestations	Signs and symptoms
Nosocomial	Diseases acquired as a consequence of being in a hospital environment
Diagnosis	Naming or identification of a disease
Prognosis	Expected outcome of a disease
Acute disease	Sudden appearance of signs and symptoms lasting a short time
Chronic disease	Develops more slowly, lasting a long time or a lifetime
Remissions	Periods when clinical manifestations disappear or diminish significantly
Exacerbations	Periods when clinical manifestations become worse or more severe
Sequelae	Any abnormal conditions that follow and are the result of a disease, treatment, or injury

concepts revolutionize current understandings. One revolution in thought that has driven intensive research is that low levels of chronic inflammation cause or contribute to many diseases.

The language that clinicians use to discuss diseases and their manifestations is powerful. Lives are altered by a few words uttered by a clinician in a white coat or uniform. “AIDS,” “cancer,” and “heart attack” have become culturally ingrained symbols that portend an individual’s future. Although some futures are determined by scientific evidence, others are determined by subjective experience.[3] For example, a person diagnosed with a familial disease may ask, “Will I suffer like my mother did?” This questioning influences individuals’ suffering.

In conclusion, pathophysiology—the understanding of disease—requires descriptive evidence as well as an evaluative component regarding suffering and the language we use to describe it. Combining objective and subjective perspectives requires new conceptual models that take into account the complex interactions among the body, mind, environment, and spirit.

- Review Questions and Answers

CHAPTER OUTLINE

All body functions depend on the integrity of cells. Therefore, an understanding of cellular biology is intrinsically necessary for an understanding of disease. An overwhelming amount of information is revealing how cells behave as a multicellular "social" organism. At the heart of cellular biology is cellular communication ("cellular crosstalk")—how messages originate and are transmitted, received, interpreted, and used by the cell. Fossil records suggest that unicellular organisms resembling bacteria were present on earth 3.5 billion years ago, yet it took another 2.5 billion years for the first multicellular organisms to appear. This delay was seemingly slow because elaborate signaling mechanisms had to evolve that would allow cells to crosstalk. This streamlined conversation between, among, and within cells maintains cellular function and specialization. Intercellular signals allow each cell to determine its position and specialized role. Cells must demonstrate a "chemical fondness" for other cells and their surrounding environment to maintain the integrity of the entire organism. When they no longer tolerate this fondness, the conversation breaks down and cells either adapt (sometimes altering function) or become vulnerable to isolation, injury, or disease.

PROKARYOTES AND EUKARYOTES

Living cells generally are divided into two major classes—eukaryotes and prokaryotes. The cells of higher animals and plants are eukaryotes, as are the single-celled organisms fungi, protozoa, and most algae. Prokaryotes include cyanobacteria (blue-green algae), bacteria, and rickettsiae. Prokaryotes traditionally were studied as core subjects of molecular biology. Current emphasis is on the eukaryotic cell; much of its structure and function has no counterpart in bacterial cells.

Eukaryotes (*eu* = good; *karyon* = nucleus) are larger and have more extensive intracellular anatomy and organization than do prokaryotes. Eukaryotic cells have a characteristic set of membrane-bound intracellular compartments, called *organelles,* that includes a well-defined nucleus. **Prokaryotes** contain no organelles, and their nuclear material is not encased by a nuclear membrane. Prokaryotic cells are characterized by lack of a distinct nucleus.

Besides having structural differences, prokaryotic and eukaryotic cells differ in chemical composition and biochemical activity. The *nuclei* of prokaryotic cells carry genetic information in a single circular chromosome, and they lack a class of proteins called *histones,* which in eukaryotic cells bind with deoxyribonucleic acid (DNA) and are involved in the supercoiling of DNA (see Figure 1-2, p. 4). We now understand that the loops and coiling of DNA are important for many diseases (see Chapter 6). Eukaryotic cells have several chromosomes. Protein production, or synthesis, in the two classes of cells also differs because of major structural differences in ribonucleic acid (RNA)–protein complexes. Other distinctions include differences in mechanisms of transport across the outer cellular membrane and differences in enzyme content.

CELLULAR FUNCTIONS

Cells become specialized through the process of **differentiation,** or maturation, so that some cells eventually perform one kind of function and other cells perform other functions. Cells with a highly developed function, such as movement, often lack some other property, such as hormone production, which is more highly developed in some other type of specialized cell.

The eight chief cellular functions follow:

1. *Movement.* Muscle cells can generate forces that produce motion. Muscles that are attached to bones produce limb movements, whereas those that enclose hollow tubes or cavities move or empty contents when they contract. For example, the contraction of smooth muscle cells surrounding blood vessels changes the diameter of the vessels; the contraction of muscles in walls of the urinary bladder expels urine.
2. *Conductivity.* Conduction as a response to a stimulus is manifested by a wave of excitation, an electrical potential that passes along the surface of the cell to reach its other parts. Conductivity is the chief function of nerve cells.
3. *Metabolic absorption.* All cells take in and use nutrients and other substances from their surroundings. Cells of the intestine and the kidney are specialized to carry out absorption. Cells of the kidney tubules reabsorb fluids and synthesize proteins. Intestinal epithelial cells reabsorb fluids and synthesize protein enzymes.
4. *Secretion.* Certain cells, such as mucous gland cells, can synthesize new substances from substances they absorb and then secrete the new substances to serve as needed elsewhere. Cells of the adrenal gland, testis, and ovary can secrete hormonal steroids.
5. *Excretion.* All cells can rid themselves of waste products resulting from the metabolic breakdown of nutrients. Membrane-bound sacs (lysosomes) within cells contain enzymes that break down, or digest, large molecules, turning them into waste products that are released from the cell.
6. *Respiration.* Cells absorb oxygen, which is used to transform nutrients into energy in the form of adenosine triphosphate (ATP). Cellular respiration, or oxidation, occurs in organelles called *mitochondria.*
7. *Reproduction.* Tissue growth occurs as cells enlarge and reproduce themselves. Even without growth, tissue maintenance requires that new cells be produced to replace cells that are lost normally through cellular death. Not all cells are capable of continuous division (see Chapter 2).
8. *Communication.* Communication is vital for cells to survive as a society of cells. Pancreatic cells, for instance, secrete and release insulin necessary to signal muscle cells to absorb sugar from the blood for energy. Constant communication allows the maintenance of a dynamic steady state.

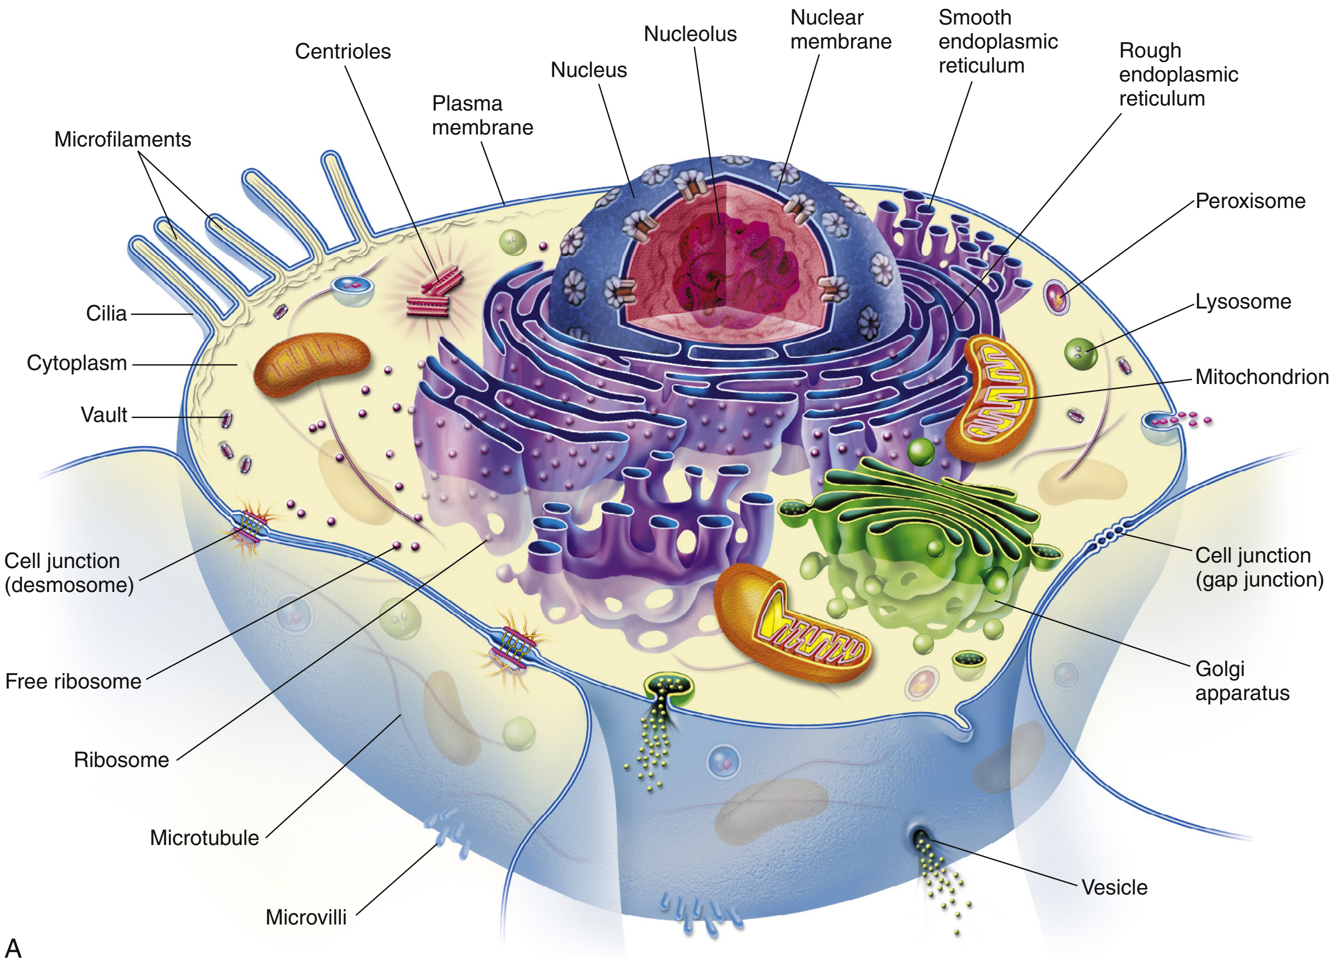
STRUCTURE AND FUNCTION OF CELLULAR COMPONENTS

Figure 1-1 shows a "typical" eukaryotic cell. It consists of three components: an outer membrane called the *plasma membrane,* or *plasmalemma;* a fluid filling called **cytoplasm;** and the intracellular "organs," or *organelles,* which are membrane bound and include the nucleus.

Nucleus

The **nucleus,** which is surrounded by the cytoplasm and generally is located in the center of the cell, is the largest membrane-bound organelle. Two membranes comprise the **nuclear envelope** (Figure 1-2, *A*). The outer membrane is continuous with membranes of the endoplasmic reticulum. The inner membrane encloses the neoplasm. The nucleus contains the **nucleolus,** a small dense structure composed largely of RNA; most of the cellular DNA; and the DNA-binding proteins, the histones, that regulate its activity. The DNA chain in eukaryotic cells is so extensive that the risk of breakage is high. Therefore, the histones that bind to DNA cause DNA to fold into chromosomes (Figure 1-2, *C*). The wrapping of DNA into tight packages of chromosomes is essential for cell division in eukaryotes.

The primary functions of the nucleus are cell division and control of genetic information. Other functions include the replication and repair of DNA and the transcription of the information stored in DNA. Genetic information is transcribed into RNA, which can be processed into messenger, transport,



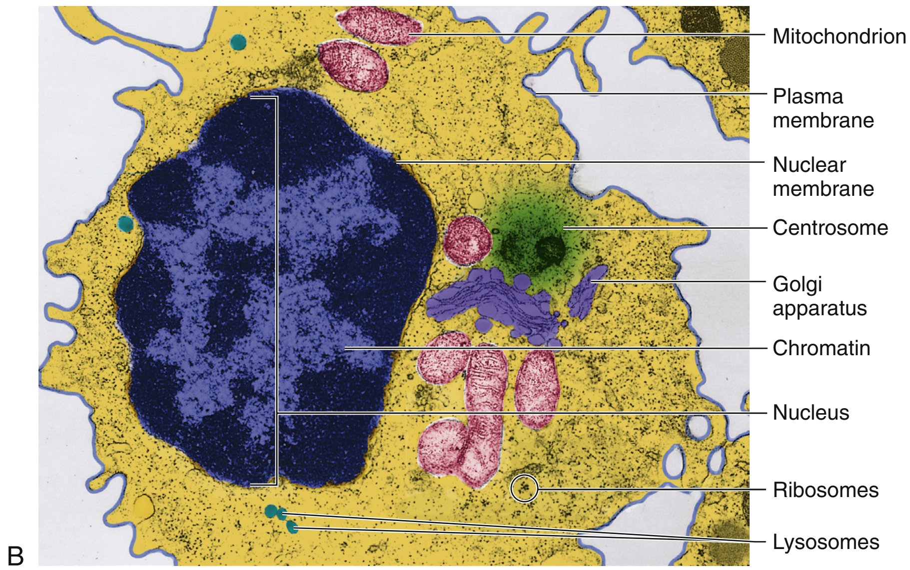


FIGURE 1-1 Typical or Composite Cell. **A,** Artist's interpretation of cell structure. **B,** Color-enhanced electron micrograph of a cell. Both show the many mitochondria known as the "power plants of the cell." Note, too, the innumerable dots bordering the endoplasmic reticulum. These are ribosomes, the cell's "protein factories." FIGURE 1-2 The Nucleus. The nucleus is composed of a double membrane, called a nuclear envelope, that encloses the fluid-filled interior, called nucleoplasm. The chromosomes are suspended in the nucleoplasm (illustrated here much larger than actual size to show the tightly packed DNA strands). Swelling at one or more points of the chromosome, shown in **A,** occurs at a nucleolus where genes are being copied into RNA. The nuclear envelope is studded with pores. **B,** The pores are visible as dimples in this freeze etch of a nuclear envelope. **C,** Histone-folding DNA in chromosomes. (**B** from Raven PH, Johnson GB: *Biology,* St Louis, 1992, Mosby.)

and ribosomal RNA and introduced into the cytoplasm, where it directs cellular activities. Most of the processing of RNA occurs in the nucleolus. (The role of DNA and RNA in protein synthesis is discussed in Chapter 4.)

Cytoplasmic Organelles

Cytoplasm is an aqueous solution (**cytosol**) that fills the **cytoplasmic matrix—**the space between the nuclear envelope and the plasma membrane. The cytosol represents about half the volume of a eukaryotic cell. It contains thousands of enzymes involved in intermediate metabolism and is crowded with ribosomes making proteins. Newly synthesized proteins remain in the cytosol if they lack a signal for transport to a cell organelle.[1] The organelles suspended in the cytoplasm are enclosed in biologic membranes, which enables them to simultaneously carry out functions that require different biochemical environments. These functions, many of which are directed by coded messages carried from the nucleus by RNA, include synthesis of proteins and hormones and their transport out of the cell, isolation and elimination of waste products from the cell, metabolic processes, breakdown and disposal of cellular debris and foreign proteins (antigens), and maintenance of cellular structure and motility. Also the cytosol functions as a storage unit for fat, carbohydrate, and secretory vesicles.

Ribosomes

Ribosomes are RNA-protein complexes (nucleoproteins) that are synthesized in the nucleolus and secreted into the cytoplasm through pores in the nuclear envelope called nuclear pore complexes (NPCs).[2] These tiny ribosomes may float free in the cytoplasm or attach themselves to the outer membranes of the endoplasmic reticulum (see Figure 1-1, *A*).

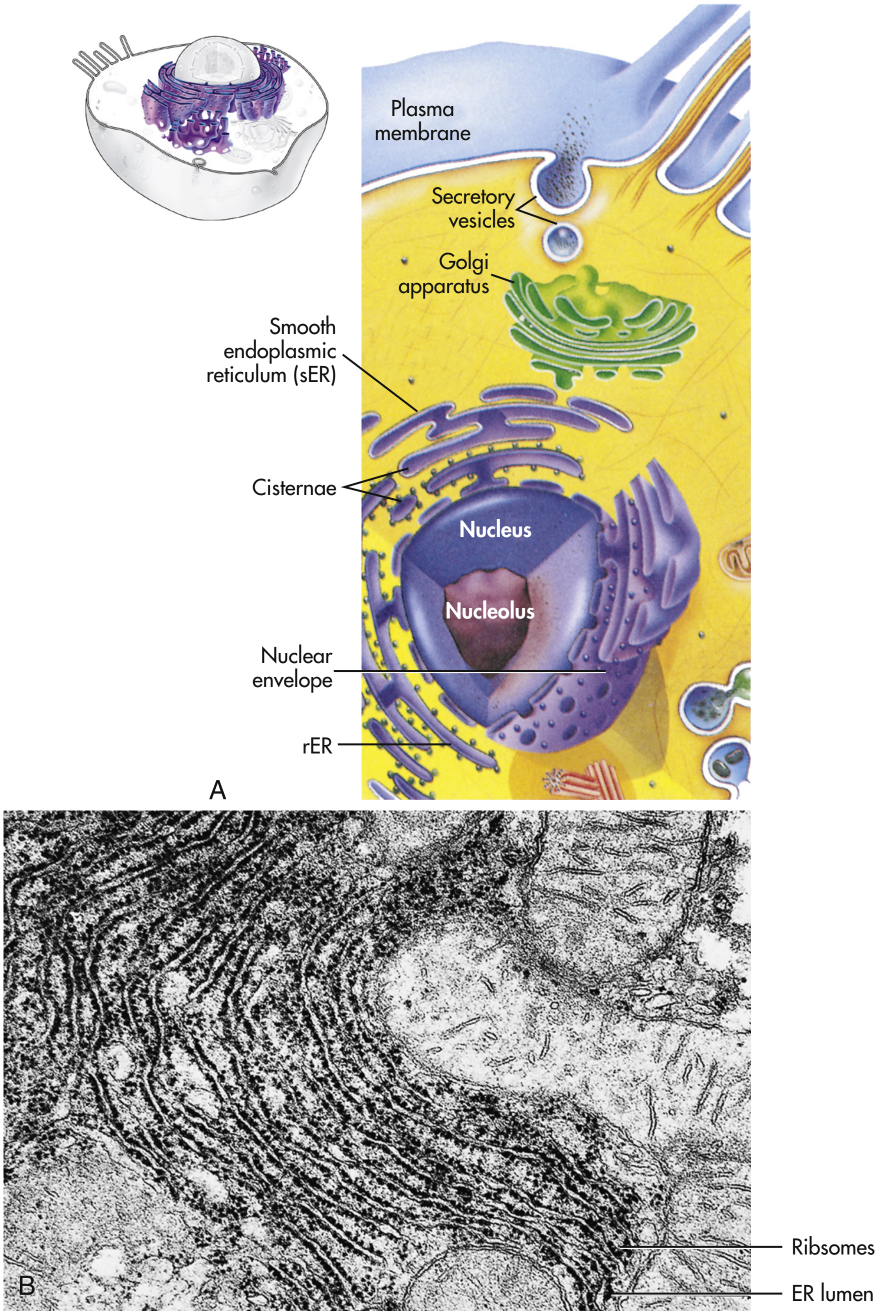

FIGURE 1-3 Endoplasmic Reticulum (ER). **A,** The ER consists of rough endoplasmic reticulum (rER) arranged into ribosome-coated cisternae and vesicles of smooth endoplasmic reticulum (sER). **B,** Electron micrograph of rough and smooth ER. (**B** courtesy Kelloes C, Farmer M, Center for Advanced Ultrastructural Research, University of Georgia. From Lindsay DT: *Functional human anatomy,* St Louis, 1996, Mosby.)

Their chief function is to provide sites for cellular protein synthesis. Newly formed ribosomes synthesize a "recognition sequence," or signal, like an address on a letter. Signal recognition particles (SRPs) in the cytosol bind to the ribosome after recognizing the SRP. Ribophorins, receiver proteins found on the rough sections of the endoplasmic reticulum (ER), act as the "address" site or binding site. The developing protein threads its way through the ER membrane into the lumen. The SRP is removed and the new protein chain is folded into its final conformation.

Endoplasmic Reticulum

The **endoplasmic reticulum (ER)** (*endo* = within; *plasma* = cytoplasm; *reticulum* = network) is a membrane factory that specializes in the synthesis and transport of the protein and lipid components of most of the cell's organelles. It consists of a network of tubular or saclike channels (cisternae) that extend throughout the cytoplasm and are continuous with the outer nuclear membrane (Figure 1-3). The folded membranes that form the cisternae of the endoplasmic reticulum may be *rough* (granular) or *smooth* (agranular). The **rough endoplasmic**

reticulum (**rER**) is rough because ribosomes and ribonucleoprotein particles are attached to it (see Figure 1-3). Some of the proteins synthesized by these ribosomes remain in the ER, and others are used to construct membranes of other organelles (the Golgi complex, lysosomes, peroxisomes, and nucleus) and of the cell itself. Importantly, the ER is responsible for much of a cell's protein synthesis and folding, and a new role is sensing cellular stress (see What's New? Endoplasmic Reticulum, Protein Folding, and ER Stress). Understanding mechanisms of cellular stress will aid diagnosis and treatment of disease.

Smooth endoplasmic reticulum (**sER**) does not contain ribosomes or ribonucleoprotein particles (see Figure 1-1). Rather, membranous surfaces of the smooth endoplasmic reticulum contain enzymes involved in the synthesis of steroid hormones and are responsible for a variety of reactions required to remove toxic substances from the cell. The endoplasmic reticulum communicates with the Golgi complex and interacts with other organelles, particularly lysosomes and peroxisomes.

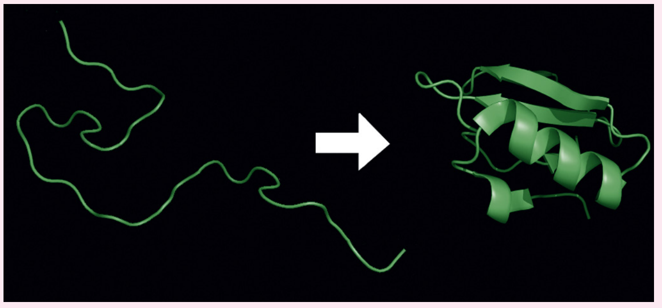
Golgi Complex

The **Golgi complex** (or **Golgi apparatus**) is a network of flattened, smooth membranes and vesicles frequently located near the nucleus of the cell (Figure 1-4). Proteins from the endoplasmic reticulum are processed and packaged into small membrane-bound

WHAT'S NEW?

Endoplasmic Reticulum, Protein Folding, and ER Stress

Protein folding in the endoplasmic reticulum (ER) is critical for us. As the biologic workhorses, proteins perform vital functions in every cell. To do these tasks proteins must fold into complex three-dimensional structures (see figure at right). Most secreted proteins *fold* and are modified in an error-free manner, but ER or cell stress, mutations, or random (stochastic) errors during protein synthesis can decrease the folding amount or the rate of folding. Pathophysiologic processes, such as viral infections, environmental toxins, and mutant protein expression, can perturb the sensitive ER environment. Natural processes also can perturb the environment, such as the large protein-synthesizing load placed on the ER. These perturbations cause the accumulation of immature and abnormal proteins in cells, leading to **ER stress.** Fortunately, the ER is loaded with protective ways to help folding, for example, protein so-called *chaperones* that facilitate folding and prevent the formation of off-pathway types. Because specialized cells produce large amounts of secreted proteins, the movement or flux through the ER is tremendous. Therefore, misfolded proteins not repaired in the ER are observed in some diseases and can initiate apoptosis or cell death. It has recently been shown that the endoplasmic reticulum mediates intracellular signaling pathways in response to the accumulation of unfolded or misfolded proteins; collectively, the pathways are known as the **unfolded-protein response (UPR).** Investigators are studying UPR-associated inflammation and how the UPR is coupled to inflammation in health and disease. Specific diseases include Alzheimer disease, Parkinson disease, prion disease, amyotrophic lateral sclerosis, and diabetes mellitus. Additionally being studied is ER stress and how it may accelerate age-related dysfunction.



Protein Folding. Each protein exists as an unfolded polypeptide *(left)* or random coil after the process of translation from a sequence of mRNA to a linear string of amino acids. From amino acids interacting with each other they produce a three-dimensional structure called the folded protein *(right)* that is its native state.

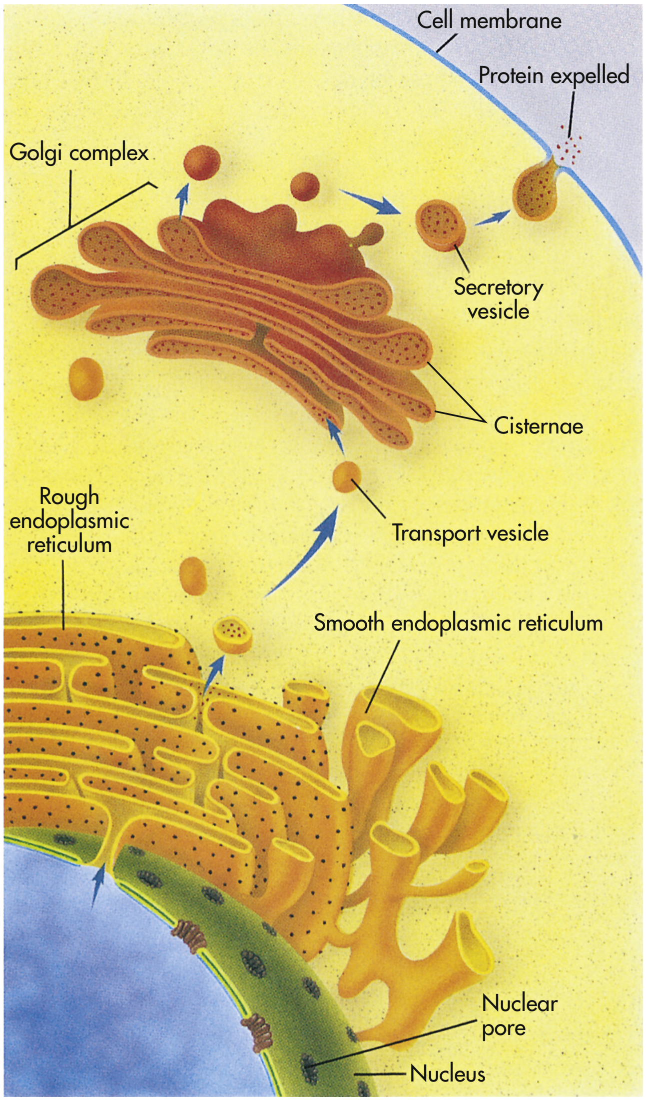

FIGURE 1-5 How the Internal Membrane System of a Cell Packages a Protein for Export. The instructions for making a protein that is destined for export from a cell, such as a digestive enzyme made by a pancreas cell, are first transcribed from DNA by RNA in the nucleus. The RNA then leaves the nucleus through a nuclear pore and proceeds to a ribosome located on the rough endoplasmic reticulum (rER). There it provides instructions for the correct sequence of amino acids for synthesizing that particular digestive enzyme. When enzyme synthesis is complete, the enzyme travels through the ER and is then encapsulated in a transport vesicle. The transport vesicle fuses with a Golgi body, releasing the enzyme. In the Golgi complex the enzyme is further modified and is then shunted to the flattened stacks, or cisternae. There the enzyme waits for a secretory vesicle, which will carry it to the perimeter of the cell, the cell membrane. The secretory vesicle membrane then fuses with the cell membrane, and the enzyme is released outside the cell. (From Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.)

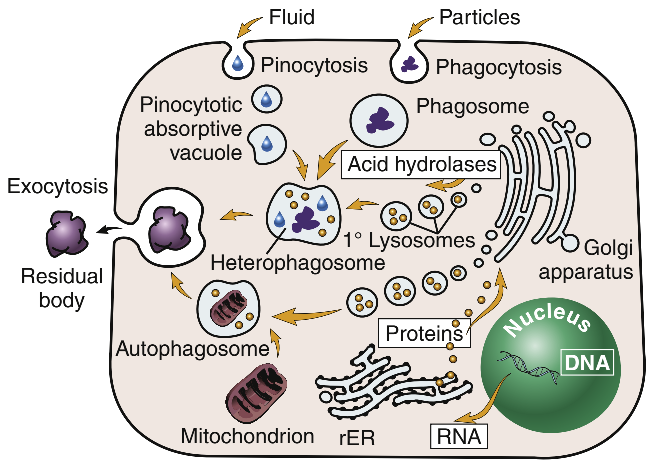

FIGURE 1-6 Lysosomes. Primary (1°) lysosomes, which originate from the Golgi apparatus, give rise to heterophagosomes and autophagosomes. Undigested material in phagosomes is extruded from the cell or remains in the cytoplasm as lipofuscin-rich residual bodies. rER, Rough endoplasmic reticulum. (From Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders.)

sacs or vesicles called **secretory vesicles,** which collect at the end of the membranous folds of the Golgi bodies—called **cisternae.** The secretory vesicles then break off from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane. The vesicles fuse with the plasma membrane, and their contents are released from the cell. The best known vesicles are those that have coats made largely of the protein **clathrin** and are called *clathrin-coated vesicles*. They bud from the Golgi complex on the outward secretory pathway and from the plasma membrane on the inward endocytotic pathway (see p. 33). Many molecules, including lipids, proteins, glycoproteins, and enzymes of lysosomes, pass through the Golgi complex at some stage in their maturation. The Golgi complex is a refining plant and directs traffic (e.g., protein, polynucleotide, polysaccharide molecules) in the cell[1] (Figure 1-5).

Lysosomes

Lysosomes (*lyso* = dissolution; *soma* = body) are saclike structures that originate from the Golgi complex (see Figure 1-1, *A*). They contain more than 40 digestive enzymes called **hydrolases,** which catalyze bonds in proteins, lipids, nucleic acids, and carbohydrates. Lysosomes function as the intracellular digestive system (Figure 1-6). Lysosomal enzymes are capable of digesting most cellular constituents completely to their basic components, such as amino acids, fatty acids, and carbohydrates.

The lysosomal membrane acts as a protective shield between the powerful digestive enzymes within the lysosome and the cytoplasm, preventing their leakage into the cytoplasmic matrix. Disruption of the membrane by various treatments or cellular injury leads to a release of the lysosomal enzymes, which can then react with their specific substrates, causing *cellular self-digestion*. Lysosomal abnormalities are involved in a number of conditions that involve cellular injury and death.

Lysosomal storage diseases may be the result of a genetic defect or lack of one or more lysosomal enzymes. For example, the lack of lysosomal α-1,4-glucosidase leads to an accumulation of glycogen in lysosomes known as *Pompe disease*. Tay-Sachs disease is characterized by an accumulation of GM2 ganglioside (a lipid) in lysosomes as a result of the deficiency or absence of lysosomal hexosaminidase A. In gout, undigested uric acid accumulates within lysosomes, damaging the lysosomal membrane. Subsequent enzyme leakage results in cell death and tissue injury.

Lysosomes are necessary for normal digestion of cellular nutrients, intracellular debris, and potentially harmful extracellular substances that must be removed from the body. Extracellular substances are taken into the cell and encapsulated in a membrane-bound vesicle (see discussion on endocytosis, p. 33). Lysosomes merge with the vesicle to form a digestive vacuole. Lysosomes remain fully active by maintaining a low internal pH. They do this by pumping hydrogen ions into their interiors. The hydrolytic enzymes are only maximally active at acid pH values. Lysosomes that are not active do not maintain such an acid internal pH. Lysosomes in this "holding pattern" are called **primary lysosomes.** When a primary lysosome fuses with a vacuole or other organelle, its pH falls and the hydrolytic enzymes become activated. When it becomes active, it is called a **secondary lysosome,** or **heterophagosome.**

As cells complete their life span and die, lysosomes digest the resultant cellular debris. Lysosomes involved in this process, which is called **autodigestion,** are called **autolysosomes,** or **autophagosomes.** In living cells, cellular debris is encapsulated within a vesicle that reacts with a lysosome to complete its degradation. The degradation process, called **autophagy,** promotes homeostasis because it involves continuous biosynthesis and cell turnover. Recent data indicate that autophagy plays a crucial role in health and disease[3,4] (see Chapter 2).

Products of autophagy (and of phagocytosis, the ingestion of harmful foreign substances; see Chapter 7) pass out of the lysosome and are reused by the cell. Indigestible material is stored in vesicles called **residual bodies,** whose contents are actively expelled from the cell (see Figure 1-6). High concentrations of lipids may accumulate within the residual bodies and remain there for a long time. The lipids are eventually oxidized, and a pigmented substance containing polyunsaturated fatty acids and proteins accumulates in the cell. This pigmented substance, termed *lipofuscin,* is often called "age pigment" or "age spots," and is noted in older individuals (see Chapter 2).

Peroxisomes

Peroxisomes (microbodies) are membrane-bound organelles that contain several oxidative enzymes such as *catalase* and *urate oxidase*. These oxidative enzymes can detoxify compounds and fatty acids. Similar to lysosomes in microscopic appearance, peroxisomes are larger and oval or irregular in shape. Like mitochondria, peroxisomes are major sites of oxygen utilization. Peroxisomes are so named because they usually contain enzymes that use oxygen to remove hydrogen atoms from specific substrates in an oxidative reaction that produces hydrogen peroxide (H_2O_2). Hydrogen peroxide is a powerful oxidant, potentially destructive if it accumulates or escapes from peroxisomes. Catalase, an antioxidant enzyme, uses the H_2O_2 to oxidize a variety of other substrates—phenols, formic acid, formaldehyde, and alcohol—by the peroxidative reaction:

$$H_2O_2 + R^1H_2 \rightarrow R^1 + 2H_2O$$

Thus the breakdown of H_2O_2 yields H_2O and O_2 (see discussion of free radicals in Chapter 2). Peroxisomes also have an important role in the synthesis of specialized phospholipids necessary for nerve cell myelination. Such reactions are important in detoxifying various wastes within the cell or foreign components that enter the cell, such as ethanol. Impairment of peroxisomes can lead to disease.

Mitochondria

Mitochondria (*mito* = thread; *chondros* = granule), organelles found in large numbers in most cells, are responsible for cellular respiration and energy production (see p. 26). These cytoplasmic organelles appear as spheres, rods, or filamentous bodies that are bound by a double membrane (Figure 1-7). The **outer membrane** is smooth and surrounds the mitochondrion itself; the inner membrane is convoluted in the mitochondrial matrix to form partitions called **cristae.** The **inner membrane** contains the enzymes of the respiratory chain—the name given to the electron-transport chain. These enzymes are essential to the process of oxidative phosphorylation that generates most of the cell's ATP. Metabolic pathways involved in the metabolism of carbohydrates, lipids, and amino acids and special pathways involving urea and heme synthesis are located in the mitochondrial matrix.

The outer membrane is permeable (passable) to many substances, but the inner membrane is highly selective and contains many transmembranous transport systems. The inner membrane contains a transporter to move electrically charged calcium (calcium ions). (Membrane transport is discussed on p. 25.) Mitochondria contain their own DNA that codes for enzymes needed for oxidative phosphorylation.

Vaults

Vaults are cytoplasmic organelles, also called ribonucleoproteins, that are much larger than ribosomes and shaped like octagonal barrels (Figure 1-8). Their name comes from their multiple arches, which reminded their discoverers of vaulted or cathedral ceilings. A single cell can contain thousands of vaults. The function of vaults is not fully understood and may be related to their octagonal shape. Vaults have a large interior volume and can encapsulate proteins.[5] Similarly, the pores in the membrane surrounding the nucleus (see Figure 1-2, *B*) are also octagonally shaped and the same size as vaults, leading to speculation that vaults may be cellular "trucks." Further, vaults would dock at nuclear pores, pick up molecules synthesized in the nucleus, and deliver their load elsewhere in the cell. Because at any given time about 5% of the vaults are localized near the nuclear pores, it is thought that vaults may be carrying messenger RNA (mRNA) from the nucleus to the ribosomal sites of protein synthesis within the cytoplasm. Investigators suggest that vaults transport several copies of untranslated RNA and that they are transported along cytoskeletal-based cellular tracks—much like an assembly line.[6] Vault complexes are being exploited for the delivery of drugs to the inside of the cell, for example, in kidney diseases.

Cytosol

Cytosol is the gelatinous, semiliquid portion of the cytoplasm accounting for about 55% of the total cell volume. Functions of the cytosol include intermediary metabolism involving enzymatic biochemical reactions; ribosomal protein synthesis; and storage of carbohydrates, fat, and secretory vesicles.

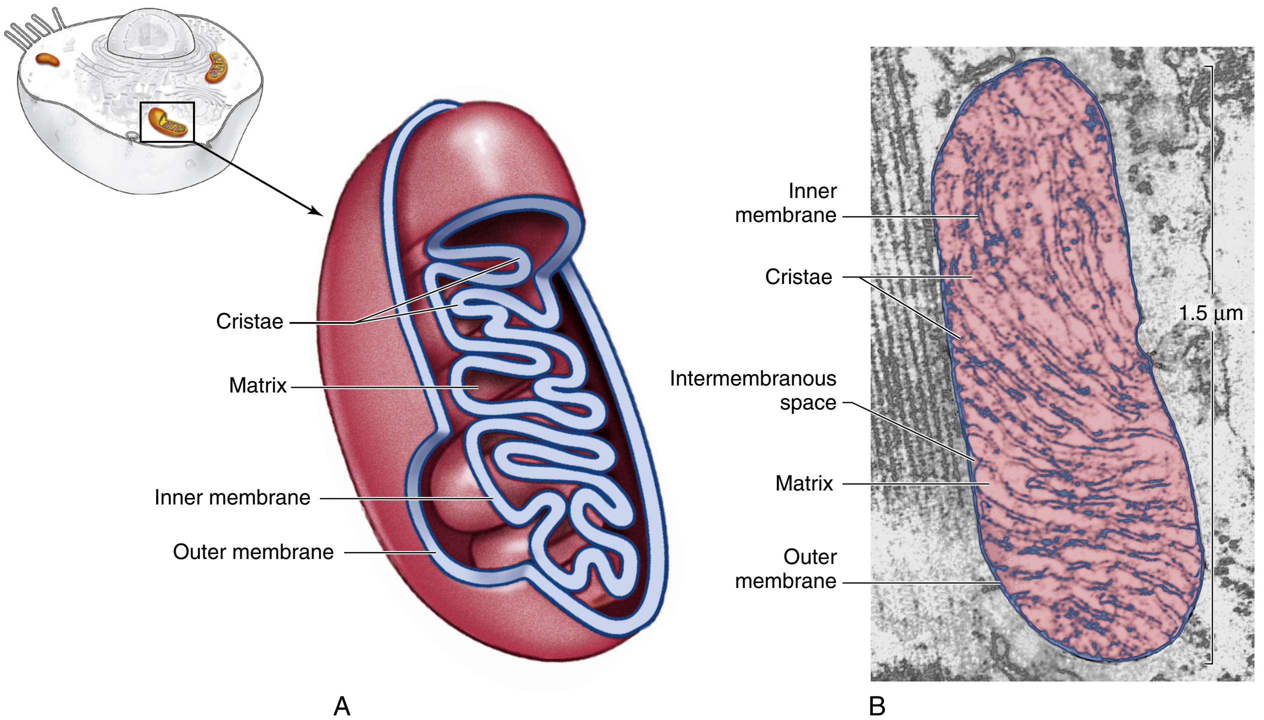

FIGURE 1-7 Mitochondrion. **A,** Cutaway sketch showing outer and inner membranes. Note the many folds (cristae) of the inner membrane. **B,** Transmission electron micrograph of a mitochondrion. Although some mitochondria have the capsule shape shown here, many are round or oval. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

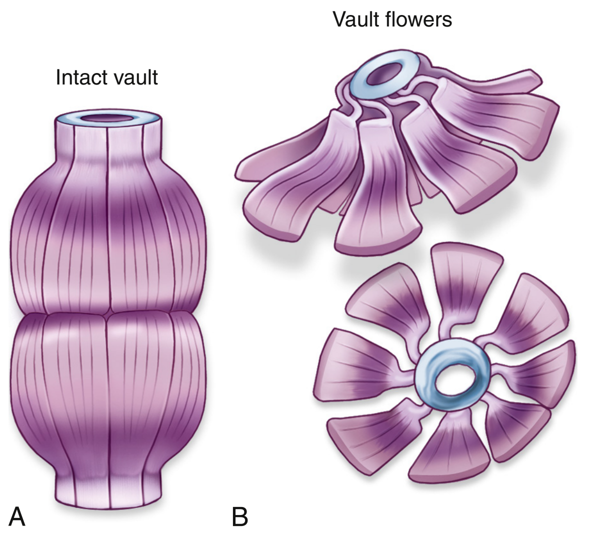

FIGURE 1-8 Vaults. **A,** Schematic three-dimensional representation of a vault, an octagonal barrel-shaped organelle believed to transport messenger RNA from the nucleus to the cytoplasmic ribosomes. **B,** Schematic representation of an opened vault, showing its octagonal structure.

Intermediary metabolism refers to the intracellular chemical reactions that include synthesis, degradation, and transformation of small organic molecules (e.g., simple sugars, fatty acids, and amino acids). All intermediary metabolism occurs in the cytoplasm or that portion of the cell interior not occupied by the nucleus—with most of the metabolism being accomplished in the cytosol. These reactions enable energy to be used for managing cellular activities and for providing substrates to maintain cell integrity.

Ribosomal protein synthesis takes place in free ribosomes in the cytosol. Cytosolic ribosomes that synthesize identical proteins are collected together in "factories" known as **polyribosomes.**

Excess stored nutrients not immediately used for ATP production are converted in the cytosol into storage forms; for example, excess glucose is stored as glycogen. These temporary masses are known as *inclusions* (see Chapter 2). Secretory vesicles that have been processed and packaged by the endoplasmic reticulum and Golgi complex also remain in the cytosol. By means of signaling, the vesicles transport and empty their contents outside the cell.

Cytoskeleton

All eukaryotic cells contain elaborate and specialized internal structures in the cytosol that provide the "bones and muscles" of the cell—the **cytoskeleton.** The cytoskeleton maintains the cell's shape and internal organization, and it permits movement of substances within the cell and movement of external projections (cilia or microvilli; flagella in sperm) outside the plasma membrane. The cytoskeleton is involved with the extracellular matrix and nuclear interior in force transmission (mechanical forces) called mechanotransduction. **Mechanotransduction** describes the cellular processes that translate mechanical stimuli into biochemical signals, allowing cells to adapt to their surroundings. Cell stresses, however, that involve alterations of mechanotransduction are associated with several diseases (see Chapter 2).[7,8]

The internal skeleton is composed of a network of protein filaments; two of the most important are microtubules and actin filaments, or microfilaments.

Microtubules are small, hollow, cylindrical, unbranched tubules made of protein. When found together, microtubules exhibit rigidity, unlike the rest of the cytoplasm. Microtubules thus add strength to the cell's structure (Figure 1-9, *A, B*). Within the cell, microtubules support and move organelles from one part of the cytoplasm to another, facilitate transport of impulses along nerve cells, and have roles in the inflammatory and immune responses and hormone secretion (Figure 1-9, *C*). Microtubules are also involved in the external movement, or motility, of some cells.

Microtubules are arranged in the thickened base, or basal body, of a protrusion from the cell's plasma membrane. This arrangement occurs in the basal bodies of sperm flagella and the cilia of certain other cells. The long, whiplike flagella enable the movement of sperm cells. Cilia usually move substances past the cell, which remains stationary. For example, cilia on cells lining the respiratory tract move together to "beat" mucus toward the throat so it can be removed by coughing.

While the cell is not in the process of division, only a few microtubules are assembled; cellular division (mitosis) or defense (phagocytosis) does, however, induce a cycle of rapid assembly and disassembly. Microtubules involved in cellular division are arranged in a **centriole.** Centrioles always consist of nine bundles containing three microtubules each. During division the pairs of centrioles split and migrate to opposite poles of the cell (see p. 37).

Alterations of microtubular function are implicated in disease processes. For example, alterations in actin microfilaments act as a driving force for cell extension during the dissemination of cancer.[9]

Actin filaments (microfilaments) are smaller fibrils that generally occur in bundles rather than singly (Figure 1-9, *B*).

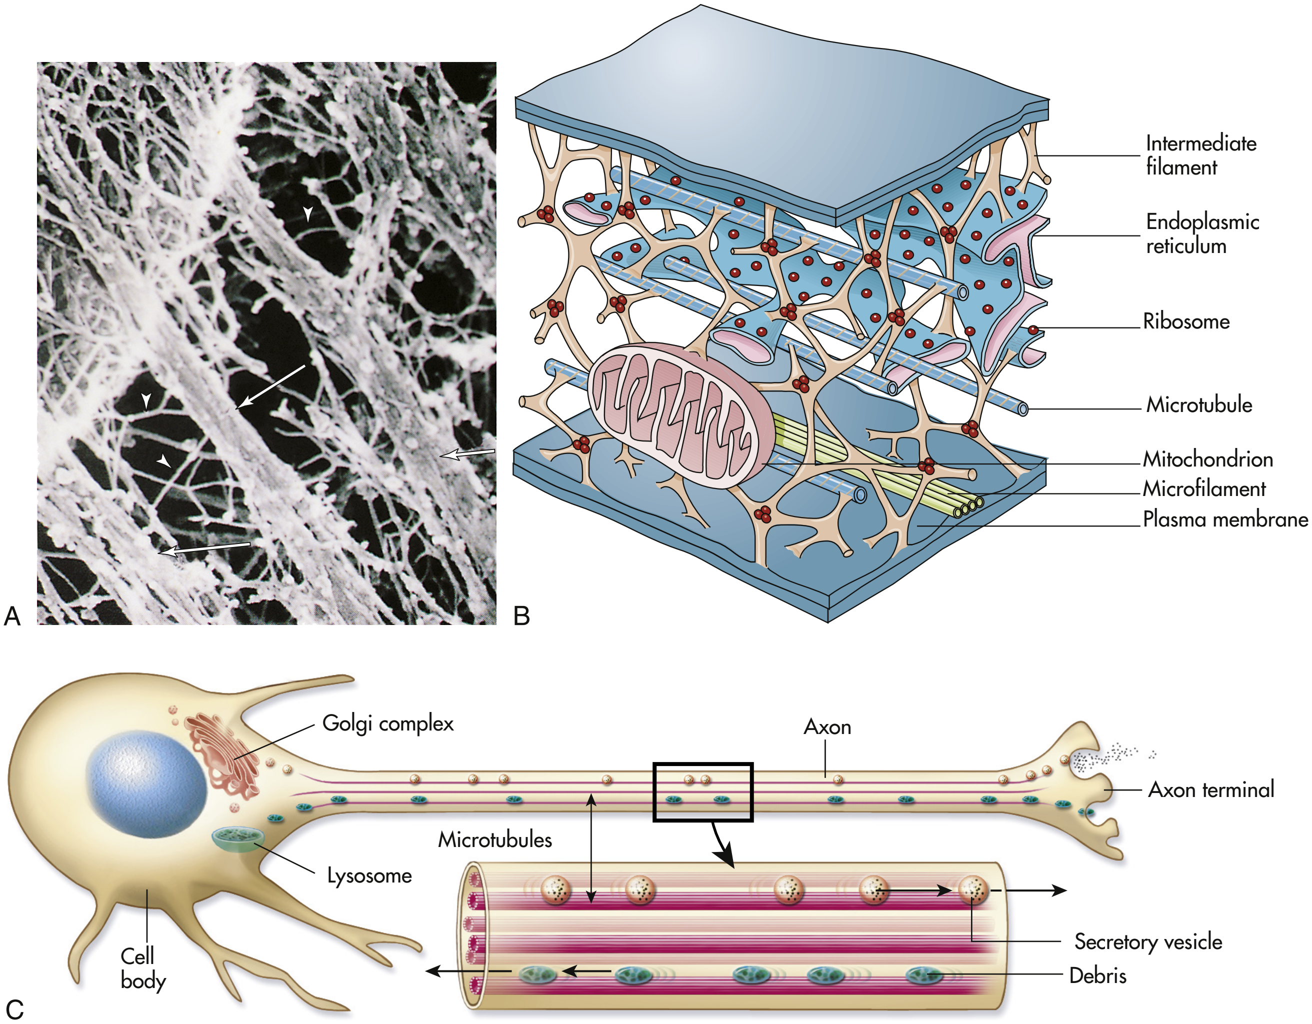

FIGURE 1-9 **Cytoskeleton. A,** Electron micrograph of a portion of the cell's internal framework. Arrowheads mark the intermediate filaments, and the complete arrows mark the microtubules. **B,** Artist's interpretation of the cell's internal framework. Note that the "free" ribosomes and other organelles are not really free at all. **C,** Microtubules are necessary for maintaining an asymmetric cell shape, such as that of a nerve cell. In addition, specific chemicals are released from the terminal end of the axon to influence neural transmission. (**A** and **B** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 6, St Louis, 2007, Mosby.)

Like microtubules, actin filaments are associated with cellular locomotion and maintenance of cell and tissue shape.[9] Actin filaments link the interior of the cell to adjacent cells through cell junctions, for example, zonula adherens and zonula occludens (see p. 19).

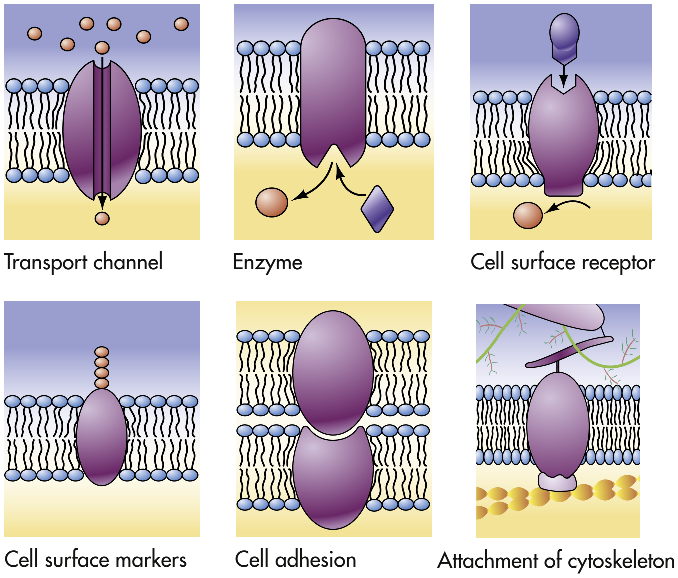

FIGURE 1-10 Functions of Plasma Membrane Proteins. The plasma membrane proteins illustrated here show a variety of functions performed by the different types of plasma membranes. (From Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.)

In addition, microfilaments are necessary for regulating cell growth.[10] Cellular locomotion depends on contractile properties that involve both microtubules and actin filaments. The actin cytoskeleton in motile cells has recently been described as a "wave of excitation" that may account for the spontaneous migration of cells.[11] Anesthetic drugs can affect both microtubules and actin filaments, disrupting intracellular movement and cellular motility.

Plasma Membranes

Whether they surround the cell or enclose an intracellular organelle, membranes are exceedingly important to normal physiologic function because they control the composition of the space, or compartment, they enclose. Membranes can allow or exclude various molecules, and because of selective transport systems, they can move molecules into or out of the space (Figure 1-10). By controlling the movement of substances from one compartment to another, membranes exert a powerful influence on metabolic pathways. Directional transport is facilitated by polarized domains, distinct apical and basolateral domains. The direction of cells—**cell polarity**—maintains normal cell and tissue structure for numerous functions, most importantly transport of nutrients in and out of the cell, and becomes altered with diseases, for example, cancer (Figure 1-11). In addition to these functions, the plasma membrane has an important role in cell-to-cell recognition. For example, protein receptors for hormones and for other chemical signals are associated with the membrane and act as markers that identify a cell to its neighbors. Other functions of the

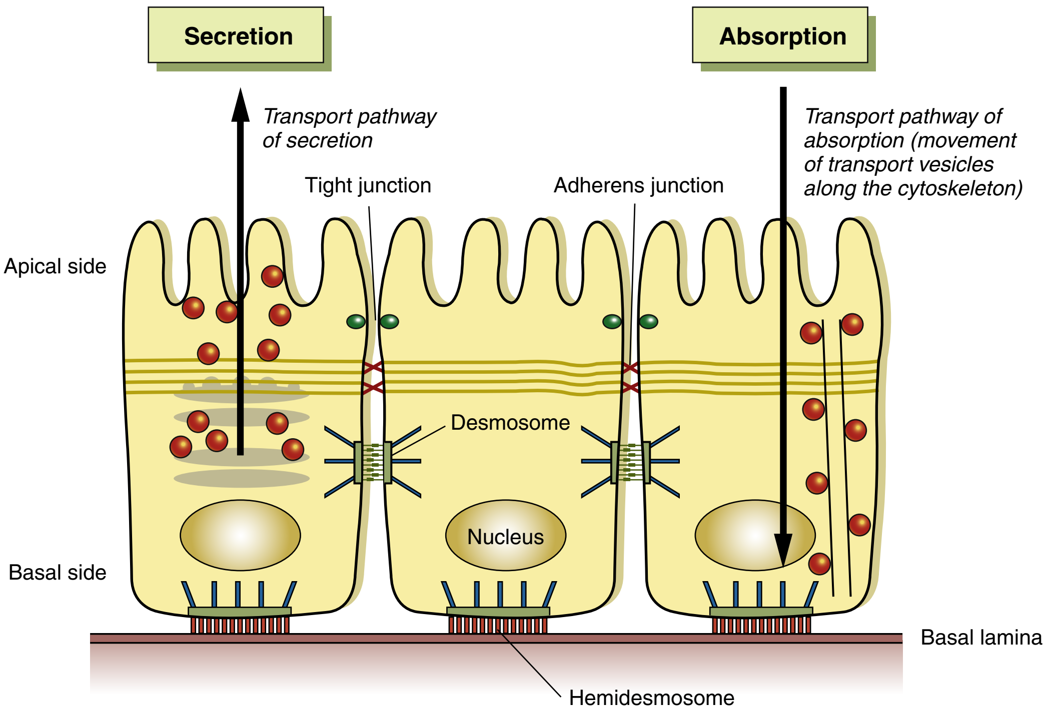

FIGURE 1-11 Cell Polarity of Epithelial Cells. A schematic of cell polarity (cell direction) of epithelial cells. Shown are the direction of the basal side and the apical side. Organelles and cytoskeleton are also arranged directionally to enable, for example, in an intestinal cell secretion and absorption. (Adapted from Life Science web textbook, The University of Tokyo.)

TABLE 1-1 PLASMA MEMBRANE FUNCTIONS

CELLULAR MECHANISM	MEMBRANE FUNCTIONS
Structure	Usually thicker than the membranes of intracellular organelles
	Containment of cellular organelles
	Maintenance of relationship with cytoskeleton, endoplasmic reticulum, and other organelles
	Outer surfaces in many cells are not smooth but are studded with cilia or even smaller cylindrical projections called microvilli; both are capable of movement; caveolae are also outer indentations
	Maintenance of fluid and electrolyte balance
Protection	Barrier to toxic molecules and macromolecules (proteins, nucleic acid, polysaccharides)
	Barrier to foreign organisms and cells
Activation of cell	Hormones (regulation of cellular activity)
	Mitogens (cellular division, see Chapter 4)
	Antigens (antibody synthesis, see Chapter 8)
	Growth factors (proliferation and differentiation)
Transport	Diffusion and exchange diffusion
	Endocytosis (pinocytosis and phagocytosis); receptor-mediated endocytosis
	Exocytosis (secretion)
	Active transport
Cell-to-cell interaction	Communication and attachment at junctional complexes
	Symbiotic nutritive relationships
	Release of enzymes and antibodies to extracellular environment
	Relationships with extracellular matrix

Modified from King DW, Fenoglio CM, Lefkowitch JH: *General pathology: principles and dynamics,* Philadelphia, 1983, Lea & Febiger.

plasma membrane include assistance with cellular mobility and maintenance of cellular shape (Table 1-1).

Membrane Composition

Historically, the plasma membrane was described as a fluid lipid bilayer composed of a *uniform* lipid distribution with inserted moving proteins.[12] It now appears that the lipid bilayer is a much more complex structure where lipids and proteins are not uniformly distributed but can separate into discrete units called microdomains, differing in their protein and lipid compositions[13] (see What's New? From the Fluid Mosaic Model to New Understandings about Biologic Membranes). Different membranes have different percentages of lipids and proteins. Intracellular membranes may have a higher percentage of proteins than do plasma membranes, presumably because most enzymatic activity occurs within organelles. The membrane organization is achieved through noncovalent bonds that allow different physical states called phases. The lipid bilayer can be structured into three main phases: a solid gel phase, a fluid liquid-crystalline (or liquid-disordered) phase, and a liquid-ordered phase (see Figure 1-13, p. 14). These phases can change under physiologic factors such as temperature and pressure alterations. The structure of a plasma membrane is shown in Figure 1-12 and Figure 1-13. Intracellular membranes have a higher percentage of proteins than do plasma membranes, presumably because most enzymatic activity occurs within organelles. Carbohydrates are mainly associated with plasma membranes, where they are chemically combined with lipids to form glycolipids and with proteins to form glycoproteins.

The outer surface of the plasma membrane in many types of cells, especially endothelial and adipocytes, is not smooth but dimpled with cavelike indentations known as caveolae ("tiny caves"). Caveolae and caveolae-like domains are structurally heterogeneous.[13] Caveolae were considered to be functionally insignificant until the mid-1990s, when evidence suggested that they (1) serve as a repository for some receptors, (2) provide a new route for transport into the cell, and (3) act as the initiator for relaying signals from several extracellular chemical messengers into the cell's interior[14] (see p. 20).

Lipids. A major component of the plasma membrane is a bilayer of lipid molecules. It is now known that membranes include up to a thousand lipids that vary in structure.[15] The wide range of lipids is thought to be the solvent for membrane proteins.[13] Lipids along with protein assemblies act as "molecular glue" for the structural integrity of the membrane. Each lipid molecule is said to be polar, or amphipathic. An **amphipathic molecule** is one in which one part is **hydrophobic** (uncharged, or "water hating") and another part is **hydrophilic** (charged, or "water loving") (see Figure 1-12). The membrane spontaneously organizes itself into a bilayer because of these two incompatible solubilities. The hydrophobic region (hydrophobic tail) of each lipid molecule is protected from water, whereas the hydrophilic region (hydrophilic head) is immersed in it. The

WHAT'S NEW?

From the Fluid Mosaic Model to New Understandings about Biologic Membranes

The understanding of biologic membranes has changed markedly, from the fluid mosaic model to the current model that lipids and proteins have the ability to separate into microdomains, differing in their protein and lipid compositions. From the fluid mosaic model in 1972, membranes were proposed as a homogeneous lipid fluid phase with proteins embedded. This model has been weak because it has not given us more decisive information on membrane structure and function and it deemphasizes the *dynamic* transitions in membrane proteins and the need for the bilayer to adapt to protein conformational changes. Specifically, it has not provided direction into protein assembly, lipid bilayer heterogeneity, monolayer or bilayer curvature, and bilayer bending and thickness changes or fluctuations (see Figure 1-13, *A-D*). With more powerful technologies to observe and define membranes, it is now clear that lipids and proteins are not homogeneously distributed but rather separated into microdomains. The presence of structured lipid microdomains in lipid bilayers and biologic membranes (e.g., lipid rafts) illustrates the need for a revision of the classic view of biologic membranes. This new view dispels the randomness and disordered nature of the classic view and instead emphasizes an orderly organization with the many different molecular components of the membrane.

Data from Bagatolli LA et al: *Prog Lipid Res* 49(4):378–389, 2010; Contreras FX et al: *Cold Spring Harb Perspect Biol* 3(6):pii a004705, 2011.

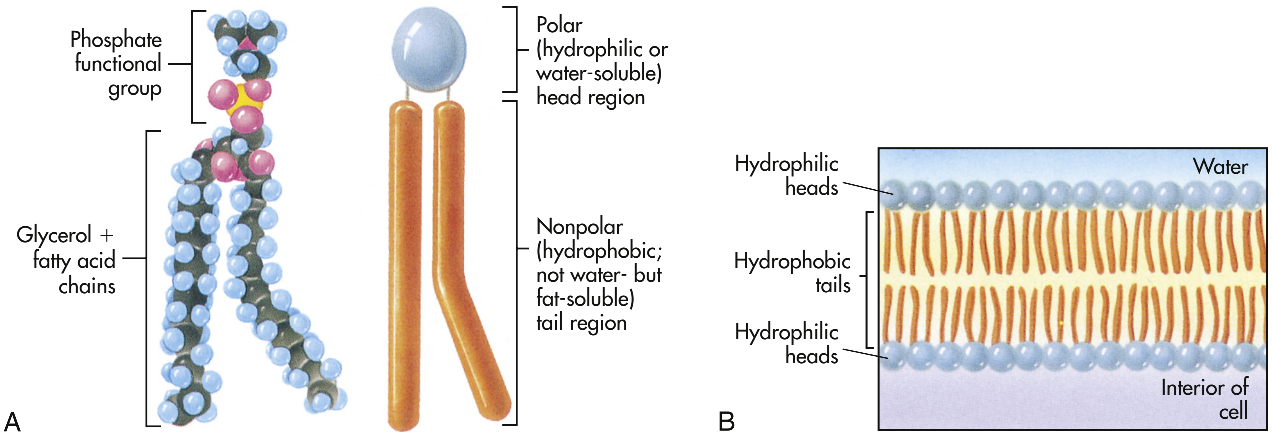

FIGURE 1-12 Structure of a Phospholipid Molecule. **A,** Each phospholipid molecule consists of a phosphate functional group and two fatty acid chains attached to a glycerol molecule. **B,** The fatty acid chains and glycerol form nonpolar, hydrophobic "tails," and the phosphate functional group forms the polar, hydrophilic "head" of the phospholipid molecule. When placed in water, the hydrophobic tails of the molecule face inward, away from the water, and the hydrophilic head faces outward, toward the water. (From Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.)

bilayer's structure accounts for one of the essential functions of the plasma membrane: it is impermeable to most water-soluble molecules (molecules that dissolve in water) because they are insoluble in the oily core region. The bilayer serves as a barrier to the diffusion of water and hydrophilic substances while allowing lipid-soluble molecules, such as oxygen (O_2) and carbon dioxide (CO_2), to diffuse through it readily. Because the bilayer is fluid at temperatures above freezing, components of the cellular environment move slowly and selectively across the membrane all the time. (Components of the cellular environment are also discussed in Chapter 3.)

Some membranes contain certain lipids that organize into lipid rafts. **Lipid rafts** consist of cholesterol and sphingolipid-dependent microdomains that form a network of lipid-lipid, protein-protein, and protein-lipid interactions (Figure 1-13). Lipid rafts may have several functions including the segregation of signaling mechanisms and molecules, the control of cytoskeletal remodeling events, and the targeted movement of associated proteins.[16]

Proteins. A **protein** is made from a chain of amino acids, known as **polypeptides.** There are 20 types of amino acids in proteins and each type of protein has a unique sequence of amino acids. Proteins are the major workhorses of the cell. After translation of a protein, **posttranslational modifications (PTMs)** are the methods used to diversify the limited numbers of proteins generated. These modifications alter the activities and functions of proteins and have become very important in understanding diseases. Researchers have known for decades that pathogens interfere with the host's PTMs.[17] New approaches are being used to understand changes in proteins—a field called **proteomics** is the study of the **proteome** or entire set of proteins expressed by a genome from synthesis, translocation, and modification (e.g., folding) and their role in a staggering number of diseases (also see What's New? Endoplasmic Reticulum, Protein Folding, and ER Stress, p. 6).

Research suggests different ways to classify membrane proteins. One way is classification as peripheral or integral proteins. **Integral membrane proteins** are those embedded in the lipid bilayer and linked either to *phosphatidylinositol,* a minor phospholipid, or a fatty acid chain. The integral proteins can be removed from the membrane only by detergents that solubilize (dissolve) the liquid. **Peripheral membrane proteins** are not embedded in the bilayer but reside at one surface or the other, bound to an integral protein.

Although the classification of membrane proteins as peripheral or integral is commonly used, it does not describe how proteins are associated with the bilayer. Another mode of classification does so by taking into account the membrane-spanning, or transmembranous, nature of membrane proteins[1] (see Figure 1-13, *A*). According to this classification, proteins are associated with the lipid bilayer in four ways:

1. Some proteins, called **transmembrane proteins,** extend across the bilayer and are exposed to an aqueous environment on both sides.
2. Some intracellular proteins extend their polypeptide chain partially through the bilayer by means of a fatty acid chain.
3. Some cell surface proteins are attached to the bilayer by a covalent linkage (i.e., a specific oligosaccharide).
4. Some proteins do not extend even partially through the bilayer but are bound to the membrane by noncovalent linkages with other membrane proteins.

Proteins exist in densely folded molecular configurations rather than straight chains; so an excess of hydrophilic units is at the surface of the molecule and an excess of hydrophobic units is inside. Membrane proteins like other proteins are synthesized by the ribosome and then travel, called *trafficking,* to different membrane locations of a cell.[18] Trafficking places unique demands on membrane proteins for folding, translocation, and stability.[18] Thus, much research is now being done to understand misfolded proteins, for example, as a cause of disease (see What's New? Endoplasmic Reticulum, Protein Folding, and ER Stress, p. 6).

Proteins facilitate transport across membranes by serving as receptors, enzymes, or transporters. Proteins act as: (1) recognition and binding units (receptors) for substances moving in and

FIGURE 1-13 Lipid Bilayer Membranes. **A,** Concepts of biologic membranes have markedly changed in the last two decades, from the classic fluid mosaic model to the current model that lipids and proteins are not evenly distributed but can isolate into microdomains, differing in their protein and lipid composition. An example of a microdomain is lipid rafts (colored yellow). Rafts are dynamic domain structures composed of cholesterol, sphinogolipids, and membrane proteins important in different cellular processes. Various models exist to clarify the functions of domains. The three major phases of lipid bilayer organization include a solid gel phase (e.g., with low temperatures), a liquid-ordered phase (high temperatures), and a fluid liquid-crystalline (or liquid-disordered) phase. **B,** Some membrane-associated proteins are integrated into the lipid bilayer; other proteins are loosely attached to the outer and inner surfaces of the membrane. Transmembrane proteins protrude through the entire outer and inner surfaces of the membrane, and they can be attracted to microdomains through specific interactions with lipids. Interaction of the membrane proteins with distinct lipids depends on the hydrophobic thickness of the membrane, the lateral pressures of the membrane (mechanical force may shift protein channels from an open to closed state), the polarity or electrical charges at the lipid-protein interface, and the presence on the protein side of amino acid side chains. Important for pathophysiology is the proposal that protein-lipid interactions can be critical for correct insertion, folding, and orientation of membrane proteins. For example, diseases related to lipids that interfere with protein folding are becoming more prevalent. **C,** Investigators are studying the cooperative behavior of lipids, membrane fluctuations, and domains that influence protein organization and consequently protein function. Here a perturbed region develops around an integral protein. **D,** Two proteins are attracted because of the sharing of a perturbed region of the lipid bilayer. (Adapted from Bagatolli LA et al: *Prog Lipid Res* 49(4):378–389, 2010; Contreras F-X et al: *Cold Spring Harb Perspect Biol* 3(6):pii a004705, 2011; Cooper GM: *The cell—a molecular approach,* ed 2, Washington, DC, 2000; Defamie N, Mesnil M: *Biochim Biophys Acta*, 2011 Oct 2. [Epub ahead of print.].)

out of the cell; (2) pores or transport channels for various electrically charged particles called *ions* or *electrolytes* and specific carriers for amino acids and monosaccharides; (3) specific enzymes that drive active pumps that promote concentration of certain ions, particularly potassium (K^+), within the cell while keeping concentrations of other ions, for example, sodium (Na^+), below concentrations found in the extracellular environment; (4) cell surface markers, such as **glycoproteins** (proteins attached to carbohydrates) that identify a cell to its neighbor; (5) **cell adhesion molecules (CAMs),** or proteins that allow cells to hook together and form attachments to the cytoskeleton for maintaining cellular shape; and (6) catalysts of chemical reactions, for example, conversion of lactose to glucose. (Membrane transport is discussed on p. 28.) Membrane proteins are key components of energy transduction, converting chemical energy into electrical energy, or electrical energy into either mechanical energy or synthesis of ATP.[18]

The interaction of plasma membrane proteins with lipids is complex and is the subject of much research. The role of proteins in the onset and progression of disease is important because they govern communication between cells through enzymatic, transport, and recognition-receptor functions in cellular physiology.

Proteolytic Cascades. **Proteases** are enzymes that cause the breakdown of proteins. Certain proteases can be tethered to cell membranes. Proteases are involved in the physiologic regulation of essential processes by participating in a tightly orchestrated sequence of events termed a **proteolytic cascade.** Four major proteolytic cascades with disease relevance are candidates for treatment modalities, including (1) cell death or caspase-mediated apoptosis, (2) blood coagulation cascade, (3) degrading membrane enzymes or matrix metalloproteinase cascade, and (4) the complement cascade. Some proteases within a proteolytic cascade act as initiators; others are involved in amplification and propagation and execution (Figure 1-14). Understanding the various steps involved is crucial for designing drug interventions. Dysregulation of proteases features prominently in many human diseases, including cancer, autoimmunity, and neurodegenerative disorders.[19-21]

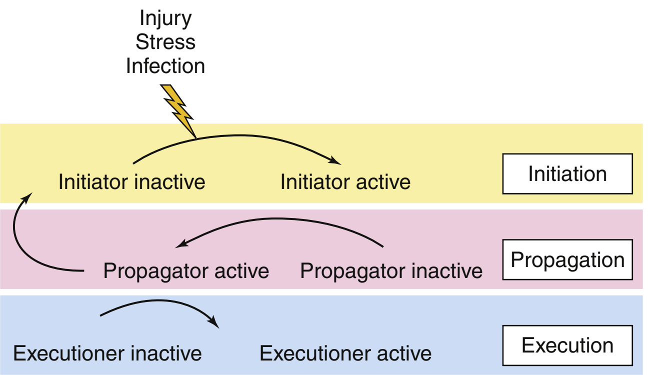

FIGURE 1-14 Schematic Representation of a Prototype Proteolytic Cascade. In the initiation phase, the cascade is triggered by an external stimulus, such as injury, stress, or infection. During the propagation phase, the initiator converts a downstream propagator into its active form by proteolysis. In the execution phase, the propagator will activate an executor. The process of coagulation is the best known proteolytic cascade. (Redrawn with permission from Amour A et al: *Biochem Soc Trans* 32:15–16, 2004. © The Biochemical Society.)

Carbohydrates. The carbohydrate (oligosaccharides) contained within the plasma membrane is generally bound to membrane proteins (glycoproteins) and lipids (glycolipids). Intercellular recognition, which is required for tissue formation, is an important function of membrane oligosaccharides.

Abnormal surface carbohydrate markers have been identified in certain tumor cells, leading investigators to claim that these

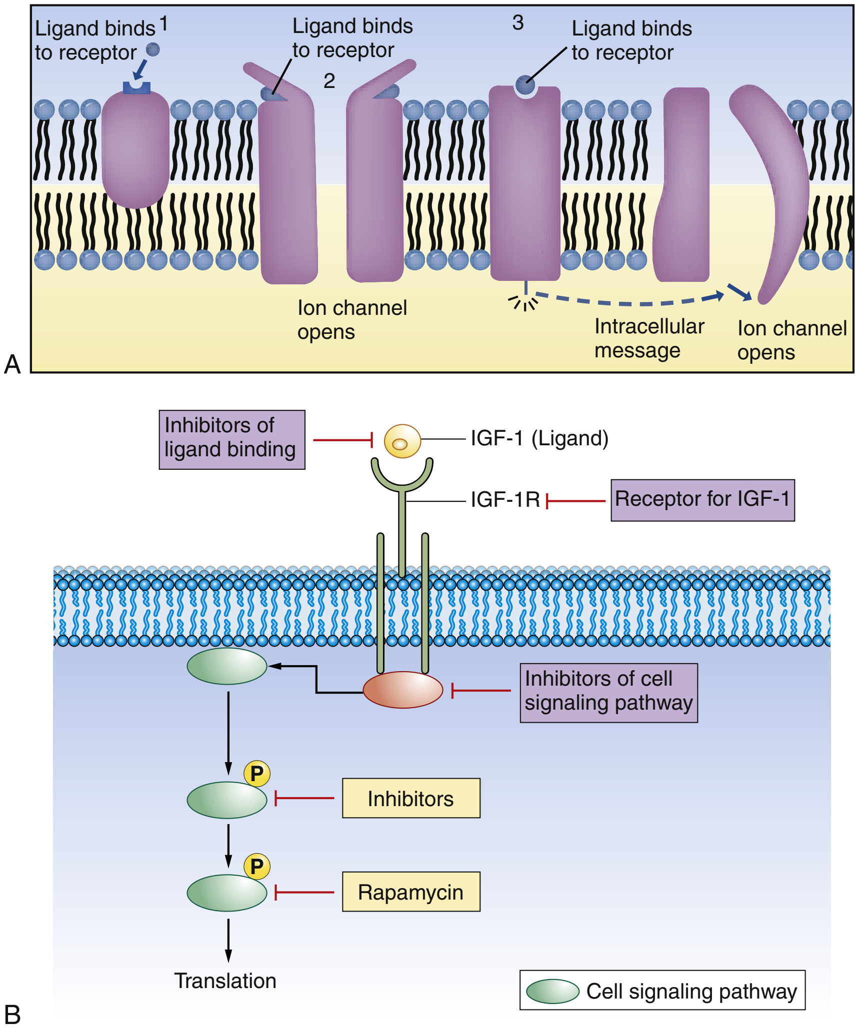

FIGURE 1-15 **Cellular Receptors. (A) 1,** Plasma membrane receptor for a ligand (here, a hormone molecule) on the surface of an integral protein. A neurotransmitter can exert its effect on a postsynaptic cell by means of two fundamentally different types of receptor proteins: **2,** channel-linked receptors, and **3,** non–channel-linked receptors. Channel-linked receptors are also known as ligand-gated channels. **(B)** Example of ligand-receptor interaction. Insulin-like growth factor 1 (IGF-1) is a ligand and binds to the insulin-like growth factor 1 receptor (IGF-1R). With binding at the cell membrane the intracellular signaling pathway is activated, causing translation of new proteins to act as intracellular communicators. This pathway is important for cancer growth. Researchers are developing pharmacologic strategies to reduce signaling at and downstream of the IGF-1R, hoping this will lead to compounds useful in cancer treatment.

markers are involved in tissue growth. Cells do not normally "trespass" their boundaries and overgrow their own territory.

Cellular Receptors

Cellular receptors are protein molecules (proteins are discussed on p. 13) on the plasma membrane, in the cytoplasm, or in the nucleus that are capable of recognizing and binding with specific smaller molecules called **ligands** (Figure 1-15). Hormones, for example, are ligands. Recognition and binding depend on the chemical configuration of the receptor and its smaller ligand, which must fit together somewhat like pieces of a jigsaw puzzle (see Chapter 21). Activation of a receptor also may depend on differences in *movement* and *binding* of the extracellular face of the receptor.[22]

Plasma membrane receptors are particularly important for cellular uptake of ligands (see Figure 1-15, *B*, and Table 1-2). They protrude from or are exposed at the external surface of the membrane and often are attached to integral proteins. Some of these recognition units have all the mobile properties related to membrane fluidity. The ligands that bind with membrane receptors include hormones, neurotransmitters, antigens, complement components, lipoproteins, infectious agents, drugs, and metabolites. The past several years have brought many new discoveries concerning the specific interactions of cellular receptors with their respective ligands. In many instances this information has provided a basis for understanding disease.

Although the chemical nature of both ligands and the receptors to which they bind differs, receptors are classified on the basis of their location and function (see Cellular Communication and Signal Transduction, p. 20). Cellular type determines overall cellular function, but plasma membrane receptors determine which ligands a cell will bind with and how the cell will

TABLE 1-2 CLASSES OF PLASMA MEMBRANE RECEPTORS

TYPE OF RECEPTOR	DESCRIPTION
Channel linked	Also called ligand-gated channels; involve rapid synaptic signaling between electrically excitable cells. Channels open and close briefly in response to neurotransmitters, changing ion permeability of plasma membrane of postsynaptic cell.
Catalytic	Once activated by ligands, function directly as enzymes. Composed of transmembrane proteins that function intracellularly as tyrosine-specific protein kinases.
G-protein linked	Indirectly activate or inactivate plasma membrane enzyme or ion channel; interaction mediated by guanosine triphosphate (GTP)–binding regulatory protein (G protein). When activated, a chain of reactions occurs that alters concentration of intracellular messengers, such as cyclic adenosine monophosphate (cAMP) and calcium, or signaling molecules. Behaviors of other target proteins are also altered. May also interact with inositol phospholipids, which are significant in cell signaling, and molecules involved in the inositol-phospholipid transduction pathway. A G-protein–linked receptor activates the enzyme phosphoinositide-specific phospholipase, which in turn generates two intracellular messengers: (1) inositol triphosphate (IP_3) releases Ca^{++}, and (2) diacylglycerol remains in the plasma membrane and activates protein kinase C. Protein kinase C further activates various cell proteins. Several different plasma membrane receptors are known to use the inositol-phospholipid transduction pathway.

Data from Alberts B et al: *Molecular biology of the cell,* ed 5, New York, 2008, Garland.

respond to binding with each. For example, the ability of a hormone or a neurotransmitter to stimulate a cell is regulated by the specificity and number of receptors present on the plasma membrane. Specific processes also control intracellular mechanisms. Hormone binding, for example, depends on special messenger molecules that regulate protein synthesis within the cell (see Chapter 21). Neurotransmitters (discussed in Chapter 15) also operate by causing special messengers to react with specific receptors.

Receptors for different drugs are found on the plasma membrane, in the cytoplasm, and in the nucleus. Membrane receptors have been found for certain anesthetics, opiates, endorphins, enkephalins, antibiotics, cancer chemotherapeutic agents, digitalis, and other drugs. Membrane receptors for endorphins, which are opiate-like peptides isolated from the pituitary gland, are found in large quantities in pain pathways of the nervous system (see Chapters 15 and 16). With binding, the endorphins (or drugs like morphine) change the cell's permeability to ions, increase the concentration of molecules that regulate intracellular protein synthesis, and initiate molecular events that modulate pain perception.

Receptors for infectious microorganisms, or antigen receptors, bind bacteria, viruses, and parasites. Antigen receptors on white blood cells (lymphocytes, monocytes, macrophages, granulocytes) recognize and bind with antigenic microorganisms and activate the immune and inflammatory responses (see Chapters 7 and 8).

CELL-TO-CELL ADHESIONS

Cells are small and squishy, not at all like bricks. They are enclosed by a flimsy membrane, yet the cell depends on the integrity of this membrane for its survival. How can cells be combined together strongly, with their membranes intact, to form a muscle that can lift this textbook? Plasma membranes not only serve as the outer boundaries of all cells but also allow groups of cells to be held together robustly, in **cell-to-cell adhesions,** to form tissues and organs. Once arranged, cells are held together by three different means: the extracellular matrix, cell adhesion molecules in the cell's plasma membrane, and specialized cell junctions.

Extracellular Matrix

Cells can be bound together by attachment to one another or via the **extracellular matrix** (also including the basement membrane), which the cells secrete around themselves. The extracellular matrix is an intricate meshwork of fibrous proteins embedded in a watery, gel-like substance composed of complex carbohydrates (Figure 1-16). The matrix is like glue; however, it does provide a pathway for diffusion of nutrients, wastes, and other water-soluble traffic between the blood and tissue cells. Interwoven within the matrix are three groups of **macromolecules:** (1) fibrous structural proteins, including collagen and elastin; (2) a diverse group of adhesive glycoproteins, such as fibronectin; and (3) proteoglycans and hyaluronic acid. The **basement membrane** is a thin layer of connective tissue underlying the epithelium of many organs and is also called the **basal lamina** (see Figure 1-16).

Collagen forms cable-like fibers or sheets that provide tensile strength or resistance to longitudinal stress. Collagen breakdown, such as occurs in osteoarthritis, destroys the fibrils that give cartilage its tensile strength.

Elastin is a rubber-like protein fiber most abundant in tissue that must be capable of stretching and recoiling, such as the lungs.

Fibronectin, a large glycoprotein, promotes cell adhesion and cell anchorage. Reduced amounts have been found in certain types of cancerous cells; this allows cancer cells to travel or metastasize to other parts of the body.

All of these macromolecules occur in intercellular junctions and cell surfaces and may assemble into two different components: interstitial matrix and basement membrane (BM)[23] (see Figure 1-16).

The extracellular matrix is secreted by **fibroblasts** ("fiber formers"), local cells that are present in the matrix. The matrix and the cells within it are known collectively as *connective tissue* because they connect cells together to form tissue and organs. Human connective tissues are enormously varied. They can be

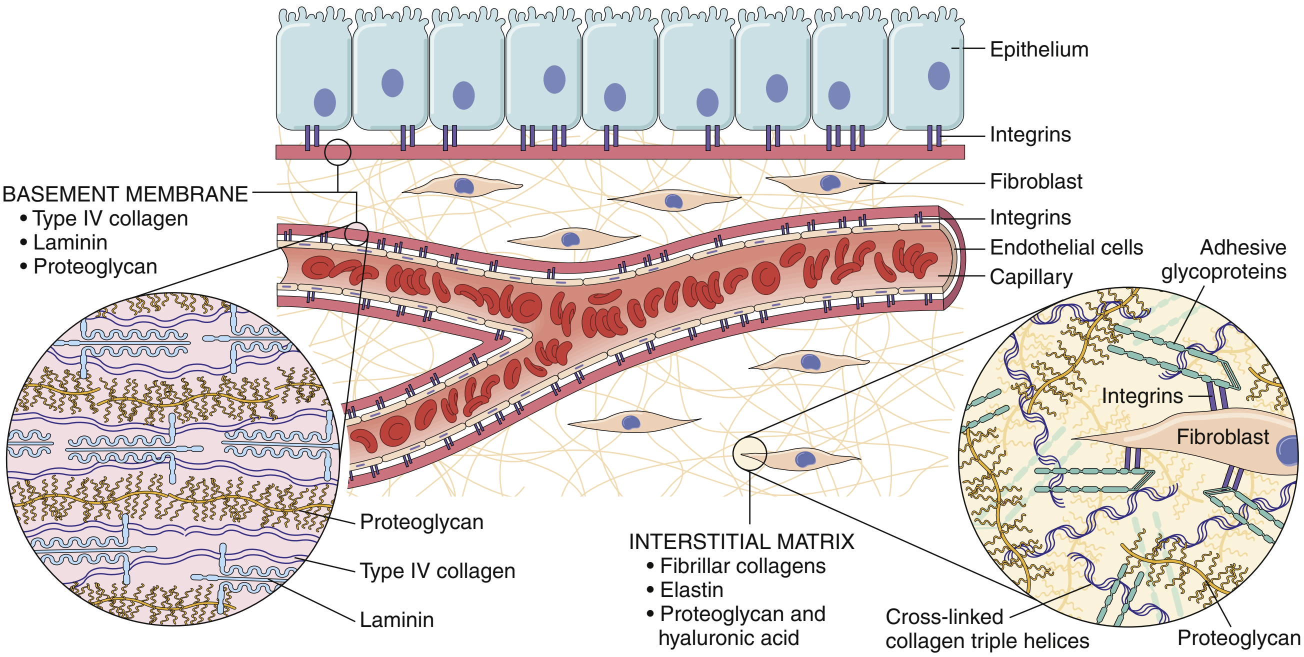

FIGURE 1-16 Extracellular Matrix. Tissues are not just cells but also extracellular space. The extracellular space is an intricate network of macromolecules called the *extracellular matrix (ECM)*. The macromolecules that constitute the ECM are secreted locally (by mostly fibroblasts) and assembled into a meshwork in close association with the surface of the cell that produced them. Two main classes of macromolecules include proteoglycans, which are bound to polysaccharide chains called glycosaminoglycans; and fibrous proteins (e.g., collagen, elastin, fibronectin, and laminin), which have structural and adhesive properties. Together the proteoglycan molecules form a gel-like ground substance in which the fibrous proteins are embedded. The gel permits rapid diffusion of nutrients, metabolites, and hormones between the blood and the tissue cells. Matrix proteins modulate cell-matrix interactions including normal tissue remodeling (which can become abnormal, for example, with chronic inflammation), embryogenesis, wound healing, and angiogenesis. Disruption of this balance results in serious diseases such as arthritis, tumor growth, and others. (From Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

hard and dense, like bone; flexible, like tendons or the dermis of the skin; resilient and shock-absorbing, like cartilage; or soft and transparent, like the jelly-like substance that fills the eye. In all these examples, the majority of the tissue is composed of extracellular matrix, and the cells that produce the matrix are scattered within it like raisins in a pudding[24] (see Figure 1-16).

The matrix is not just passive scaffolding for cellular attachment; it also helps regulate the functions of the cells within which it interacts. The matrix helps regulate cell growth, movement, and differentiation.

Cell-Adhesion Molecules (CAMs)

Cell adhesion molecules (CAMs) are cell-surface proteins that bind the cell to an adjacent cell and to components of the extracellular matrix (ECM). CAMs include four protein families: the integrins, the cadherins, the selectins, and Ig (immunoglobulin) superfamily. **Integrins** are a major class of receptors within the ECM and regulate cell-ECM interactions with collagen, fibronectin, vitronectin, and fibrinogen. **Cadherins** are Ca^{+2} –dependent glycoproteins and have a unique pattern of tissue distribution, for example, epithelial (E-cadherin). **Selectins** are a family of proteins that bind certain carbohydrates, for example mucins. The **immunoglobulin superfamily CAMs (IgSF CAMs)** bind integrins or other IgSF CAMs.

Specialized Cell Junctions

Cells in direct physical contact with neighboring cells are often linked together at specialized regions of their plasma membranes called **cell junctions.** Cell junctions have two main functions: (1) to hold cells together and (2) to allow small molecules to pass from cell to cell, allowing coordination of the activities of cells that form tissues. The three main types of cell junctions are (1) desmosomes (adhering junctions, or macula adherens), (2) tight junctions (impermeable junctions, or zonula occludens), and (3) gap junctions (adhering [communicating] junctions) (Figure 1-17, *A*). Together they form the **junctional complex. Desmosomes** hold cells together by forming either continuous bands or belts of epithelial sheets or button-like points of contact. Desmosomes also act as a system of braces to maintain structural stability. **Tight junctions** are barriers to diffusion, prevent the movement of substances through transport proteins in the plasma membrane, and prevent the leakage of small molecules between the plasma membranes of adjacent cells. **Gap junctions** are clusters of communicating tunnels, **connexons,** that allow small ions and molecules to pass directly from the inside of one cell to the inside of another. Connexons are joining proteins that extend outward from each of the adjacent plasma membranes (see Figure 1-17, *C*). The integrity of connexons and dysregulation of intercellular ion movement

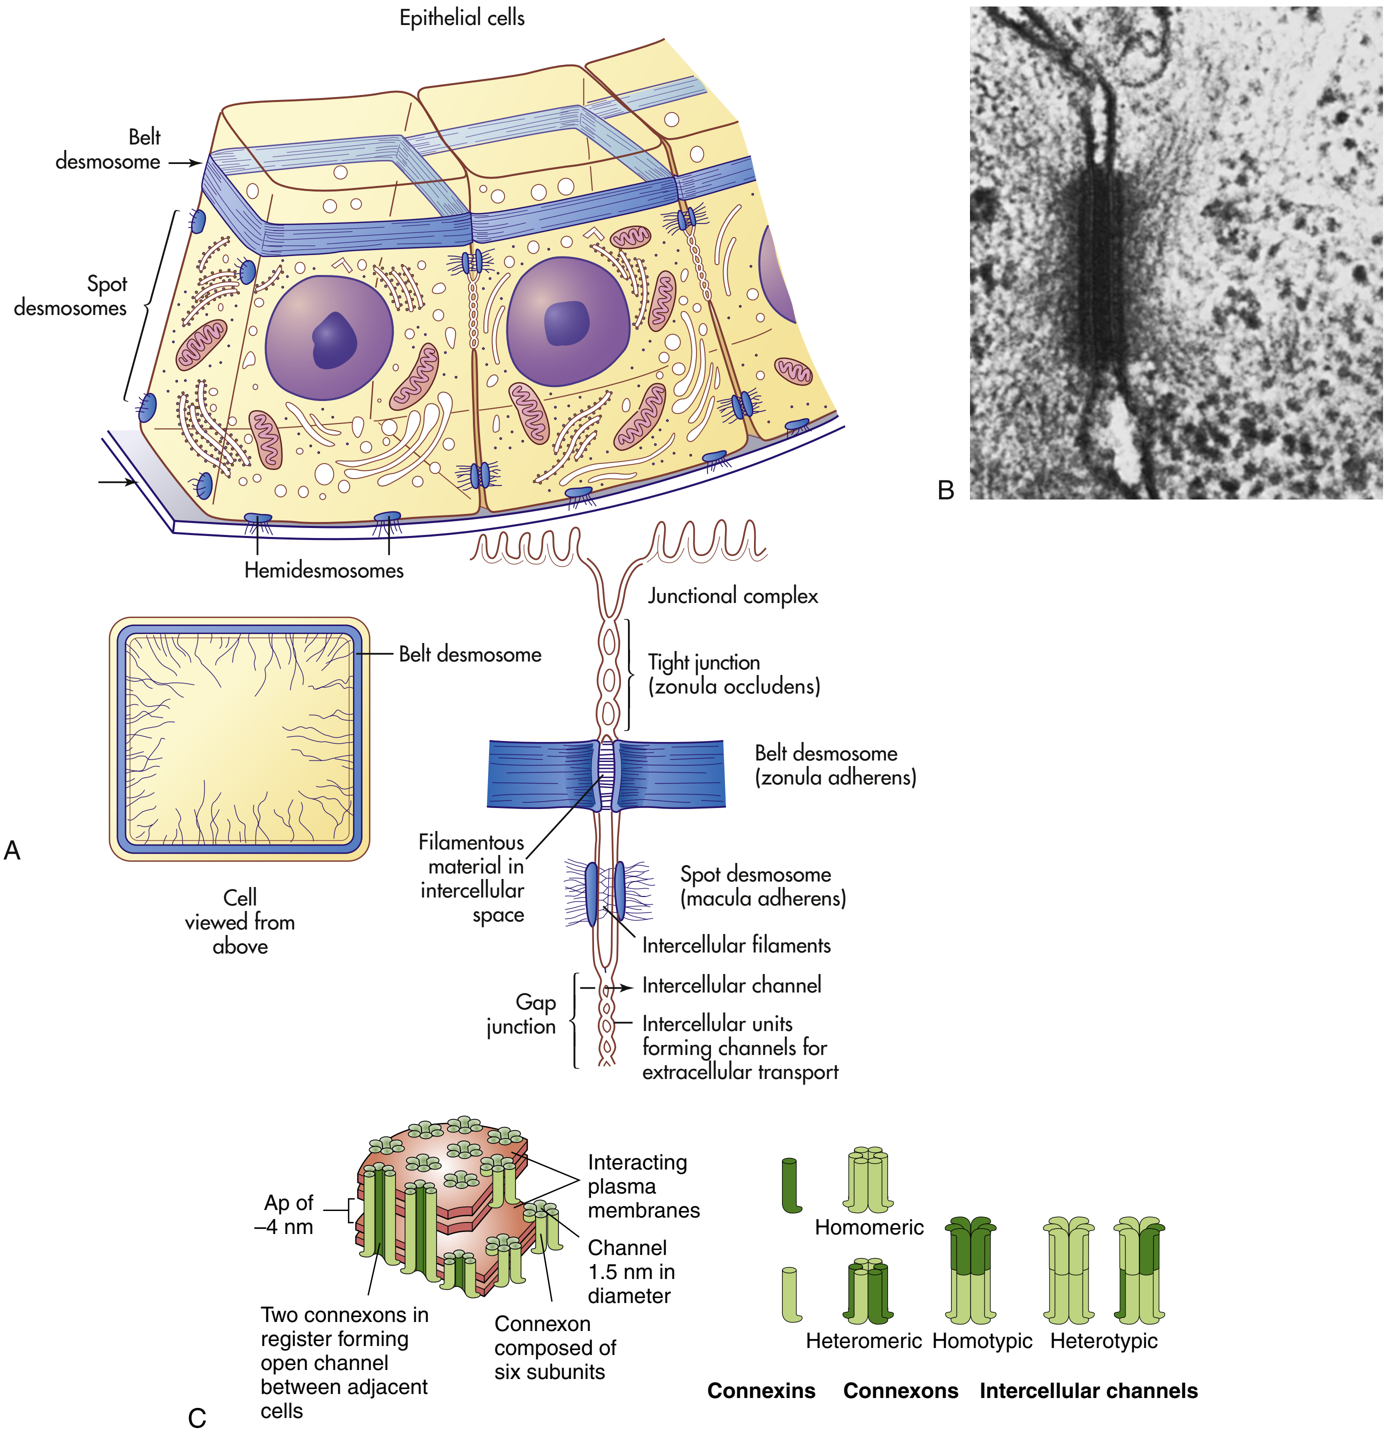

FIGURE 1-17 Types of Cell Connections. **A,** Schematic drawing of a belt desmosome between epithelial cells. This junction, also called *zonula adherens,* encircles each interacting cell. The spot desmosomes and hemidesmosomes, like the belt desmosomes, are adhering junctions. This tight junction is an impermeable junction that holds cells together but seals them in such a way that molecules cannot leak between them. The gap junction, as a communicating junction, mediates the passage of small molecules from one interacting cell to the other. **B,** Electron micrograph of desmosomes. **C,** Connexons. (**A, B** from Raven PH, Johnson GB: *Biology,* St Louis, 1992, Mosby. **C** from Alberts B et al: *Molecular biology of the cell,* ed 5, New York, 2008, Garland.)

has been linked to certain disorders, for example, atrial fibrillation.[25] Cells connected by gap junctions are considered ionically (electrically) and metabolically coupled. Gap junctions coordinate the activities of adjacent cells. They are important, for example, in synchronizing contractions of heart muscle cells through ionic coupling and in permitting action potentials to spread rapidly from cell to cell in neural tissues. The reason that gap junctions occur in tissues that are not electrically active is unknown. Although most gap junctions are associated with junctional complexes, they sometimes exist as independent structures.

The junctional complex is a highly permeable part of the plasma membrane. Its permeability is controlled by a process called **gating,** which depends on concentrations of calcium ions in the cytoplasm. Increased cytoplasmic calcium concentration causes decreased permeability at the junctional complex. Gating is an important cellular defense mechanism because it enables uninjured cells to seal themselves off from injured neighbors. As damaged cells release calcium, it travels through the junctional complex and increases calcium levels in neighboring cells. (The damaging effects of calcium influx are described in Chapter 2.) The increased calcium concentration decreases the permeability of the junctional complexes of the neighboring cells, which form a relatively impermeable wall around the injured area.

CELLULAR COMMUNICATION AND SIGNAL TRANSDUCTION

Cells need to communicate with each other to maintain a stable internal environment, or **homeostasis;** to regulate their growth and division and their development and organization into tissues; and to coordinate their functions. Cells communicate by using hundreds of kinds of signal molecules, for example, insulin (see Figure 1-15, *B*). Cells communicate in three main ways: (1) they display plasma membrane–bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact (Figure 1-18, *A*); (2) they affect receptor proteins *inside* the target cell and the signal molecule has to enter the cell to bind to them (Figure 1-18, *B*); and (3) they form protein channels (gap junctions) that directly coordinate the activities of adjacent cells (Figure 1-18, *C*). Alterations in cellular communication affect disease onset and progression. In fact, if a cell is unable to perform gap junctional intercellular communication, it is hypothesized that normal growth control and cell differentiation are compromised, favoring cancerous tumor development (see Chapter 12). (Communication through gap junctions is discussed earlier, and contact signaling by plasma membrane–bound molecules is shown in Figure 1-18.) Secreted chemical signals involve communication at a distance. Primary modes of intercellular signaling are contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter (Figure 1-19).

Contact-dependent signaling requires cells to be in close membrane-membrane contact. In **paracrine signaling,** cells secrete local chemical mediators that are quickly absorbed, destroyed, or immobilized. Paracrine signaling usually involves different cell types; however, cells also can produce signals that they, themselves, respond to called **autocrine signaling** (see Figure 1-19). For example, cancer cells use this form of signaling to stimulate their survival and proliferation. Autocrine circuits function as a component of normal growth-regulatory mechanisms in many adult tissue types.[26] **Hormonal signaling** involves specialized endocrine cells that secrete chemicals called hormones (e.g., thyroid-stimulating hormone); hormones are released by one set of cells and travel through the tissue and through the bloodstream to produce a response in other sets of cells (see Chapter 21). In **neurohormonal signaling,** hormones (e.g., angiotensin II) are released into the blood by neurosecretory neurons. Like endocrine cells, neurosecretory neurons release blood-borne chemical messengers, whereas ordinary neurons secrete short-range neurotransmitters into a small, discrete space (i.e., synapse). Neurons communicate directly with the cells they innervate by releasing chemicals or **neurotransmitters** at specialized junctions called **chemical synapses;** the neurotransmitter diffuses across the synaptic cleft and acts on the postsynaptic target cell (see Figure 1-20). Many of these same signaling molecules are receptors used in hormonal, neurohormonal, and paracrine signaling. The important differences lie in the speed and selectivity with which the signals are delivered to their targets.[1]

Plasma membrane receptors belong to one of three classes that are defined by the signaling (transduction) mechanism used. Table 1-2 summarizes these classes of receptors.

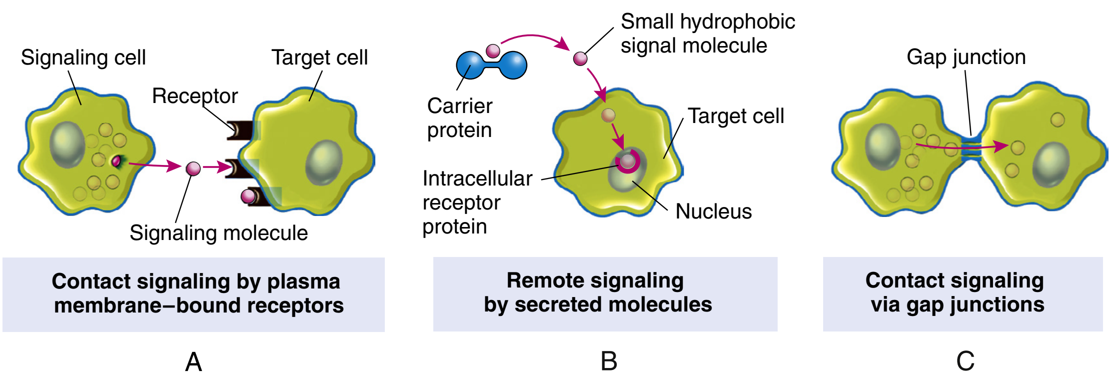

FIGURE 1-18 Cellular Communication. Three ways in which cells communicate with one another. (**B** adapted from Alberts B et al: *Molecular biology of the cell,* ed 5, New York, 2008, Garland.)

Signal Transduction

Signal transduction involves incoming signals or instructions from extracellular chemical messengers (ligands) that are conveyed to the cell's interior for execution. Cells respond to external stimuli by activating a variety of **signal transduction pathways,** which are communication pathways, or signaling cascades (Figure 1-20). Signals are passed between cells when a particular type of molecule is produced by one cell—the **signaling cell**—and received by another—the **target cell**—by means of a **receptor protein** that recognizes and responds specifically to the signal molecule (Figure 1-20, *A* and *B*). In turn, the signaling molecules activate a path of intracellular protein kinases that results in responses, such as grow and divide, survive, or differentiate (Figure 1-20, *C* and *D*). If deprived of appropriate signals, most cells undergo a form of cell suicide known as *programmed cell death,* or *apoptosis* (see p. 88).

Signal transduction pathways, or relay chains, of intercellular signaling molecules have several important functions (see Figure 1-20):

1. They physically *transfer* the signal from the place at which it is received to some other part of the cell where the response is expected.
2. They *amplify* the signal received, making it stronger; this is caused by a multiplying effect in the pathways; for example, binding of one ligand molecule to a receptor activates a number of adenylyl cyclase molecules.
3. They *distribute* the signal so that it influences several processes in parallel; at any step in the pathway, the signal can *diverge* and be relayed to several different intracellular targets, creating branches in the flow and causing a complex response (see Figure 1-20).
4. Last, the signal can be *modulated* by other interfering factors prevailing inside or outside the cell.

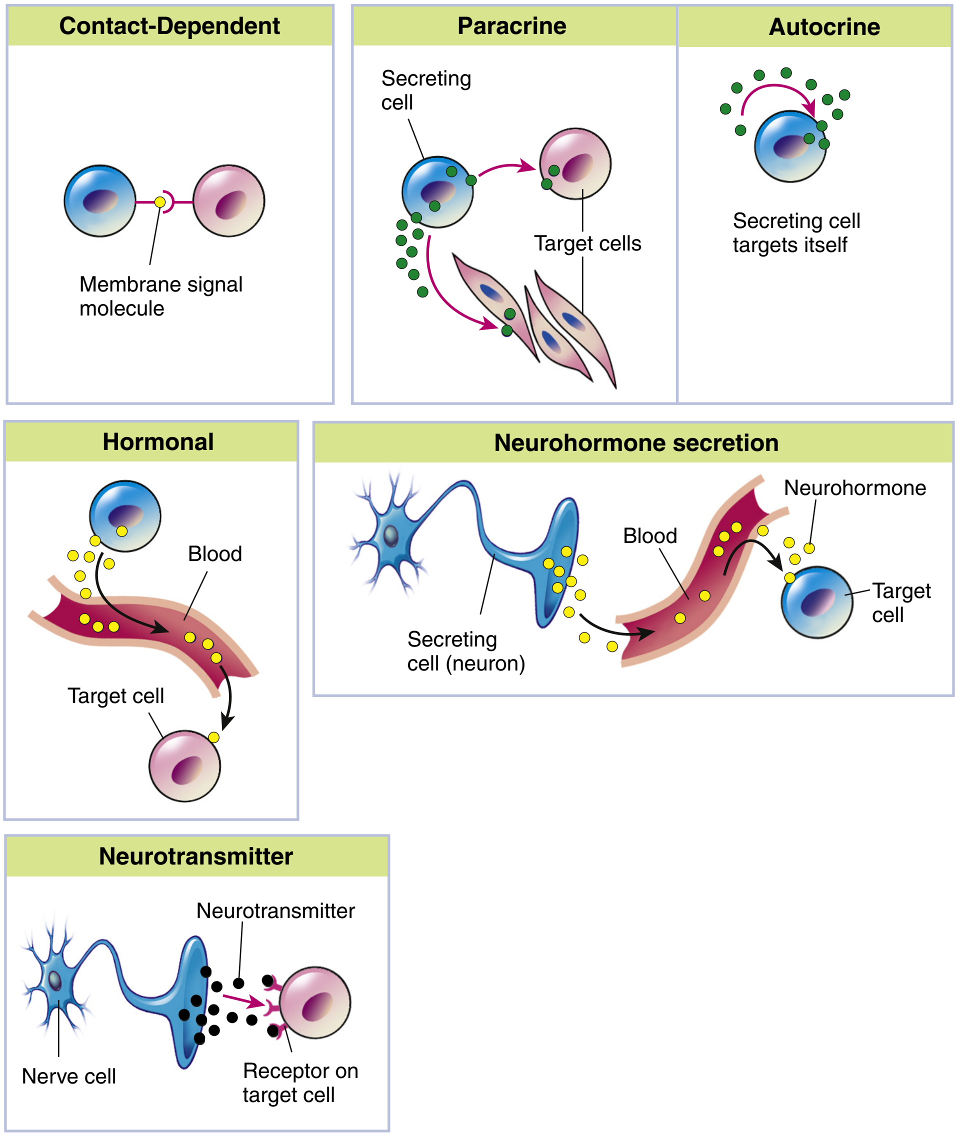

FIGURE 1-19 Primary Modes of Chemical Signaling. Five forms of signaling mediated by secreted molecules. Hormones, paracrines, neurotransmitters, and neurohormones are all intercellular messengers that accomplish communication between cells. Autocrines bind to receptors on the same cell. Not all neurotransmitters act in the strictly synaptic mode shown; some act in a contact-dependent mode as local chemical mediators that influence multiple target cells in the area.

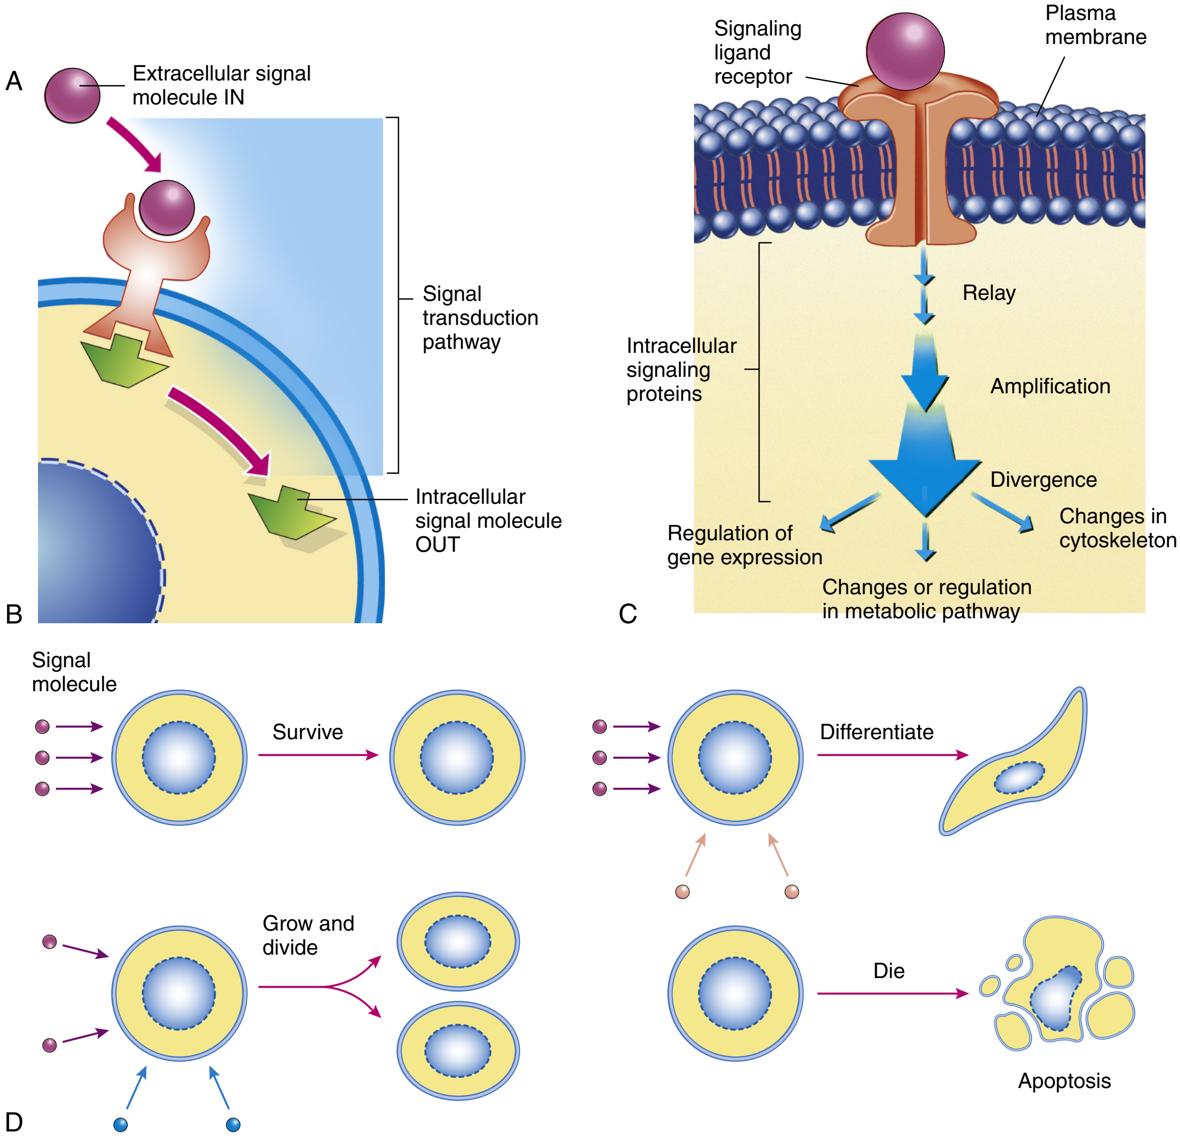

FIGURE 1-20 **Schematic of a Signal Transduction Pathway.** Like a telephone receiver that converts an electrical signal into a sound signal, a cell converts an extracellular signal, **A,** into an intracellular signal, **B. C,** An extracellular signal molecule (ligand) binds to a receptor protein located on the plasma membrane, where it is transduced into an intracellular signal. This process initiates a signaling cascade that relays the signal into the cell interior, amplifying and distributing it en route. Amplification is often achieved by stimulating enzymes. Steps in the cascade can be modulated by other events in the cell. **D,** Different cell behaviors rely on multiple extracellular signals.

Two general responses from binding of the extracellular signaling messenger (i.e., ligand), or **first messenger,** to the membrane receptors occur: (1) opening or closing specific channels in the membrane to regulate the movement of ions into or out of the cell, and (2) transferring the signal to an intracellular messenger, or **second messenger,** which in turn triggers a cascade of biochemical events within the cell.

Extracellular Messengers and Channel Regulation

Membrane channels, or "gates," can open and close depending on the circumstances of the first messenger. Opening and closing occur because of conformational changes (shaping) of the proteins that form the channels—blocking the channel (closing) or permitting passage through it (opening). Channel opening and closing can be initiated in one of three ways: (1) by binding of a ligand to a specific membrane receptor that is closely associated with the channel (for example, G proteins); (2) by making changes in the electrical current in the plasma membrane, altering the flow of Na^+ and K^+; and (3) by stretching or other mechanical deformation of the channel. Figure 1-21 summarizes ways by which extracellular messengers regulate channel function for the other two methods of controlling channels (see p. 23).

Second Messengers

Many ligands cannot enter their target cells to bring about the desired intracellular response. Instead, the first messengers, or ligands, issue orders by binding with receptors on the surface membrane, triggering a "pass it on" signal. Second messengers

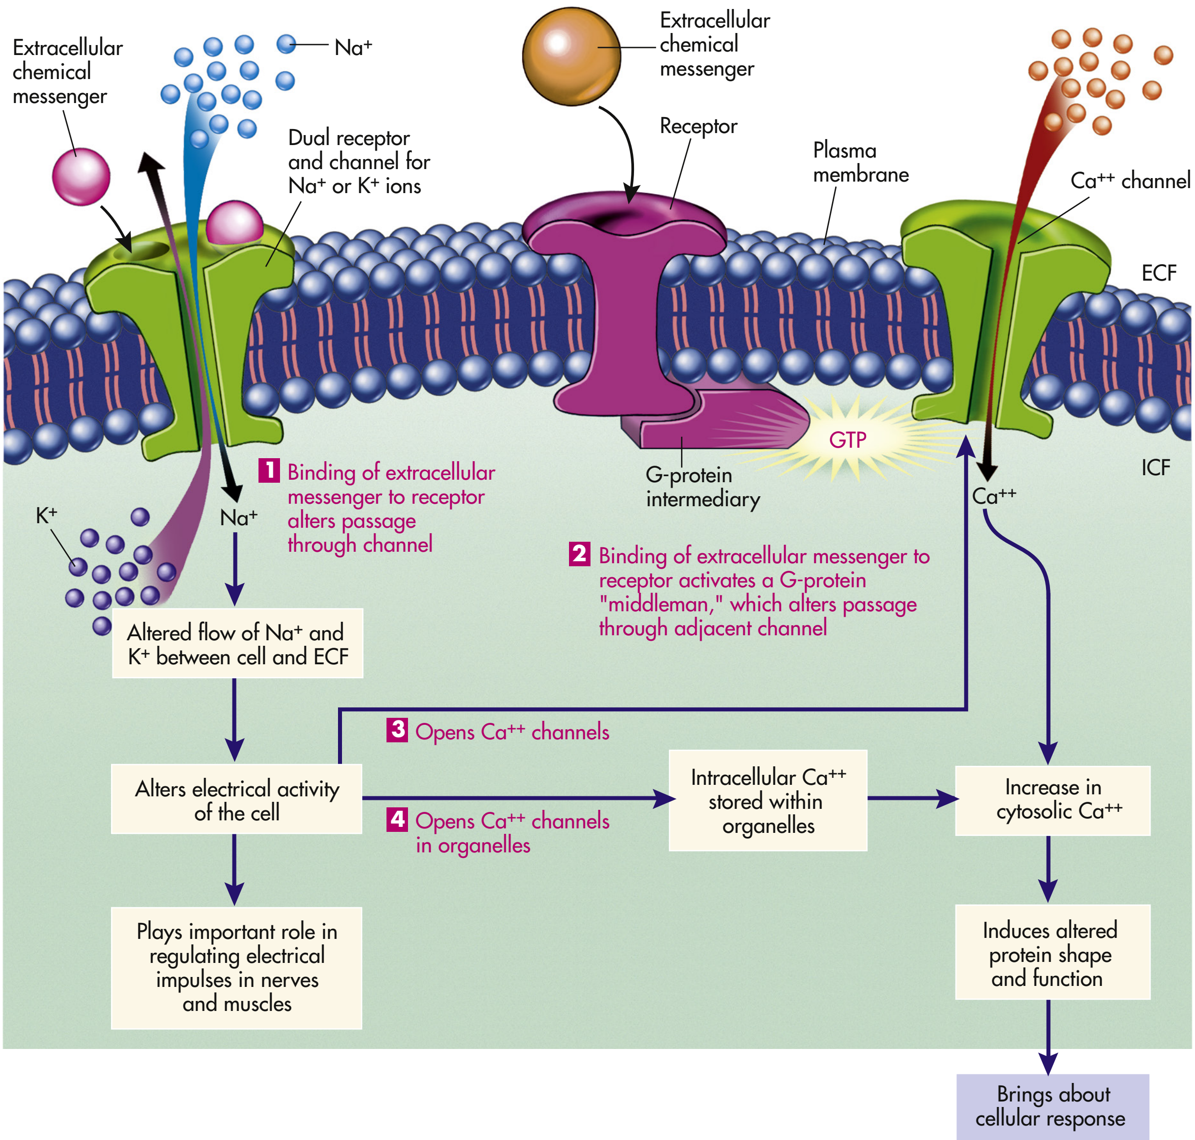

FIGURE 1-21 How Extracellular Messengers Regulate Channel Function. Binding of an extracellular messenger to a dual receptor/channel brings about a quick opening or closing of ion channels, such as Na^+ or K^+ channels, which generates electrical impulses **(1).** A transient opening of membrane Ca^{++} channels occurs when binding of an extracellular messenger to a receptor activates a G-protein intermediary, which alters a nearby ion channel, such as a Ca^{++} channel **(2).** A transient opening of Ca^{++} channels also occurs indirectly in response to electrical impulses produced by extracellular messenger-induced changes in Na^+ and K^+ channels **(3).** Release of Ca^{++} from intracellular stores results when Ca^{++} channels in organelles open in response to electrical impulses **(4).** An increase in cytosolic Ca^{++} concentration arising from pathways **2, 3,** or **4** causes change in the shape and function of specific intracellular proteins to produce the desired cellular response. *ECF,* Extracellular fluid; *GTP,* guanosine triphosphate; *ICF,* intracellular fluid. are generated in large numbers when the membrane-bound enzyme is activated, and they then rapidly diffuse away from their source, broadcasting the signal throughout the cell (Figure 1-22). Remember, most cell surface receptor proteins belong to one of three large classes: ion channel–linked receptors, G-protein–linked receptors, or enzyme-linked receptors.

The two major second messenger pathways are **cyclic adenosine monophosphate (cyclic AMP, cAMP)** and Ca^{++}. In the cAMP pathway, binding of the ligand to its surface receptor eventually activates the enzyme adenylyl cyclase on the inner surface of the membrane. A membrane-bound "middleman," a **G protein,** acts as an intermediary between the receptor and adenylyl cyclase. G proteins are named because they are bound to guanine nucleotides—**guanosine triphosphate (GTP)** or **guanosine diphosphate (GDP).** An unactivated G protein consists of a complex of alpha (α), beta (β), and gamma (γ) subunits, with a GDP molecule bound to the α subunit. The cAMP pathway with G proteins is summarized in Figure 1-22.

Instead of cAMP, some cells use Ca^{++} as a second messenger. In this pathway, binding of the first messenger to the surface

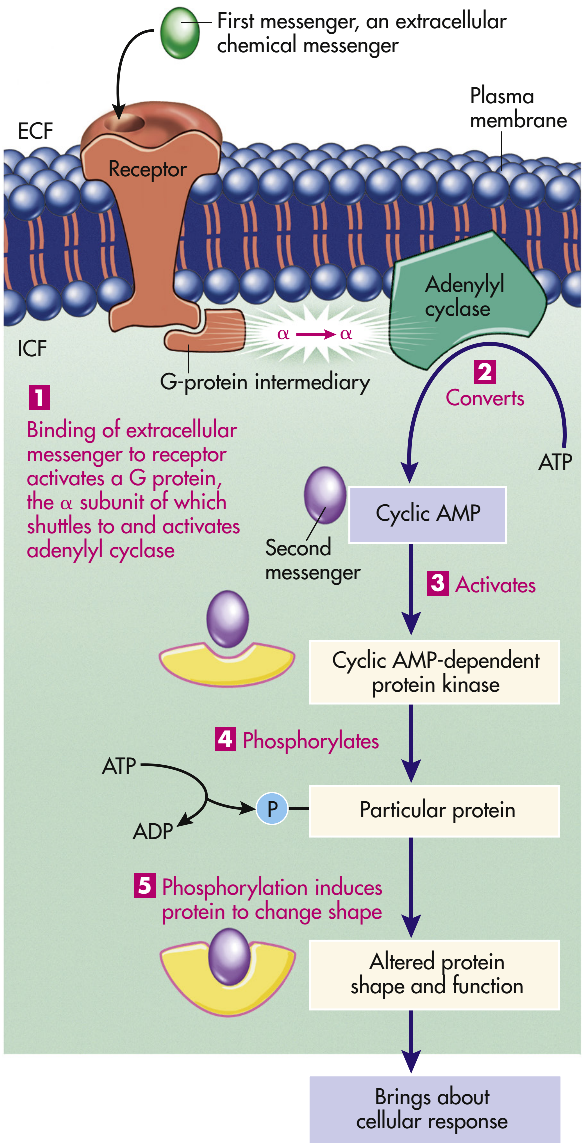

FIGURE 1-22 Extracellular Messenger and Activation of the cAMP Second Messenger System. The first messenger, or binding of an extracellular chemical messenger to a surface membrane receptor, activates the membrane-bound enzyme adenylyl cyclase by means of a G-protein intermediary **(1)**, which in turn converts intracellular ATP into cAMP **(2)**. cAMP is an intracellular second messenger, triggering the cellular response by activating the cAMP-dependent protein kinase **(3)**, which in turn phosphorylates **(4)**, and therefore modifies **(5)** a specific intracellular protein. The altered protein then directs the cellular response dictated by the extracellular messenger. *ADP,* Adenosine diphosphate; *AMP,* adenosine monophosphate; *ATP,* adenosine triphosphate; *ECF,* extracellular fluid; *ICF,* intracellular fluid. FIGURE 1-23 Extracellular Messenger and Activation of the Calcium Second Messenger System. Binding of an extracellular messenger to a membrane receptor activates the membrane-bound enzyme phospholipase C by means of a G-protein intermediary **(1)**. Phospholipase C converts phosphatidylinositol biphosphate *(PIP_2)* into diacylglycerol *(DAG)* and inositol triphosphate *(IP_3)* **(2)**. IP_3 then mobilizes Ca^{++} stored within organelles **(3)**. Ca^{++}, as a second messenger, activates calmodulin **(4)**, causing a change in the shape and function of a specific intracellular protein to produce the cellular response **(5)**. *ECF,* Extracellular fluid; ICF, intracellular fluid. (Redrawn with permission from Sherwood L: *Human physiology,* ed 3, © 1997 Brooks/Cole, a part of Cengage Learning, Inc. Reproduced by permission. www.cengage.com/permissions.)

receptor eventually leads, by means of G proteins, to activation of the enzyme phospholipase C, an enzyme protein effector (an ion channel for an enzyme) that is bound to the inner side of the membrane. Figure 1-23 summarizes the Ca^{++} second messenger pathway. The cAMP and Ca^{++} pathways frequently overlap in triggering a specific cellular response. For example, cAMP and Ca^{++} can influence each other. Calcium-activated calmodulin can regulate adenylyl cyclase and thus influence cAMP; conversely, cAMP-dependent kinase may phosphorylate and thereby change the activity of Ca^{++} channels or carriers. In some instances, both Ca^{++} and cAMP regulate the same intracellular protein. In a few cells, **cyclic guanosine monophosphate**

TABLE 1-3 HORMONE-INDUCED CELL RESPONSES MEDIATED BY cAMP

SIGNALING LIGANDS	TARGET TISSUE	MAJOR RESPONSE
Epinephrine	Heart	Increase in heart rate and force of contraction
Epinephrine, ACTH	Muscle	Glycogen breakdown
Glucagon	Fat	Fat breakdown
ACTH	Adrenal gland	Cortisol secretion
Antidiuretic hormone	Liver	Glycogen breakdown
Acetylcholine	Pancreas; smooth muscle	Amylase secretion; contraction
Antigen	Mast cells	Histamine secretion
Thrombin	Blood platelets	Serotonin and platelet-derived growth factor secretion; platelet aggregation

ACTH, Adrenocorticotropic hormone; *cAMP,* cyclic adenosine monophosphate.

TABLE 1-4 MAJOR TYPES OF RECEPTORS AND SIGNALING TRANSDUCTION PATHWAYS

RECEPTOR AND SIGNALING PATHWAY	LIGANDS
Receptors with Intrinsic Tyrosine Kinase Activity	
P13 kinase pathway, MAP-kinase pathway, IP_3 pathway	Signaling ligands include most growth factors (EGF, TGF-α, HGF, PDGF, VEGF, FGF), stem cell factor, insulin
Receptors Lacking Intrinsic Tyrosine Kinase Activity	
JAK/STAT pathway	Several cytokines including IL-2, IL-3, others; interferons α, β, and γ; erythropoietin; G-CSF; growth hormone; and prolactin
G-Protein–Coupled Receptors	
cAMP pathway	ADH, serotonin, histamine, epinephrine, norepinephrine, calcitonin, glucagon, parathyroid hormone, corticotropin, rhodopsin, and many drugs
Steroid Hormone Receptors	
Includes steroid hormone receptors as well as a group called peroxisome proliferator-activated receptors (PPARs)	Many steroid hormones, thyroid hormone, vitamin D, and retinoids

ADH, Antidiuretic hormone; *cAMP,* cyclic adenosine monophosphate; *EGF,* epidermal growth factor; *FGF,* fibroblast growth factor; *G-CSF,* granulocyte colony-stimulating factor; *HGF,* hepatocyte growth factor; IL-2, IL-3, interleukin-2 and interleukin-3; IP_3, inositol triphosphate; *JAK/STAT,* Janus kinase-signal transducers and activators of transcription; *MAP-kinase,* mitogen-activated protein kinase; *PDGF,* platelet-derived growth factor; *TGF-α,* transforming growth factor-alpha; *VEGF,* vascular endothelial growth factor.

(**cyclic GMP, cGMP**) serves as a second messenger similar to the cAMP pathway. For example, cGMP is the signal transduction pathway involved in vision. Some cellular responses mediated by cAMP and phospholipase C are summarized in Table 1-3. Major types of receptors and signal transduction pathways are contained in Table 1-4.

A large number of human disorders involve problematic signaling in cells. Cancer, for example, results from genetic mutations leading to the overactivity of proteins in signal relaying pathways that normally induce the cells to divide. Affected proteins cause cells to behave as if other cells were constantly telling them to reproduce, even when no such orders were sent.[27] Signal blockers are already in use against tumors.

CELLULAR METABOLISM

All the chemical tasks of maintaining essential cellular functions are referred to as **cellular metabolism.** The energy-using process of metabolism is called **anabolism** (*ana* = upward), and the energy-releasing process is known as **catabolism** (*cata* = downward). Metabolism provides the cell with the energy it needs to synthesize (produce) cellular structures.

Dietary proteins, fats, and starches are hydrolyzed in the intestinal tract into amino acids, fatty acids, and glucose, respectively. These constituents are then absorbed, circulated, and taken up by the cell, where they may be used for various vital cellular processes, including the production of ATP. The process by which ATP is produced is one example of a series of reactions called a **metabolic pathway.** A metabolic pathway involves several intermediate steps whose end products are not always detectable. A key feature of cellular metabolism is the directing of biochemical reactions by protein catalysts, or enzymes. Most biochemical reactions in a pathway are catalyzed by a specific enzyme. Each enzyme has a high affinity for a **substrate**—a specific substance that is converted to a product of the reaction.

Role of Adenosine Triphosphate

For a cell to function it must be able to extract and use the chemical energy contained within the structure of organic molecules. When 1 mole (mol) of glucose is metabolically broken down in the presence of oxygen into carbon dioxide (CO_2) and water (H_2O), 686 kilocalories (kcal) of energy are released. In a test tube this energy is released as heat. Because a cell cannot transform heat into work, chemical energy, rather than heat, is created by metabolism. The chemical energy lost by one molecule is transferred to the chemical structure of another molecule by an energy-carrying or transferring molecule, such as ATP. The energy stored in ATP can be used in a variety of energy-requiring reactions and in the process is generally converted to adenosine diphosphate (ADP) and inorganic phosphate (Pi). The energy available as a result of this reaction is about 7 kcal/mol of ATP. In addition to its use in synthesis (anabolism) of organic molecules, ATP is used by the cell for muscle contraction and active transport of molecules across cellular membranes. The function of ATP is not only to *store* energy but also to *transfer* it from one molecule to another. Energy is stored

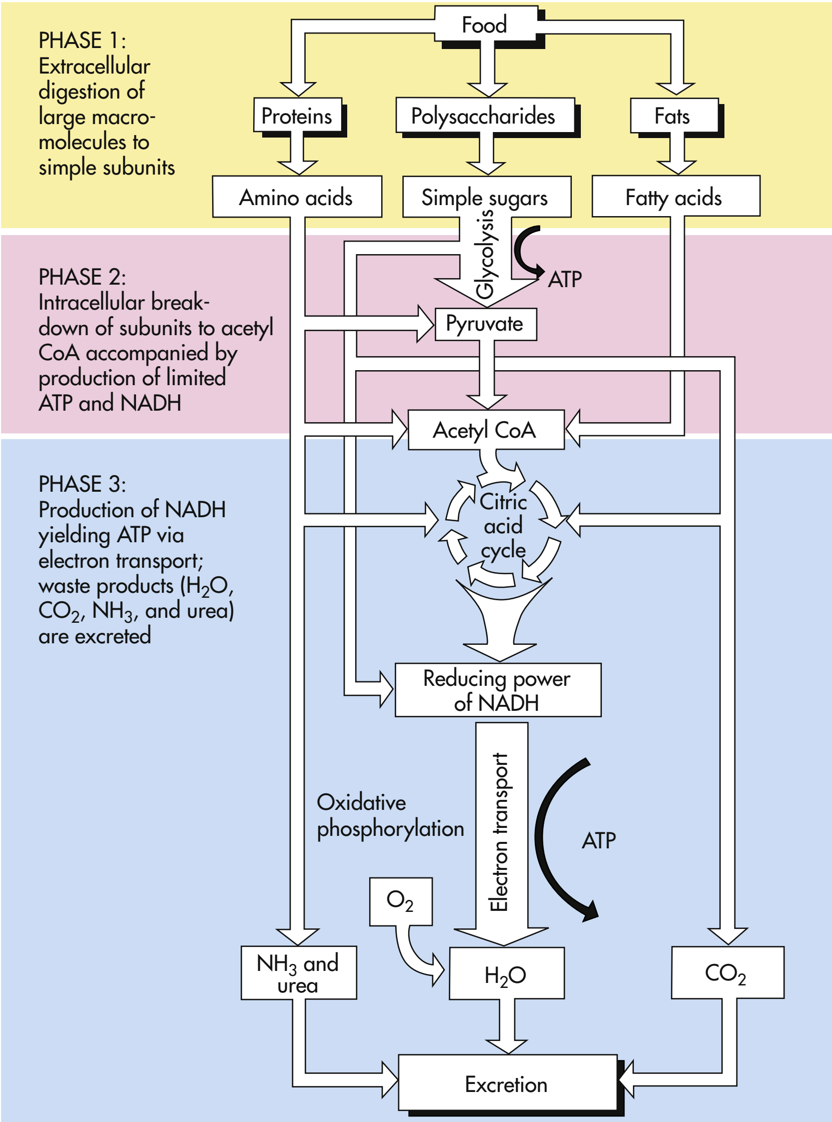

FIGURE 1-24 Three Phases of Catabolism, Which Leads from Food to Waste Products. These reactions produce ATP, which is used to drive other processes in the cell.

by molecules of carbohydrate, lipid, and protein, which, when catabolized, transfer energy to ATP.

Food and Production of Cellular Energy

The process of catabolism of the proteins, lipids, and polysaccharides found in food can be divided into the following three phases (Figure 1-24).

Phase 1: **Digestion.** Large molecules are broken down into their smaller subunits—proteins into amino acids, polysaccharides into simple sugars, and fats into fatty acids and glycerol. These processes occur outside the cell by the action of secreted enzymes.

Phase 2: **Glycolysis** and **oxidation.** The small molecules enter cells and are further broken down in the cytoplasm. Most of the sugars are converted into pyruvate. Pyruvate then enters mitochondria and is converted to the acetyl groups of acetyl coenzyme A (acetyl CoA). Acetyl CoA, like ATP, releases energy when it is hydrolyzed. The most important part of phase 2 is the lysis (splitting) of glucose, known as **glycolysis** (Figure 1-25). Glycolysis produces a net of two molecules of ATP per glucose molecule through the process of **oxidation,** or the removal and transfer of a pair of electrons. This process, often called **oxidative cellular metabolism,** involves 10 biochemical reactions. In reactions 1 through 5, glucose is converted to two, three-carbon aldehyde compounds (glyceraldehyde-3-phosphate [G3P]), which requires energy in the form of ATP. The next five reactions convert G3P molecules into pyruvate molecules and generate four molecules of ATP for each two molecules of G3P. In addition, two molecules of nicotinamide adenine dinucleotide (NAD) are further oxidized to produce four more molecules of ATP. After subtracting two molecules of ATP to drive the reactions, the net yield is six ATP molecules for each molecule of glucose.

Phase 3: **Citric acid cycle (Krebs cycle, tricarboxylic acid cycle).** Most of the ATP is generated during this final phase.

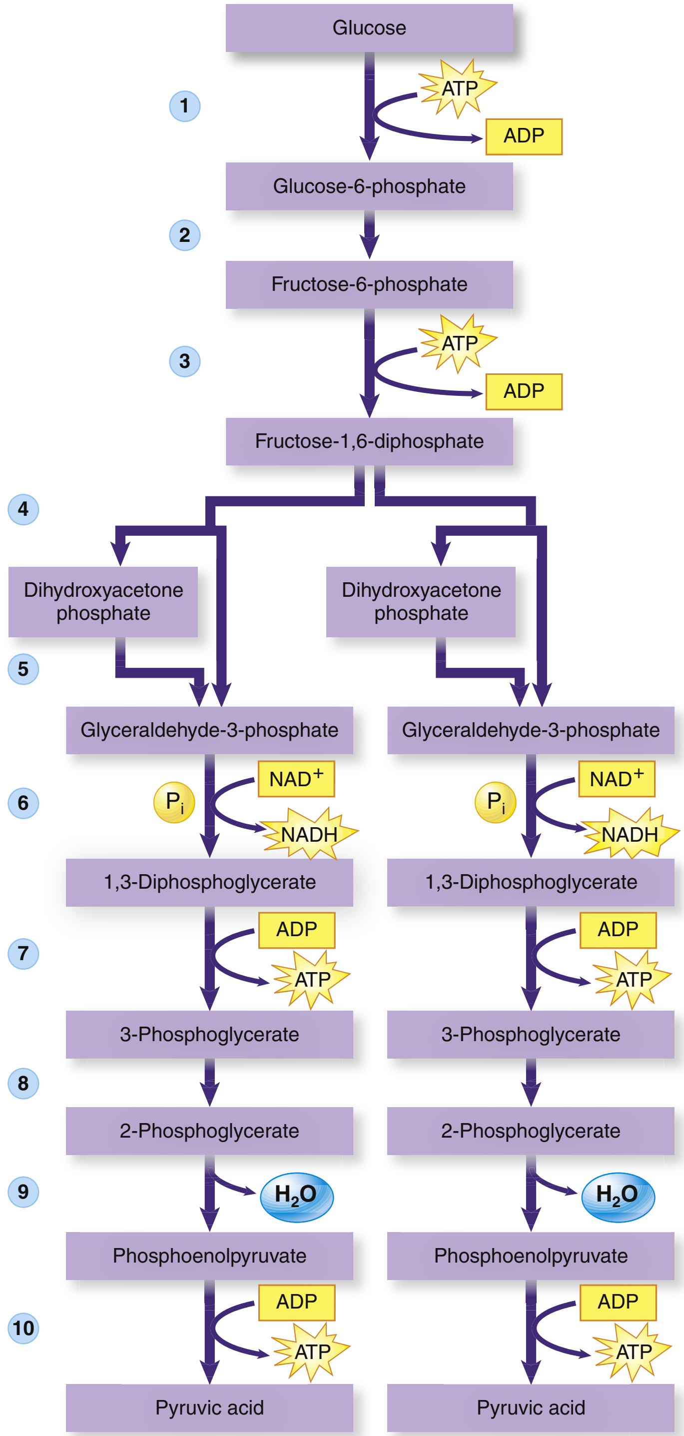

FIGURE 1-25 **Glycolysis.** Each of the numbered reactions is catalyzed by a different enzyme. At step **4,** a six-carbon sugar is broken down to give two, three-carbon sugars, so that the number of molecules at every step after this is doubled. Reactions **5** and **6** are the reactions responsible for the net synthesis of adenosine triphosphate *(ATP)* and reduced nicotinamide adenine dinucleotide *(NADH)* molecules. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

It begins with the citric acid cycle and ends with oxidative phosphorylation. About two thirds of the total oxidation of carbon compounds in most cells is accomplished during this phase. The major end products are carbon dioxide (CO_2) and two dinucleotides—reduced nicotinamide adenine dinucleotide (NADH) and the reduced form of flavin adenine dinucleotide ($FADH_2$)—which transfer their electrons into the electron-transport chain.

Oxidative Phosphorylation

Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from

carbohydrates, fats, and proteins is transferred to ATP. During the breakdown (catabolism) of foods, many of the reactions involve the removal of electrons from various intermediates. These reactions generally require a coenzyme (a nonprotein carrier molecule), such as nicotinamide adenine dinucleotide (NAD), to transfer the electrons and thus are called **transfer reactions.**

Molecules of NAD and flavin adenine dinucleotide (FAD) transfer electrons they have gained from the oxidation of substrates to molecular oxygen, O_2. The electrons from reduced NAD and FAD, NADH and $FADH_2$, respectively, are transferred to a series of carrier molecules (the **electron-transport chain**) on the inner surfaces of the mitochondria with the release of hydrogen ions. Some carrier molecules are a group of brightly colored iron-containing proteins known as **cytochromes** that accept a pair of electrons. These electrons eventually combine with molecular oxygen. If oxygen is not available to the electron-transport chain, ATP will not be formed by the mitochondria. Instead, an anaerobic (without oxygen) metabolic pathway synthesizes ATP. This process, called **substrate phosphorylation,** or **anaerobic glycolysis,** is linked to the breakdown (glycolysis) of carbohydrate (Figure 1-26).

Because glycolysis occurs in the cytoplasm of the cell, it provides energy for cells that lack mitochondria. However, as noted, glycolysis also provides energy to the cell when oxygen delivery is insufficient or delayed (e.g., with strenuous exercise). The reactions in anaerobic glycolysis involve the conversion of glucose to pyruvic acid (pyruvate) with the simultaneous production of ATP. With the glycolysis of one molecule of glucose, two ATP molecules and two molecules of pyruvate are liberated.

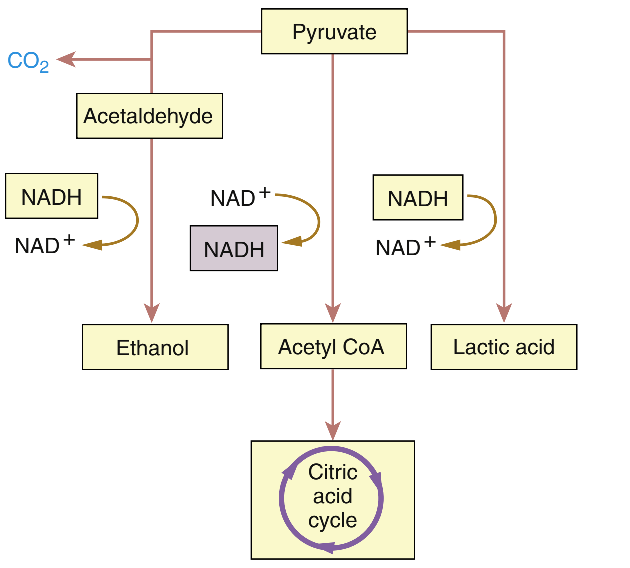

FIGURE 1-26 What Happens to Pyruvate, the Product of Glycolysis? In the presence of oxygen, pyruvate is oxidized to acetyl coenzyme A *(acetyl CoA)* and enters the citric acid cycle. In the absence of oxygen, pyruvate instead is reduced, accepting the electrons extracted during glycolysis and carried by reduced nicotinamide adenine dinucleotide *(NADH)*. When pyruvate is reduced directly, as it is in muscle, the product is lactic acid. When CO_2 is first removed from pyruvate and the remainder reduced, as it is in yeasts, the product is ethanol.

If oxygen is present, the two molecules of pyruvate move into the mitochondria, where they enter the citric acid cycle.

If oxygen is absent, pyruvate is converted to lactic acid, which is released into the extracellular fluid (see Figure 1-26). Elevated lactate level is indicative of tissue hypoxia or low oxygen concentration. The conversion of pyruvic acid to lactic acid is reversible; therefore, once oxygen is restored, lactic acid is quickly converted back to either pyruvic acid or glucose. The anaerobic generation of ATP from glucose, through the reactions of glycolysis, is not as efficient as the aerobic generation of ATP. The addition of an oxygen-requiring stage to the catabolic process (stage 3) provides cells with a much more powerful method for extracting energy from food molecules.

MEMBRANE TRANSPORT: CELLULAR INTAKE AND OUTPUT

Cells continually take in nutrients, fluids, and chemical messengers from the extracellular environment and expel metabolites or the products of metabolism and end products of lysosomal digestion. Intake and output, or transport, occur by different mechanisms, depending on the characteristics of the substance to be transported. Water and small electrically uncharged molecules move easily through pores in the plasma membrane's lipid bilayer. This process, called **passive transport,** will occur naturally through any semipermeable barrier. It is driven by osmosis, hydrostatic pressure, and diffusion, all of which depend on the laws of physics and do not require life. The process is passive in that it does not require any expenditure of energy by the cell.

Other molecules cannot be driven across the plasma membrane solely by forces of diffusion, hydrostatic pressure, or osmosis because they are too large or are ligands that have bound with receptors on the cell's plasma membrane. Some of these molecules are moved into the cell by mechanisms of **active transport,** which requires life, biologic activity, and the expenditure of metabolic energy by the cell. Unlike passive transport, which can be duplicated across any semipermeable barrier in a laboratory, active transport occurs only across living membranes that (1) use energy generated by cellular metabolism and (2) have receptors that are capable of recognizing and binding with the substance to be transported. Large molecules (macromolecules), along with fluids, are transported by means of endocytosis (taking in) and exocytosis (expelling). Water and electrically charged molecules are transported by protein channels embedded in the plasma membrane. Ligands enter the cell by means of receptor-mediated endocytosis.

Movement of Water and Solutes

Cellular membranes are semipermeable and generally allow passage of water and small particles of dissolved substances called **solutes.** The movement of solute molecules through membranes is related to their size, solubility, electrical properties, and concentration on either side of the membrane (also see Chapter 3). Small lipid-soluble particles, such as oxygen, carbon dioxide, and urea, can readily pass through the lipid bilayers of the plasma membrane. Larger, water-soluble particles may pass through pores in the membranes. Although large protein

molecules, such as albumin and globulin, pass through membranes by endocytosis, they influence the movement of water by exerting an osmotic effect (see p. 30).

Body fluids are composed of two types of solutes: **electrolytes,** which are electrically charged and dissociate into constituent **ions** when placed in solution; and nonelectrolytes, such as glucose, urea, and creatinine, which do not dissociate. Electrolytes account for approximately 95% of the solute molecules in body water. Electrolytes exhibit **polarity** by orienting themselves toward the positive or negative pole. Ions with a positive charge are known as **cations** and migrate toward the negative pole, or cathode, if an electrical current is passed through the electrolyte solution. **Anions** carry a negative charge and migrate toward the positive pole, or anode, in the presence of electrical current. Anions and cations are located in both the intracellular fluid (ICF) and extracellular fluid (ECF) compartments, although the concentration of particular ions varies depending on their location. (Fluid and electrolyte balance between body compartments is discussed in Chapter 3.) For example, Na^+ is the predominant extracellular cation, and K^+ is the principal intracellular cation. The difference in ICF and ECF concentrations of these ions is important to the transmission of electrical impulses across the plasma membranes of nerve and muscle cells.

Electrolytes are measured in milliequivalents per liter (mEq/L) or milligrams per deciliter (mg/dl). Milliequivalents per liter indicate the number of electrical charges per unit volume of fluid. The term *milliequivalent* thus indicates the chemical-combining activity of an ion, which depends on the electrical charge, or valence, of its ions. In abbreviations, valence is indicated by the number of plus or minus signs. Monovalent ions, or ions with one charge, include sodium (Na^+), chloride (Cl^-), and potassium (K^+). Divalent ions, which have two charges, include calcium (Ca^{++}) and magnesium (Mg^{++}). One milliequivalent of any cation can combine chemically with 1 mEq of any anion: one monovalent anion will combine with one monovalent cation. Divalent ions combine more strongly than monovalent ions. To maintain electrochemical balance, one divalent ion will combine with two monovalent ions (e.g., $Ca^{++} + 2\ Cl^- = CaCl_2$).

Passive Transport: Diffusion, Filtration, and Osmosis

Diffusion. **Diffusion** is the movement of a solute molecule from an area of greater solute concentration to an area of lesser solute concentration. This difference in concentration is known as a **concentration gradient.** Particles in a solution move randomly in any direction. If the concentration of particles in one part of the solution is greater than that in another part, the particles distribute themselves evenly throughout the solution. According to the same principle, if the concentration of particles is greater on one side of a *permeable membrane* than on the other side, the particles diffuse spontaneously from the area of greater concentration to the area of lesser concentration until equilibrium is reached. The higher the concentration on one side, the greater the diffusion rate. The overall effect of diffusion is the passive movement of particles "down" a concentration gradient, that is, from an area of high concentration to an area of low concentration.

The diffusion rate is influenced by differences of electrical potential across the membrane (see p. 36). Because the pores in the lipid bilayer are often linked with Ca^{++}, other cations (e.g., Na^+ and K^+) diffuse slowly because they are repelled by positive charges in the pores.

The rate of diffusion of a substance depends also on its size (diffusion coefficient) and its lipid solubility (Figure 1-27). Usually the smaller the molecule and the more soluble it is in oil, the more hydrophobic or nonpolar it is and the more rapidly it will diffuse across the bilayer. Oxygen, carbon dioxide, and the steroid hormones are all examples of nonpolar molecules. Water-soluble substances, such as sugars and inorganic ions, diffuse very slowly, whereas uncharged lipophilic ("lipid-loving") molecules, such as fatty acids and steroids, diffuse rapidly. Ions and other polar molecules generally diffuse across cellular membranes more slowly than lipid-soluble substances.

Water readily diffuses through biologic membranes because water molecules are small and uncharged. Although the mechanism is not known with certainty, the dipolar structure of water allows it to cross rapidly through the regions of the bilayer containing the lipid head groups. Lipid head groups constitute the two outer regions of the lipid bilayer.

Filtration: Hydrostatic Pressure. **Filtration** is the movement of water and solutes through a membrane because of a greater pushing pressure (force) on one side of the membrane than on the other side. **Hydrostatic pressure** is the mechanical force of water pushing against cellular membranes (Figure 1-28, *A*). In the vascular system, hydrostatic pressure is the *blood pressure* generated in vessels by the contraction of the heart. Blood

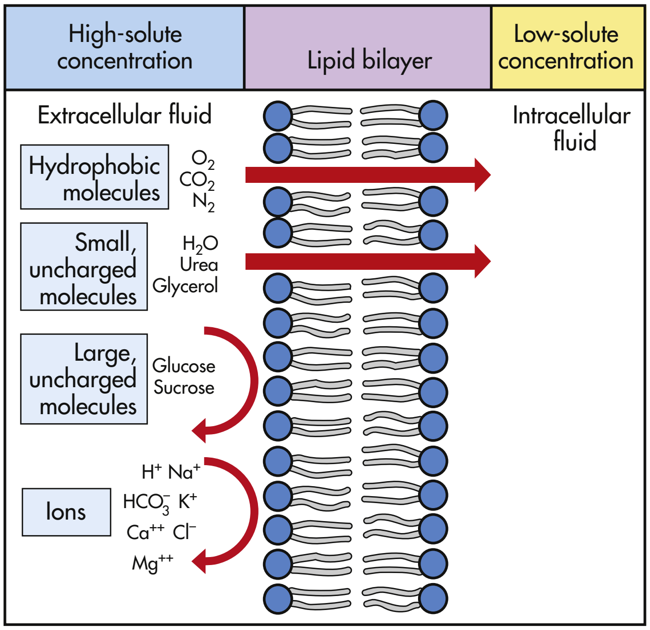

FIGURE 1-27 Passive Diffusion of Solute Molecules Across the Plasma Membrane. Oxygen, nitrogen, water, urea, glycerol, and carbon dioxide can diffuse readily down the concentration gradient. Macromolecules are too large to diffuse through pores in the plasma membrane. Ions may be repelled if the pores contain substances with identical charges. If the pores are lined with cations, for example, other cations will have difficulty diffusing because the positive charges will repel one another. Diffusion can still occur, but it occurs more slowly.

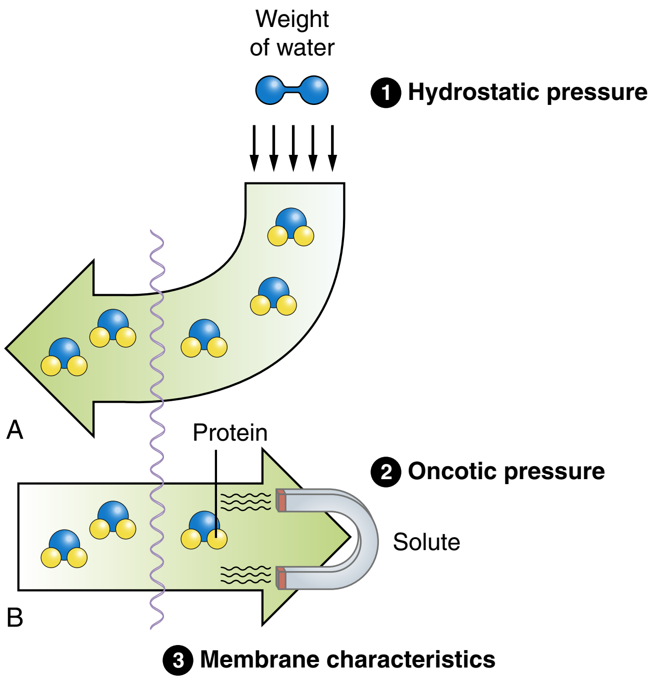

FIGURE 1-28 Hydrostatic Pressure and Oncotic Pressure in Plasma. **1,** Hydrostatic pressure in plasma. **2,** Oncotic pressure exerted by proteins in the plasma usually tends to *pull* water into the circulatory system. **3,** Individuals with low protein levels (e.g., starvation) are unable to maintain a normal oncotic pressure; therefore, water is not reabsorbed into the circulation and, instead, causes body edema.

reaching the capillary bed has a hydrostatic pressure of 25 to 30 mmHg, which is sufficient force to push water across the thin capillary membranes into the interstitial space. Hydrostatic pressure is partially balanced by osmotic pressure, whereby water moving *out* of the capillaries is partially balanced by osmotic forces that tend to *pull* water *into* the capillaries. Water that is not osmotically attracted back into the capillaries moves into the lymph system (see discussion of Starling forces in Chapter 3).

Osmosis. **Osmosis** is the movement of water "down" a concentration gradient, that is, across a semipermeable membrane from a region of higher water concentration to a region of lower water concentration. For osmosis to occur, the membrane must be more permeable to water than to solutes and the concentration of solutes must be greater so that water moves more easily. Osmosis is directly related to both hydrostatic pressure and solute concentration but *not* to particle size or weight. For example, particles of the plasma protein albumin are small but more concentrated in body fluids than the larger and heavier particles of globulin. Therefore, albumin exerts a greater osmotic force than globulin.

Osmolality controls distribution and movement of water between body compartments. The terms *osmolality* and *osmolarity* are often used interchangeably in reference to osmotic activity, but they define different measurements. **Osmolality** is a measure of the number of milliosmoles per kilogram (mOsm/kg) of water, or the concentration of molecules per *weight* of water. **Osmolarity** is a measure of the number of milliosmoles per liter (mOsm/L) of solution, or the concentration of molecules per *volume* of solution. When solute is added to water, the volume is expanded and includes the original liter of water plus the volume occupied by the solute particles. In measuring osmolarity, the volume of water is therefore reduced by an amount equal to the volume of added solute.

In solutions that contain only dissociable substances, such as Na^+ and Cl^-, the difference between the two measurements is negligible. In considering all the different solutes in plasma (e.g., proteins, glucose, lipids), however, the difference between osmolality and osmolarity becomes more significant. In plasma, less of the plasma weight is water and the overall concentration of particles is therefore greater. The osmolality will be greater than the osmolarity because of the smaller proportion of water. Osmolality is thus the preferred measure of osmotic activity in clinical assessment of individuals.

The normal osmolality of body fluids is 280 to 294 mOsm/kg. The osmolality of intracellular and extracellular fluid tends to equalize and so provides a measure of body fluid concentration and thus the body's hydration status (see Chapter 3). Hydration is also affected by hydrostatic pressure because the movement of water by osmosis can be opposed by an equal amount of hydrostatic pressure. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the **osmotic pressure** of the solution. Factors that determine osmotic pressure are the type and thickness of the plasma membrane, the size of the molecules, the concentration of molecules or the concentration gradient, and the solubility of molecules within the membrane. Examples of movement of water in relation to hydrostatic and osmotic forces occur in the glomerulus of the kidney (see Chapter 37) and in the capillaries of the microcirculation (see Chapter 31).

Effective osmolality is sustained osmotic activity and depends on the concentration of solutes remaining on one side of a permeable membrane. If the solutes penetrate the membrane and equilibrate with the solution on the other side of the membrane, the osmotic effect will be diminished or lost. For example, urea is a small solute that readily diffuses across cellular membranes. Solutions containing urea rapidly lose their effective osmolality because they rapidly equilibrate. Solutes too large to pass through the membrane thus sustain an effective osmolality, meaning that they enhance osmotic activity. Plasma proteins are examples of molecules that provide effective osmolality because they normally do not cross cellular membranes.

Plasma proteins also influence osmolality because they have a negative charge (see Figure 1-28, *B*). The principle by which the plasma protein charge influences osmolality is known as *Gibbs-Donnan equilibrium,* and it affects the distribution of ions across cellular membranes. Gibbs-Donnan equilibrium occurs when fluid in one compartment contains small, diffusible ions such as Na^+ and Cl^-, together with large, nondiffusible charged particles, such as plasma proteins. Because the body tends to maintain an electrical equilibrium, the nondiffusible protein molecules cause asymmetry in the distribution of small ions. Anions such as Cl^- are thus driven out of the cell or plasma, and cations such as Na^+ are attracted. The protein-containing compartment will maintain a state of electroneutrality, but the

osmolality will be higher. The overall osmotic effect of colloids, such as plasma proteins, is called the **oncotic pressure,** or **colloid osmotic pressure.**

Tonicity describes the effective osmolality of a solution. (The terms *osmolality* and *tonicity* may be used interchangeably; also see Chapter 3.) Solutions, then, have relative degrees of tonicity. An **isotonic solution** (or isoosmotic solution) has the same osmolality or concentration of particles (285 mOsm/kg) as the ICF or ECF. Diarrhea, for example, is loss of isoosmotic fluid from the gastrointestinal tract. As a result, ECF volume decreases but there is no change in ECF osmolarity. Examples of isotonic solutions include 5% dextrose in water and normal (0.9%) saline solution. A **hypotonic solution** has a lower concentration and is thus more dilute than body fluids. Water is a hypotonic solution. Consequently, water is osmotically pulled into the cells, causing them to swell or burst. A **hypertonic solution** has a concentration of more than 285 to 294 mOsm/kg. An example of a hypertonic solution is 3% saline solution. Water can be pulled out of the cells by a hypertonic solution, so the cells shrink. The concept of tonicity is important when correcting water and solute imbalances by administering different types of replacement solutions.

Mediated and Active Transport

Mediated Transport. **Mediated transport** (passive and active) involves integral or transmembrane proteins with receptors having a high degree of specificity for the substance being transported. Inorganic anions and cations (e.g., Na^+, K^+, Ca^{++}, Cl^-, $HCO^-{}_3$) and charged and uncharged organic compounds (e.g., amino acids, sugars) require specific transport systems to facilitate movement through different cellular membranes. Rates at which substances are moved by mediated transport mechanisms have often been measured, yet the specific membrane proteins involved have not been identified. Mediated transport is much faster than simple diffusion.

A **transport protein** (carrier protein) is a transmembrane or integral protein that binds with and transfers a specific solute molecule across the lipid bilayer. (Proteins are discussed on p. 13.) Each transport protein, or transporter, has receptors for a specific solute. When the transporter is saturated—that is, when all receptor sites are occupied by solute molecules—the rate of transport is maximal. Solute binding can be blocked by **competitive inhibitors** that compete for the same receptor site and may or may not be transported by the transport protein. Noncompetitive inhibitors bind elsewhere but can alter the structure of the transporter.

The transporter protein is a multipass transmembrane protein; that is, its polypeptide chain crosses the lipid bilayer multiple times. This chain forms a continuous pathway enabling solutes to pass across the membrane without coming into direct contact with the hydrophobic interior of the lipid bilayer (Figure 1-29).

Another mechanism of mediated transport is the channel protein. The protein transporter creates a water-filled pore or channel across the bilayer through which specific ions can diffuse. These channels are sometimes called *ion channels,* and because they are permeable mainly to K^+, they are also called K^+ *leak channels* (Figure 1-30). The channel is controlled by a gate mechanism that determines which receptor-bound solutes can move into the channel that is created after receptor-solute contact. Binding stimulates conformational changes in the protein transporter that move the solute through the channel short distances at a time until it reaches the other side of the membrane. Ion channels are responsible for the electrical excitability of nerve and muscle cells and play a critical role in the membrane potential.

Mediated transport systems can move solute molecules singly or two at a time. Two molecules can be moved simultaneously in one direction (a process called **symport**) or in opposite directions (called **antiport**), or a single molecule can be moved in one direction (called **uniport**) (Figure 1-31).

In **passive mediated transport,** also called **facilitated diffusion,** the protein transporter moves solute molecules through cellular membranes without expending metabolic energy. The direction of movement is the same as in simple diffusion—down

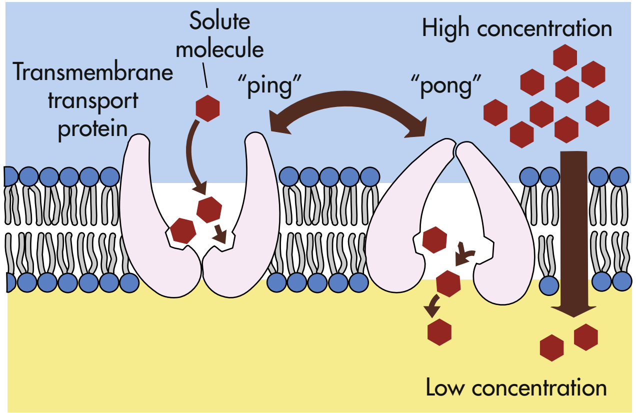

FIGURE 1-29 Conformational-Change Model of Mediated Transport (Facilitated Diffusion). The transporter protein has two states, "ping" and "pong." In the ping state, sites for molecules of a specific solute are exposed on the outside of the bilayer. In the pong state, the sites are exposed to the inner side of the bilayer.

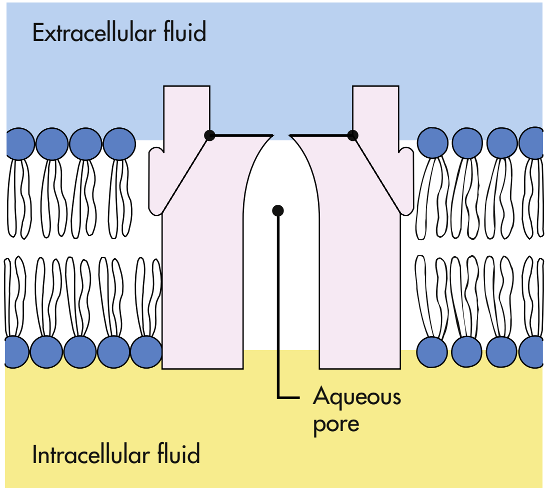

FIGURE 1-30 Channel Mode of Mediated Transport (Facilitated Diffusion). A channel protein forms a water-filled pore across the bilayer through which specific ions can diffuse.

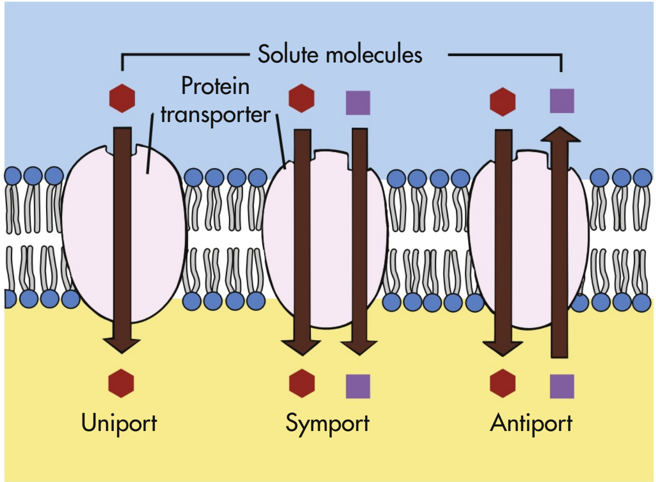

FIGURE 1-31 Mediated Transport. Simultaneous movement of a single solute molecule in one direction (uniport), of two different solute molecules in one direction (symport), and of two different solute molecules in opposite directions (antiport).

the concentration gradient. Perhaps the most widely referred to passive transport system is that for glucose in erythrocytes (red blood cells). Glucose is transported by a uniport mechanism and demonstrates saturation kinetics; that is, the transport system is saturated when all the glucose-specific receptors on the membrane are occupied and operating at their maximal capacity.

The anions Cl^- and bicarbonate HCO_3^- also undergo passive mediated transport in the erythrocyte. This antiport mechanism allows Cl^- movement in one direction and simultaneous HCO_3^- movement in the opposite direction. The directions of movement depend on the concentration gradients of the ions across the membrane.

In **active mediated transport,** also called **active transport,** the protein transporter moves molecules against, or up, the concentration gradient. Unlike passive mediated transport, active mediated transport requires the expenditure of energy. Many active mediated transport systems, or pumps, have ATP as their primary energy source, but not all. Some use the electrochemical gradient of Na^+ across the membrane (Figure 1-32). Energy in the form of ATP, however, is required for activation of the Na^+ gradient.

A "carrier" mechanism in the plasma membrane mediates the transport of ions, such as Na^+, K^+, H^+, Cl^-, and HCO_3^-, and of nutrients, such as glucose and amino acids. Energy supplied by ATP is required to pump ions against a concentration gradient. The best known pump is the Na^+– K^+–dependent ATPase pump. It continuously regulates the cell's volume by controlling leaks through pores or protein channels and maintains the ionic concentration gradient necessary for cellular excitation and membrane conductivity (see below). The maintenance of intracellular K^+ concentrations is also required for enzyme activity, including that of enzymes involved in protein synthesis.

Active Transport of Na^+ and K^+. The active transport system for Na^+ and K^+ is found in virtually all mammalian cells. The Na^+-K^+ antiport system (Na^+ moving out of and K^+ moving into the cell) uses the direct energy of ATP to move these cations. The transporter protein is an enzyme, adenosine triphosphatase (ATPase). ATPase has a requirement for Na^+, K^+, and Mg^{++} ions. The concentration of ATPase in plasma membranes is directly related to Na^+-K^+ transport activity. Approximately 60% to 70% of the ATP synthesized by cells, especially muscle and nerve cells, is used to maintain the Na^+-K^+ transport system. Excitable tissues (e.g., muscle and nerve tissues) have a high concentration of Na^+-K^+ ATPase, as do other tissues that transport significant amounts of Na^+, for example, kidneys and salivary glands. For every ATP molecule hydrolyzed, three molecules of Na^+ are transported out of the cell, whereas only two molecules of K^+ move into the cell. The process leads to an electrical potential and is called *electrogenic,* with the inside of the cell more negative than the outside. The exact mechanism for transport of Na^+ and K^+ across the membrane is uncertain.

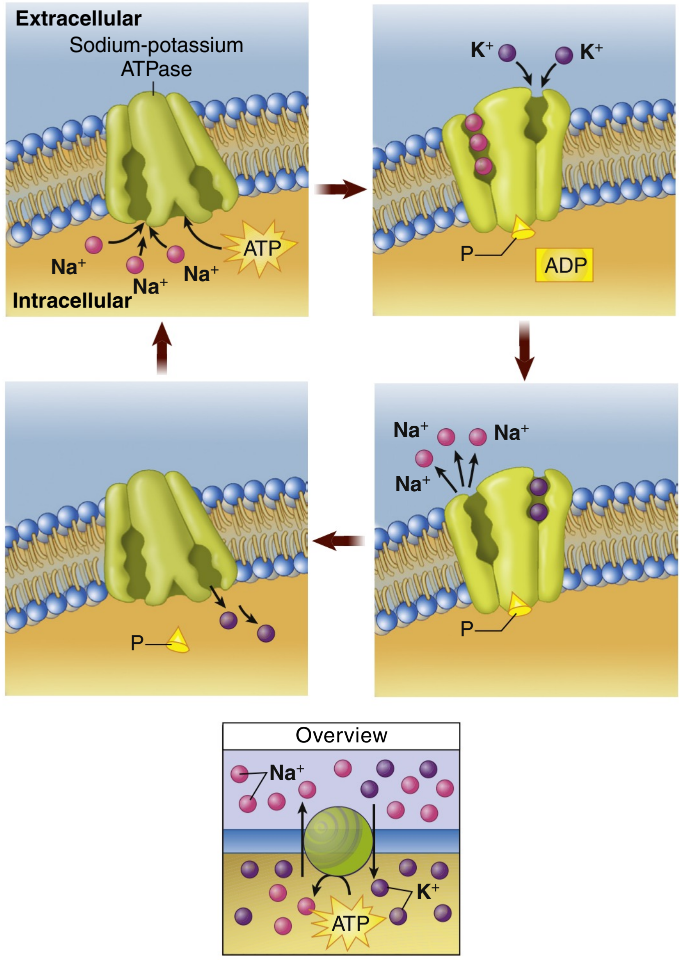

FIGURE 1-32 Active Transport and the Sodium-Potassium Pump. Three Na^+ ions bind to sodium-binding sites on the carrier's inner face. At the same time an energy-containing adenosine triphosphate (ATP) molecule produced by the cell's mitochondria binds to the carrier. The ATP breaks apart, transferring its stored energy to the carrier. The carrier then changes shape, releases the three Na^+ ions to the outside of the cell, and attracts two K^+ ions to its potassium-binding sites. The carrier then returns to its original shape, releasing the two K^+ ions and the remnant of the ATP molecule to the inside of the cell. The carrier is now ready for another pumping cycle. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

One proposal is that ATPase induces the transporter protein to undergo several conformational changes, causing Na^+ and K^+ to move short distances (see Figure 1-32). The conformational change creates a lowering affinity for Na^+ and K^+ to the ATPase transporter, resulting in the release of the cations after transport.

The sarcoplasmic reticulum of heart muscle and skeletal muscle has an ATP-dependent Ca^{++} active transport system that regulates the Ca^{++} levels in the cell's cytoplasm, which in turn regulates muscle contraction and relaxation cycles (see Chapter 31). The Ca^{++} transport system depends on ATPase activity and is similar to that of Na^+-K^+ ATPase.

The transport of sugars and amino acids across the plasma membrane depends on the simultaneous movement (symport) of Na^+ or Na^+-dependent transport (see Figure 1-31). Na^+-dependent symport occurs primarily in the plasma membrane of epithelial cells of the kidney tubules and intestines. The transport of glucose is not directly dependent on the hydrolysis of ATP; however, the Na^+ gradient is ATP dependent, and thus ATP is indirectly involved in glucose transport.

The epithelial cells that line the intestines depend on Na^+ to transport various amino acids. Similarly, the uptake of Cl^- by the small intestine depends on Na^+ symport and antiport mechanisms for the secretion of Ca^{++} from the cell.

Table 1-5 summarizes the major mechanisms of transport through pores and protein transporters in the plasma membranes. Many disease states are caused or manifested by loss of these membrane transport systems.

TABLE 1-5 MAJOR TRANSPORT SYSTEMS IN MAMMALIAN CELLS*

SUBSTANCE TRANSPORTED	MECHANISM OF TRANSPORT	TISSUES
Sugars		
Glucose	Passive protein channel	Most tissues
Fructose	Active: symport with Na^+	Small intestines and renal tubular cells
	Passive	Intestines and liver
Amino Acids	Coupled channels	
Amino acid–specific transporters	Active: symport with Na^+	Intestines, kidney, and liver
All amino acids except proline	Active: group translocation	Liver
Specific amino acids	Passive	Small intestine
Other Organic Molecules		
Cholic acid, deoxycholic acid, and taurocholic acid	Active: symport with Na^+	Intestines
Organic anions (e.g., malate, α-ketoglutarate, glutamate)	Antiport with counter–organic anion	Mitochondria of liver cells
ATP-ADP	Antiport transport of nucleotides; can be active	Mitochondria of liver cells
Inorganic Ions		
Na^+	Passive	Distal renal tubular cells
Na^+/H^+	Active antiport, proton pump	Proximal renal tubular cells and small intestines
Na^+/K^+	Active: ATP driven, protein channel	Plasma membrane of most cells
Ca^{++}	Active: ATP driven, antiport with Na^+	All cells, antiporter in red cells
H^+/K^+	Active	Parietal cells of gastric cells secreting H^+
Cl^-/HCO_3^- (perhaps other anions)	Mediated: antiport (anion transporter–band 3 protein)	Erythrocytes and many other cells
Water	Osmosis passive	All tissues

ADP, Adenosine diphosphate; ATP, adenosine triphosphate.
*NOTE: The known transport systems are listed here; others have been proposed. Most transport systems have been studied in only a few tissues, and their sites of activity may be more limited than indicated.

Transport by Vesicle Formation

Endocytosis

Endocytosis is a cellular internalizing process where a section of the plasma membrane enfolds substances from outside the cell, invaginates (folds inward), and separates from the plasma membrane, forming a vesicle that moves into the inside of the cell (Figure 1-33, *A*). Endocytosis mediates cellular uptake of nutrients, regulates quantities of proteins in the plasma membrane, controls the signaling output of receptors, and is used by pathogens to gain entry into cells.[28] Thus endocytosis is important to counterbalance exocytosis and maintain homeostasis. Transport of nutrients involves the sequential formation and fission of membrane-bound vesicles.

Different mechanisms mediate endocytotic uptake of a large variety of distinctly sized cargoes, ranging from small molecules such as receptor ligands to large cargoes including viruses, bacteria, and extracellular aggregates.[29] Depending on the size of the cargoes and other factors binding of ligands on the cell surface activates appropriate intracellular mechanisms that then trigger changes in membrane shape to mediate their cell entry (Figure 1-34). Endocytosis can be subdivided into four different categories: (1) clathrin-mediated endocytosis, (2) caveolae-mediated endocytosis, (3) macropinocytosis, and (4) phagocytosis. Over time, however, these categories may change.

Because most cells continually ingest fluid and solutes by **pinocytosis,** the terms *pinocytosis* (cell ingestion of extracellular fluid and its contents) and *endocytosis* are often used interchangeably. **Micropinocytosis** is the taking up of specific macromolecules by invagination of the cell membrane, which is then pinched off, forming a small vesicle in the cytoplasm. In micropinocytosis the vesicle containing fluids, solutes, or both, fuses with a lysosome and lysosomal enzymes digest them for use by the cell. **Macropinocytosis** is when large droplets of fluid are trapped underneath the ruffles of the cell membrane.

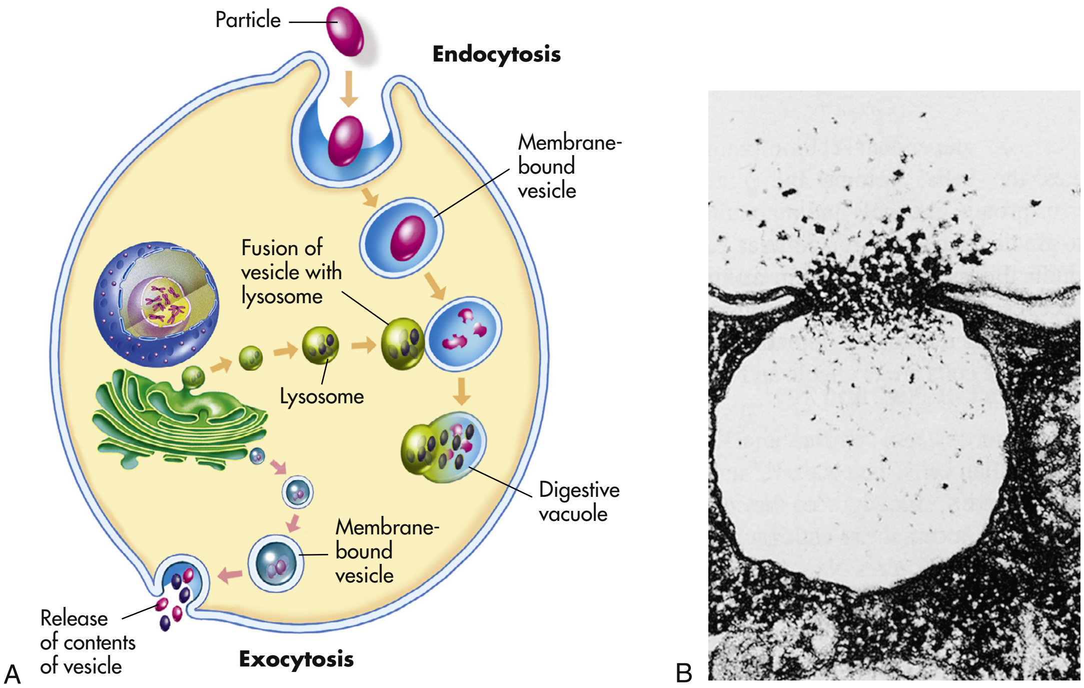

FIGURE 1-33 **Endocytosis and Exocytosis. A,** Endocytosis and fusion with lysosome and exocytosis. **B,** Electron micrograph of exocytosis. (**B** from Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

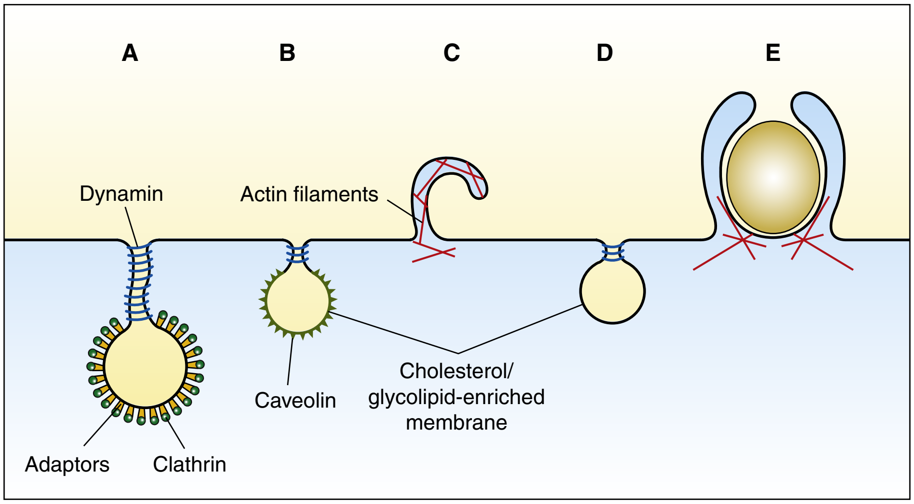

FIGURE 1-34 **Multiple Pathways of Endocytosis.** The pathways of endocytosis depend on the class of cargo (receptors, ligands, and lipid-associated molecules), the mechanism of vesicle formation (coats, GTPases, and dynamin), and the size of the endocytotic vesicle that eventually pinches off into the cytoplasm. **A,** *Clathrin-mediated endocytosis* (CME) uses adaptor proteins that link cargo proteins to the clathrin scaffold, forming the endocytotic vesicle. **B,** *Caveolae,* formed by caveolin proteins, are adorned in cholesterol, sphingolipids, and glycolipids believed concentrated in membrane microdomains. **C,** During *macropinocytosis* fluid-phase uptake is dependent on actin-driven membrane protrusions that enclose extracellular fluid and fuse with the plasma membrane. **D,** Some cargoes associate with membrane microdomains that eventually are internalized in a clathrin- and caveolin-independent manner. Different modes of internalization are distinguished by their dependence on dynamin, a membrane-remodeling GTPase. **E,** *Phagocytosis* mediates internalization by membrane protrusions formed around large, ligand-coated molecules. (Adapted from Krauss M, Haucke V: *Rev Physiol Biochem Pharmacol* 161:45–66, 2011.)

Macropinocytosis is an important pathway for antigen presentation by specialized antigen presenting cells.[30] In **phagocytosis** the large molecular substances are engulfed by the plasma membrane and enter the cell so that they can be isolated and destroyed by lysosomal enzymes (see Chapter 7). Substances that are not degraded by lysosomes are isolated in residual bodies and released by the cell by exocytosis. Both pinocytosis and phagocytosis require metabolic energy and often involve binding of the substance with plasma membrane receptors before membrane invagination and fusion with lysosomes in the cell.

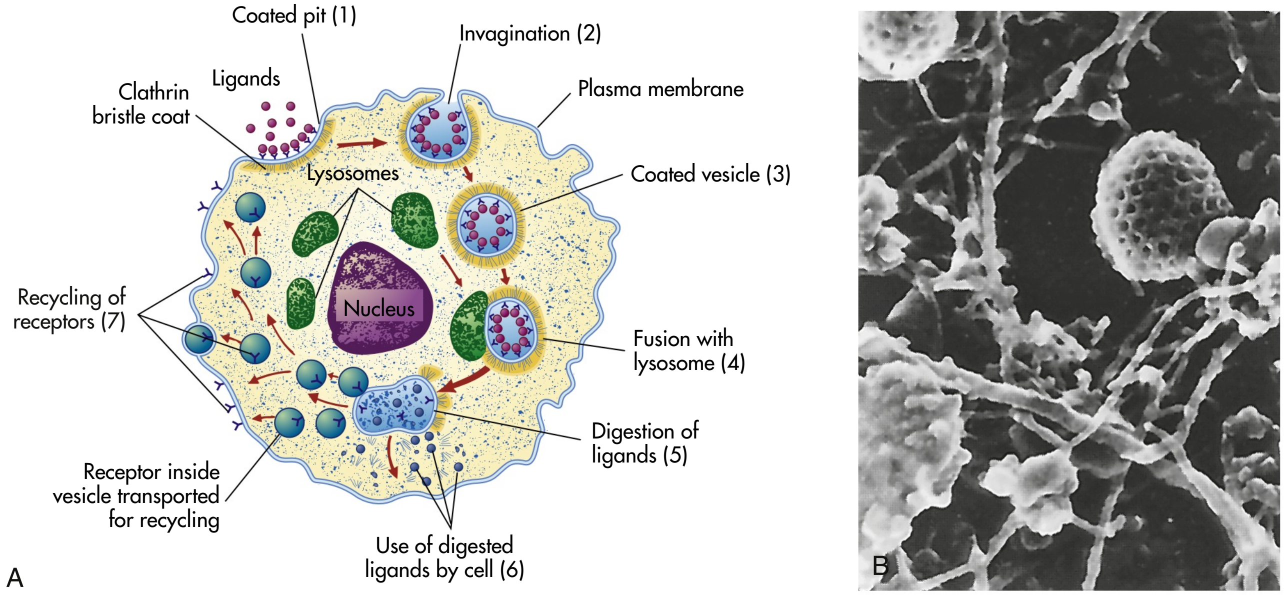

FIGURE 1-35 Ligand Internalization by Means of Receptor-Mediated Endocytosis. **A,** The ligand attaches to its surface receptor (through the bristle coat or clathrin coat) and, through receptor-mediated endocytosis, enters the cell **(1-3).** The ingested material fuses with a lysosome **(4)** and is processed by hydrolytic lysosomal enzymes **(5).** Processed molecules can then be transferred to other cellular components **(6)** or recycled **(7). B,** Electron micrograph of a coated pit showing different sizes of filaments (× 382,000). (**B** from Erlandsen SL, Magney JE: *Color atlas of histology,* St Louis, 1992, Mosby.)

Clathrin-Mediated Endocytosis. Ligand binding to *some* plasma membrane receptors leads to clustering, aggregation, and immobilization of the receptors in specialized areas of the membrane called **coated pits** (Figure 1-35). The pits, which are coated with a complex of proteins and cytosolic bristle-like structures (or clathrin), deepen and enfold (invaginate), internalizing ligand-receptor complexes and forming clathrin coated vesicles (CCVs). This internalization process, called **clathrin-mediated endocytosis,** is rapid and enables the cell to ingest large amounts of specific ligands, for example, low-density lipoprotein, growth factors, and antibodies, without ingesting large volumes of extracellular fluid. Additionally, clathrin is required for the internalization of pumps and transporters for ions and small nutrients to maintain homeostasis and synaptic transmission in neurons.[29] Inside the cell, the ingested material is processed by lysosomal enzymes.

Caveolae-Mediated Endocytosis. The outer surface of the plasma membrane is dimpled with tiny flask-shaped pits (cavelike) called caveolae. Caveolae are also called **microdomains. Caveolae** are cholesterol- and glycosphingolipid-rich microdomains where the protein caveolin is thought to be involved in several processes, including clathrin-independent endocytosis. Caveolae are present in most mammalian cell types and are abundant in endothelial and smooth muscle cells, adipocytes, and fibroblasts.[31] Although the role of caveolae in endocytic events is debated and still needs conclusive proof, caveolae-mediated endocytosis has been implicated in the endocytosis of simian virus 40 (SV40).[29] Additionally, evidence is accumulating that these microdomains are important in regulating endothelial cell functions mainly because they compartmentalize various signaling molecules.[31] Cavins have recently been found to be important in caveolae.[32,33]

Cavins are proteins present or isolated in caveolae and may be important for molecular organization of caveolae and certain protein degradations. Caveolae not only function as uptake vesicles but also are important sites for signal transduction (see p. 21). For example, strong evidence exists that plasma membrane estrogen receptors localize in caveolae and crosstalk with estradiol, causing several intracellular functions, including cell growth and survival, migration, and new blood vessel formation.[34-36]

Clathrin- and Caveolin-Independent Endocytosis. Some proteins or small molecules enter cells by clathrin- and caveolin-independent pathways (see Figure 1-34, *C* and *D*).[29] These routes are defined and classified by their requirements for dynamin during fission, and the regulatory roles of guanosinetriphosphatases (GTPases). The mechanism by which internalization occurs is not known but is thought to be dependent on cargo concentration and membrane curvature.

Exocytosis

In eukaryotic cells, secretion of macromolecules almost always occurs by exocytosis (see Figure 1-33, *B*). **Exocytosis** is the discharge or secretion of material from the intracellular vesicles at the cell surface. For example, to secrete macromolecules of insulin across plasma membranes, insulin-producing cells store and package insulin molecules in intracellular vesicles, which fuse with the plasma membrane and open to the extracellular space, or matrix, releasing the insulin. Not all secreted substances are secreted into the extracellular matrix. Some adhere to the plasma membrane and are thought to replace segments of the membrane lost through endocytosis or diffuse into the blood to nourish or signal other cells. Recent findings suggest membrane lipids may be a regulator of exocytosis.[37] Exocytosis

has two main functions: (1) replacement of portions of the plasma membrane that have been removed by endocytosis, and (2) release of molecules synthesized by the cells into the extracellular matrix.

Movement of Electrical Impulses: Membrane Potentials

All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in electrical charge, or voltage, is known as the **resting membrane potential** and is about −70 to −85 millivolts. The difference in voltage across the plasma membrane is a result of the differences in ionic composition of ICF and ECF. Sodium ions have a greater concentration in the ECF, and potassium ions have a greater concentration in the ICF. The concentration difference is maintained by the active transport of Na^+ and K^+ (the sodium-potassium pump), which transports sodium outward and potassium inward (Figure 1-36). Because the resting plasma membrane is more permeable to K^+ than to Na^+, K^+ can diffuse easily from its area of higher concentration in the ICF to its area of lower concentration in the ECF. Because Na^+ and K^+ are both cations, the net result is an excess of anions inside the cell, resulting in the resting membrane potential.

Nerve and muscle cells are excitable and can change their resting membrane potential in response to electrochemical stimuli. Changes in resting membrane potential convey messages from cell to cell. When a nerve or muscle cell receives a stimulus that exceeds the membrane threshold value, there is a rapid change in the resting membrane potential known as the **action potential.** The action potential carries signals along the nerve or muscle cell and conveys information from one cell to another. (Nerve impulses are described in Chapter 15.) When a resting cell is stimulated through voltage-regulated channels, the cell membranes become more permeable to sodium. There is a net movement of sodium into the cell, and the membrane potential decreases, or "moves forward," from a negative value (in millivolts) to zero. This decrease is known as **depolarization.** The depolarized cell is more positively charged, and its polarity is neutralized.

To generate an action potential and the resulting depolarization, a critical value known as the **threshold potential** must be reached. Generally this occurs when the cell has depolarized by 15 to 20 millivolts. When the threshold is reached, the cell will continue to depolarize with no further stimulation. The sodium gates open, and sodium rushes into the cell, causing the membrane potential to reduce to zero and then become positive (depolarization). The rapid reversal in polarity results in the action potential.

During **repolarization** the negative polarity of the resting membrane potential is reestablished. As the voltage-gated sodium channels begin to close, voltage-gated potassium

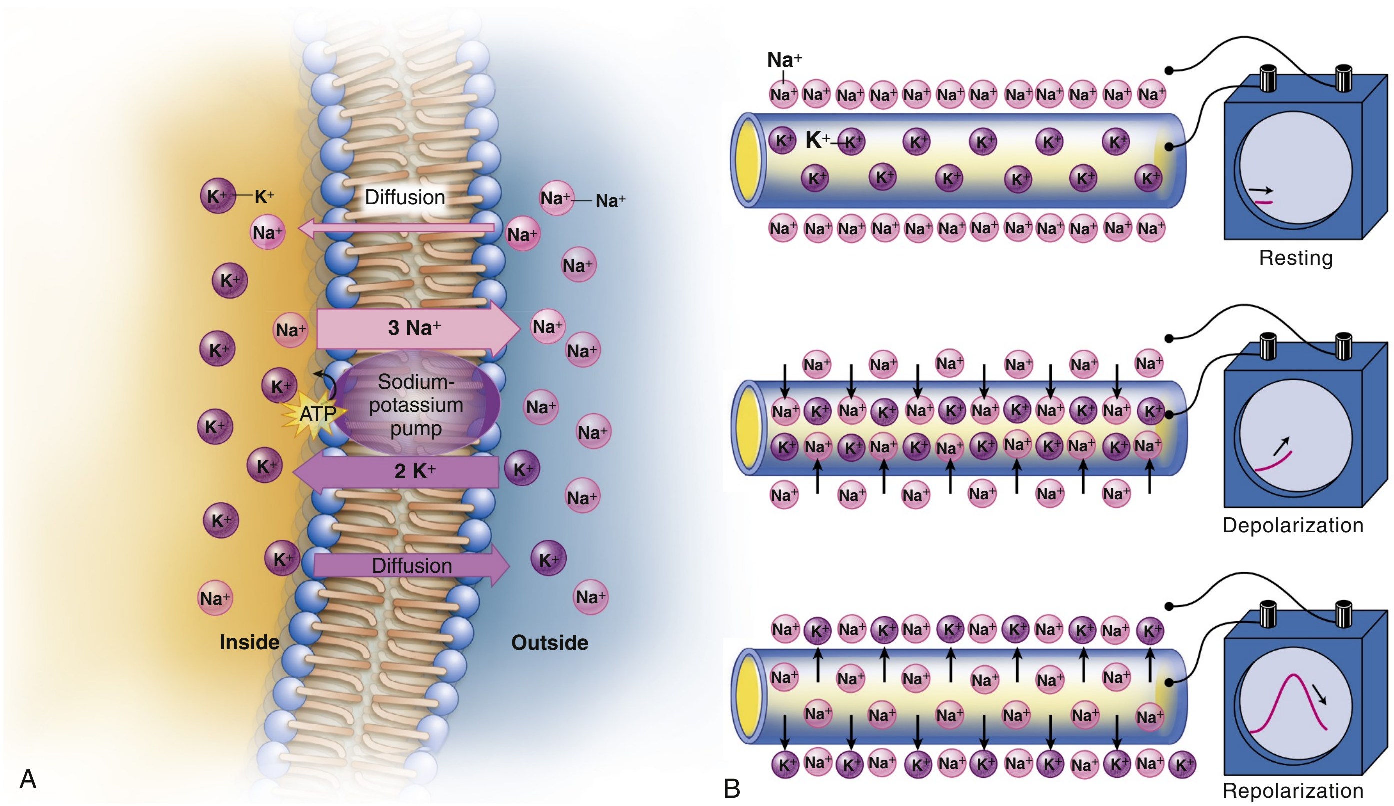

FIGURE 1-36 **Sodium-Potassium Pump and Propagation of an Action Potential. A,** Concentration difference of Na^+ and K^+ intracellularly and extracellularly. The direction of active transport by the sodium-potassium pump is also shown. **B,** Top diagram represents the polarized state of a neuronal membrane when at rest. The lower diagrams represent changes in sodium and potassium membrane permeabilities with depolarization and repolarization. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

channels open. Membrane permeability to sodium decreases, and potassium permeability increases, with an outward movement of potassium ions. The sodium gates close, and with the outward movement of potassium, the membrane potential becomes more negative. The Na^+-K^+ pump then returns the membrane to the resting potential by pumping potassium back into the cell and sodium out of the cell.

During most of the action potential, the plasma membrane cannot respond to an additional stimulus. This time is known as the **absolute refractory period** and is related to changes in permeability to sodium. During the latter phase of the action potential, when permeability to potassium increases, a stronger-than-normal stimulus can evoke an action potential, known as the **relative refractory period.**

When the membrane potential is more negative than normal, the cell is in a *hyperpolarized* (less excitable) state. A larger-than-normal stimulus is then required to reach the threshold potential and generate an action potential. When the membrane potential is more positive than normal, the cell is in a *hypopolarized* (more excitable than normal) state, and a smaller-than-normal stimulus is required to reach the threshold potential. Changes in the intracellular and extracellular concentration of ions or a change in membrane permeability can cause these alterations in membrane excitability. Understanding the mechanisms of ion movement and membrane excitability led to the discovery of calcium blocking agents for heart disease and migraine.

CELLULAR REPRODUCTION: THE CELL CYCLE

Human cells are subject to wear and tear, and most do not last for the lifetime of the individual. In almost all tissues, new cells are created as fast as old ones die. Cellular reproduction is therefore necessary for the maintenance of life. Reproduction of gametes (sperm and egg cells) occurs through a process called *meiosis,* described in Chapter 4. The reproduction, or division, of other body cells (somatic cells) involves two sequential phases: **mitosis,** or nuclear division, and **cytokinesis,** or cytoplasmic division. These two phases occur in close succession, with cytokinesis beginning toward the end of mitosis. Before a cell can divide, however, it must double its mass and duplicate all its contents. Most of the work of preparing for division occurs during the growth phase, called **interphase.** The alternation between mitosis and interphase in all tissues with cellular turnover is known as the **cell cycle.**

Most of the early work on the cell cycle was limited to microscopic observation of mitosis and cytokinesis. Interphase was considered the "resting stage" of the cell. With recent technologic advances a considerable amount has been learned about the interphase part of the cell cycle. During interphase many important processes are taking place as the cell produces DNA, RNA, protein, lipids, and other substances, and each pair of **chromosomes** (paired organelles that carry genetic information) makes exact copies of themselves.

The four designated phases of the cell cycle are (1) the G_1 phase (G = gap), which is the period between the M phase and the start of DNA synthesis; (2) the S phase (S = synthesis), in which DNA is synthesized in the cell nucleus; (3) the G_2 phase, in which RNA and protein synthesis occurs, the period between the completion of DNA synthesis and the next phase (M); and (4) the M phase (M = mitosis), which includes both nuclear and cytoplasmic division (Figure 1-37).

Phases of Mitosis and Cytokinesis

Interphase (the G_1, S, and G_2 phases) is the longest phase of the cell cycle. During interphase the chromatin consists of very long, slender rods that are jumbled together in the nucleus. Late in interphase, strands of **chromatin** (the substance that gives the nucleus its granular appearance) begin to coil, causing them to shorten and thicken.

The M phase of the cell cycle, mitosis and cytokinesis, begins with **prophase,** the first appearance of chromosomes. As the phase proceeds, each chromosome is seen as two identical halves called **chromatids,** which lie together and are attached at some point by a spindle attachment site called a **centromere.** (The two chromatids of each chromosome, which are genetically identical, are sometimes called *sister chromatids.*)

The nuclear membrane, which surrounds the nucleus, disappears. Spindle fibers are microtubules formed in the cytoplasm. **Spindle fibers** radiate from two centrioles located at opposite poles of the cell. The role of the spindle fibers is to pull the chromosomes to opposite sides of the cell.

During **metaphase,** the next phase of mitosis and cytokinesis, the spindle fibers begin to pull the centromeres of the chromosomes. The centromeres become aligned in the middle of the spindle, which is called the **equatorial plate** (or **metaphase plate**) of the cell. In this stage chromosomes are easiest to observe microscopically because they are highly condensed and arranged in a relatively organized fashion in the two-dimensional equatorial plate.

Anaphase begins when the centromeres split and the sister chromatids are pulled apart. The spindle fibers shorten, causing the sister chromatids to be pulled, centromere first, toward opposite sides of the cell. When the sister chromatids are separated, each is considered to be a chromosome. Thus the cell has 92 chromosomes during this stage. By the end of anaphase, 46 chromosomes are lying at each side of the cell. Barring mitotic errors, each of the two groups of 46 chromosomes is identical to the original 46 chromosomes present at the start of the cell cycle.

During **telophase,** the final stage, a new nuclear membrane is formed around each group of 46 chromosomes, the spindle fibers disappear, and the chromosomes begin to uncoil. Cytokinesis causes the cytoplasm to divide into roughly equal parts during this phase. At the end of telophase, two identical diploid cells, called *daughter cells,* have been formed from the original cell.

Rates of Cellular Division

Although the complete cell cycle lasts 12 to 24 hours, about 1 hour is generally required for the four stages of mitosis and cytokinesis. All types of cells undergo mitosis during formation of the embryo, but some adult cells, such as nerve cells, lens cells of the eye, and muscle cells, lose their ability to replicate and divide. The cells of other tissues, particularly epithelial cells (e.g., of the intestine, lung, skin), divide continuously and rapidly, completing the entire cell cycle in less than 10 hours.

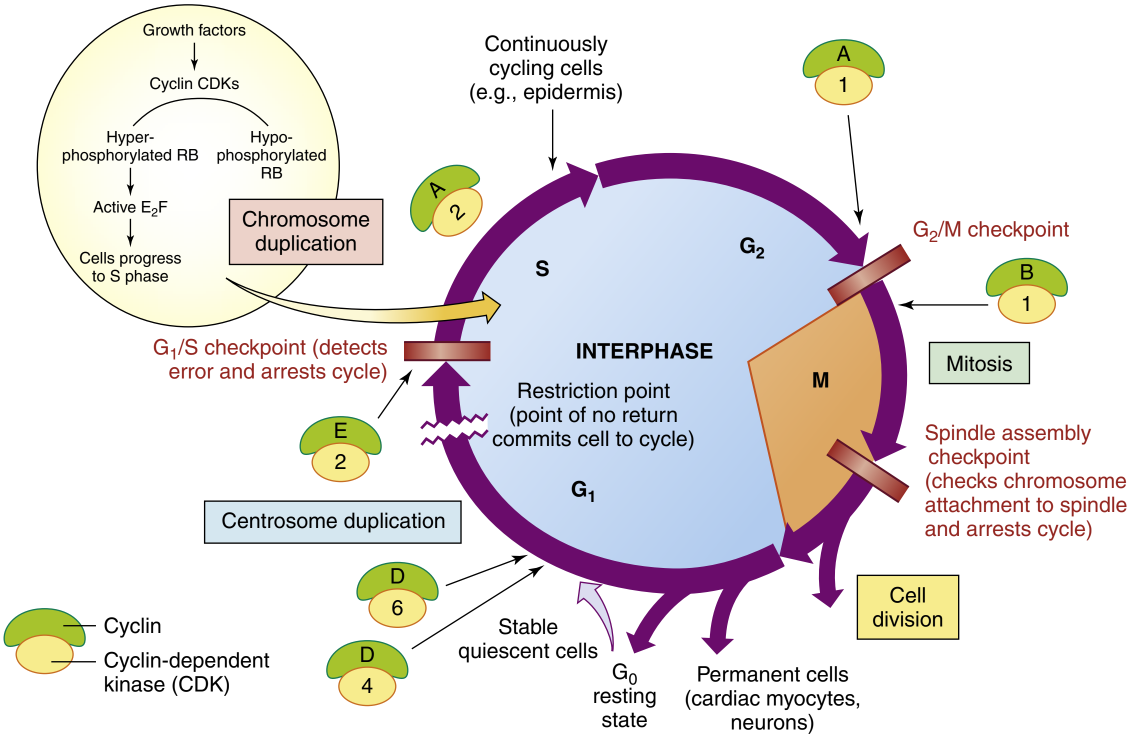

FIGURE 1-37 **The Cell Cycle.** The cell cycle consists of gap 1 (or G_1) (presynthesis), S (DNA synthesis), G_2 (premitotic), and M (mitotic) phases. Quiescent cells (quiet or resting state) are in the G_0 phase; however, most mature tissues have a combination of continuously dividing cells, terminally differentiated cells, stem cells, and some quiescent cells that infrequently enter the cell cycle. Continuously dividing cells replace those that are destroyed (e.g., epithelia of the oral cavity, skin). Quiescent or stable tissues exhibit a low level of replication; however, these cells can undergo rapid division in response to stimuli such as growth factors (e.g., EGF, TGF-α). Cyclins increase and activate cyclin-dependent protein kinase (CDK) complexes at the G_1/S restriction point, causing phosphorylation (addition of phosphate group) of the molecular ON-OFF switch, the retinoblastoma susceptibility protein (RB). In its hypophosphorylated state, RB prevents cells from replicating by forming a tight inactive complex with the transcription factor E_2F. Phosphorylation of RB eliminates the "brakes" to cell cycle progression and promotes cell replication. The orderly progression of cells through the phases of the cell cycle is regulated by cyclins, CDKs, and their inhibitors. Cyclin levels rise and fall (thus the name cyclin) during the cell cycle, periodically activating CDKs. Unless CDKs are bound to cyclins, they have no protein kinase activity. Cyclin-CDK complexes trigger cell cycle events. Each complex phosphorylates a different set of proteins that then promote advancement to the next phase (G_1, S, G_2, M, G_0). After completion of the task, cyclin levels decline rapidly. The activity of cyclin-CDK complexes is regulated by CDK inhibitors including Cip/Kip and 7NK4/ARF.

The difference between cells that divide slowly and cells that divide rapidly is the length of time spent in the G_1 phase of the cell cycle. Some cells that divide very slowly remain in the G_1 phase for days or even years. Once the S phase begins, however, progression through mitosis takes a relatively constant amount of time. Once a cell has progressed out of the G_1 phase, there is no turning back; it is committed to completing the S, G_2, and M phases. Times associated with the four successive phases differ.

The mechanisms that control cell division depend on the integrity of genetic, epigenetic (heritable changes in genome function that occur without alterations in the DNA sequence; see Chapters 6 and 12), and protein growth factors.[38] Individual cells are members of a complex cellular society in which survival of the *entire organism* is key and not survival or proliferation of just the *individual cells.* To grow and divide, a cell must receive specific positive signals from other cells. Many of these signals *are* protein growth factors that act by overriding intracellular negative controls that block progress of the cell cycle.[1]

When a need arises for new cells, as in repair of injured cells, previously nondividing cells must be rapidly triggered to reenter the cell cycle. With continual wear and tear, the cell birth rate and the cell death rate must be kept in balance. Therefore, cell-division controls must govern this balance. Protein growth factors governing the proliferation of different cell types and genes involved in the social control of cell division are being identified.[1]

The best model for understanding disruption of cell division and study of these genetic, epigenetic, and protein factors is tumor biology. Current emphasis in locating and identifying these genes is to study tumor cells that have presumably originated because of mutations to these genes, or proto-oncogenes (see Chapter 12).

Growth Factors

Growth factors, also called *cytokines,* are peptides that transmit signals within and between cells. They have a major role in the regulation of tissue growth and development (Table 1-6). Having nutrients is not enough for a cell to proliferate; it must

TABLE 1-6 EXAMPLES OF GROWTH FACTORS AND THEIR ACTIONS

GROWTH FACTOR	PHYSIOLOGIC ACTIONS
Platelet-derived growth factor (PDGF)	Stimulates proliferation of connective tissue cells and neuroglial cells
Epidermal growth factor (EGF)	Stimulates proliferation of epidermal cells and other cell types
Insulin-like growth factor 1 (IGF-1)	Collaborates with PDGF and EGF; stimulates proliferation of fat cells and connective tissue cells
Insulin-like growth factor 2 (IGF-2)	Collaborates with PDGF and EGF; stimulates proliferation of fat cells and connective tissue cells
Transforming growth factor-beta (TGF-β)	Stimulates or inhibits response of most cells to other growth factors; regulates differentiation of some cell types (e.g., cartilage)
Fibroblast growth factor (FGF)	Stimulates proliferation of fibroblasts, endothelial cells, myoblasts, and other cell types
Interleukin-2 (IL-2)	Stimulates proliferation of T lymphocytes
Nerve growth factor (NGF)	Promotes axon growth and survival of sympathetic and some sensory and CNS neurons
Hematopoietic cell growth factors (IL-3, GM-CSF, M-CSF, G-CSF, erythropoietin)	See Chapter 27

CNS, Central nervous system; *CSF,* colony-stimulating factor; *G,* granulocyte; *GM,* granulocyte-macrophage; *M,* macrophage.

also receive stimulatory chemical signals (growth factors) from other cells, usually its neighbors. These signals act to overcome intracellular braking mechanisms that tend to restrain cell growth and block progress through the cell cycle.

Different types of cells require different factors; for example, **platelet-derived growth factor (PDGF)** stimulates the production of connective tissue cells. Table 1-6 summarizes the most significant growth factors. Cells that respond to a particular growth factor have specific receptors for the growth factor in their plasma membrane. Recent evidence shows that some growth factors are also regulators of other cell processes, such as cellular differentiation. In addition to growth factors that stimulate cellular processes, there are factors that inhibit functions; these factors are not well understood. Cells that are starved of growth factors come to a halt after mitosis and enter the **arrested,** or **G_0, state** of the cell cycle[1] (see p. 37 for cell cycle). Certain growth factors can help move tumor cells from the G_0 state (resting) to the G_1 state, where they might be destroyed by chemotherapy or radiation.

TISSUES

The body is made up of four levels of organization: cells, tissues, organs, and systems. Cells of common structure and function are organized into **tissues,** of which there are four primary types: *muscle, neural, epithelial,* and *connective* tissue.

Tissue Formation

To form tissues, cells must exhibit intercellular recognition and adhesion. Specialized cells are thought to form a tissue in one of two ways. First and simplest is mitosis of one or more **founder cells** (the most basic precursor cell). Founder cells are prevented from "wandering away" by the presence of macromolecules in the extracellular matrix and by adherence to one another at specialized junctions on their plasma membranes. Mitosis of founder cells forms, for example, epithelial cell sheets (Figure 1-38, *A*).

The second way in which specialized cells form tissues involves their migration to and subsequent assembly at the site of tissue formation. During embryonic development, for example, cells from the neural crest migrate to several different regions, where they differentiate and assemble into a variety of tissues, including those of the peripheral nervous system. Migrant cells are thought to arrive at the site of tissue formation through chemotaxis or contact guidance. **Chemotaxis** is movement along a chemical gradient caused by chemical attraction (see Chapter 7). Cells at the migrant cells' destination secrete a chemical, called *chemotactic factor,* that attracts specific migrant cells. **Contact guidance** is movement along a pathway, or "pavement," in the extracellular matrix.[1]

Tissues are not randomly arranged into organs. No matter how tissue is formed, staying together in groups means that cells must recognize each other and remain distinct from the cells of surrounding tissues. Little is known about the mechanisms involved in these processes.

Stem cells are cells with the potential to develop into many different cell types during early development and growth. In many tissues, stem cells serve as an internal repair and maintenance system by dividing indefinitely. These cells can maintain themselves over very long periods of time, called **self-renewal,** and can generate all the differentiated cell types of the tissue, which is termed **multipotency.** This stem cell–driven tissue renewal is very evident in the epithelial lining of the intestine, stomach, and skin, which is continuously exposed to environmental factors.[39] There is growing evidence that stem cells self-renew through **asymmetric division,** where cellular contents and cell fates are distributed asymmetrically.[40] One daughter cell remains a stem cell and the other follows a pathway that ends in terminal differentiation. Differentiation occurs progressively as the offspring of stem cells commit to various cell lineages.

Types of Tissues

Epithelial Tissue

Epithelial tissue covers most internal and external surfaces of the body. Epithelial cells are closely joined and are attached to a basement membrane or lamina (extracellular matrix), which provides a supporting layer and separates the epithelium from underlying connective tissue (see Figure 1-15, p. 16). Because of its variety of locations, epithelial tissue has several diverse functions, including protection, absorption, secretion, and excretion. For example, the epidermis provides a protective barrier between the host and the outside environment, and the linings

of the internal body organs help absorb substances into the body, excrete waste products, and secrete substances into body cavities.

Epithelial cell surfaces differ according to their location and function. Epithelial cells that line body cavities and blood vessels are smooth, whereas other epithelial cells have tiny cytoplasmic projections called **microvilli** on their free surfaces. Microvilli considerably increase a cell's surface area and are found on cells whose main functions are absorption and secretion, such as the epithelial cells lining the digestive tract. **Cilia,** which are hairlike projections that propel mucus, pus, and dust particles out of the body, characterize cells lining the respiratory passages.

Epithelial tissue is classified in two ways: (1) according to the number and arrangement of cell layers and (2) according to cell shape. Epithelium that is formed by a single layer of cells, all of which are in contact with the basement membrane, is called **simple epithelium. Stratified epithelium** has two or more layers of cells, and only the deepest layer is in contact with the basement membrane. Tissue that appears to consist of several cellular layers but is actually a single layer with all cells contacting the basement membrane is called **pseudostratified epithelium.**

Three basic cell shapes are found in epithelium: squamous, cuboidal, and columnar. **Squamous cells** are flat and thin; **cuboidal cells** are as high as they are wide and thus appear square in vertical sections; and **columnar cells** are taller than they are wide and appear rectangular in vertical sections. Overall classifications of epithelial tissue, which take into account both the number of cell layers and the cell shape, are summarized in Table 1-7.

Connective Tissue

Connective tissue varies considerably in structure and function but is most common as the framework on which epithelial cells cluster to form organs. Other functions include binding various tissues and organs together, supporting them in their locations, and serving as storage sites for excess nutrients.

In contrast to epithelial tissue, connective tissue is characterized by an abundant extracellular matrix that surrounds few cells. The extracellular matrix is composed of ground substance and fibers. **Ground substance** is a homogeneous mass that varies in consistency from fluid to semisolid gel. Fibers are produced by connective tissue cells (fibroblasts) found within the ground substance. The three types of fibers are collagenous (white), elastic (yellow), and reticular. **Collagenous fibers** are formed of bundles of smaller fibers appearing as wavy bands under the microscope. These fibers are composed of the protein collagen and are strong and inelastic. (Collagen synthesis by fibroblasts is described with respect to tissue repair in Chapter 7.) **Elastic fibers** are long, branching fibers composed of a protein called *elastin* that enables the fibers to return to

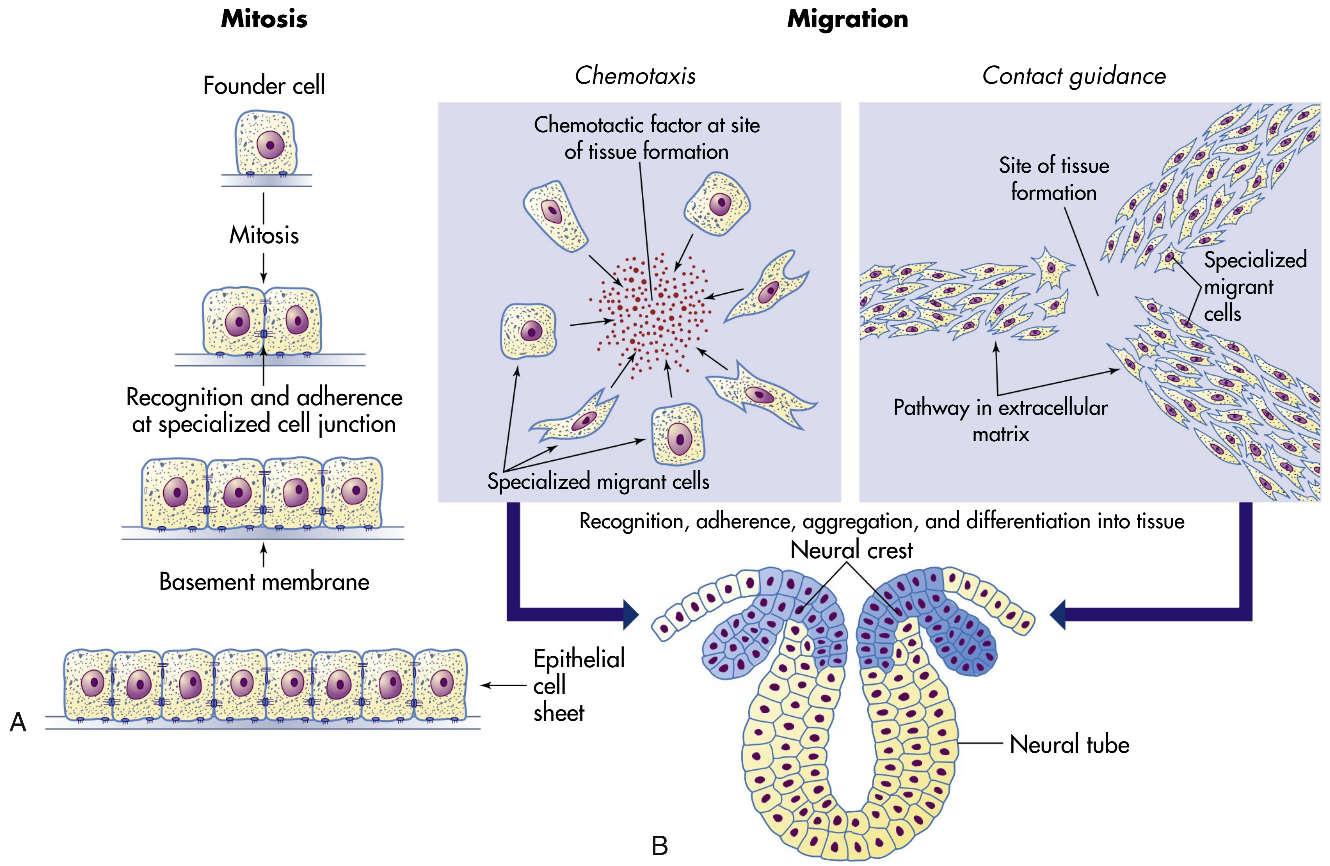

FIGURE 1-38 Tissue Formation by Mitosis and Migration. **A,** Tissue formation by mitosis. Founder cells are kept in place by extracellular matrix and recognition and adherence at cell junctions. **B,** Tissue formation by migration. Specialized cells are attracted to the site of tissue formation by chemotaxis or contact guidance; then they aggregate and differentiate into organized tissue.

their original length after stretching. Elastin occurs not only as fibers but also as membranes, particularly the membranes of blood vessels. **Reticular fibers** are thin, short, branching fibers that form an inelastic network made from a collagen-like protein called *reticulum*. Reticular fibers form the internal framework (stroma) to which the epithelial cells of glands are attached. They are found in loose connective tissue, generally in bone marrow and in the **parenchyma** (i.e., the essential substance of an organ rather than its framework) of the liver, spleen, and lymph nodes.

Connective tissues are classified according to the consistency (e.g., loose, dense) of the ground substance and the type and organization of the fibers within it. Table 1-8 summarizes the characteristics of connective tissues.

Muscle Tissue

Muscle tissue is composed of long, thin cells or fibers called *myocytes*. Myocytes are highly contractile. The three types of muscle tissues are skeletal, cardiac, and smooth (Table 1-9). (Muscles are discussed in detail in Chapter 43.)

Neural Tissue

Neural tissue is composed of highly specialized cells called *neurons,* which receive and transmit electrical impulses very rapidly across junctions called synapses. **Synapses** are points of functional contact between neurons. At synapses, impulses pass from neuron to neuron or from a neuron to a muscle cell while chemical messengers called *neurotransmitters* are released (see Chapter 15). The total number of neurons is fixed at birth, and replacement is impossible thereafter.

Different types of neurons have special characteristics that depend on their distribution and function within the nervous system. All neurons, however, are composed of the following parts: (1) a cell body, (2) a single axon, and (3) one or more dendrites (see Figure 15-1 on p. 449). The cell body contains special cytoplasmic structures, as well as microtubules, actin filaments, Golgi complex, lysosomes, and lipofuscin. The axons and dendrites can be very long. Generally, the axon conducts nerve impulses away from the cell body, and dendrites conduct nerve impulses toward the cell body. (Neuronal transmission is discussed in Chapter 15.)

TABLE 1-7 SOME TYPES OF EPITHELIAL TISSUE WITH LOCATION AND FUNCTION

TYPE OF EPITHELIAL TISSUE	LOCATION	FUNCTION
 Simple squamous	Lines major organs (heart, air sacs of lungs, Bowman's capsule of kidney); lines body cavity	Absorption, exchange of materials, filtration, secretion
 Simple cuboidal	Lines tubules and ducts of glands; covers surface of ovary; lines interior of eye	Absorption and secretion
 Simple columnar	Lines gastrointestinal tract	Secretion from special goblet cells of materials, absorption

Continued

TABLE 1-7 SOME TYPES OF EPITHELIAL TISSUE WITH LOCATION AND FUNCTION—cont'd

TYPE OF EPITHELIAL TISSUE	LOCATION	FUNCTION
 Stratified squamous	Lines interior of mouth, tongue, esophagus, vagina	Protection
 Transitional	Lines urinary bladder	Permits stretching

Data from Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.

TABLE 1-8 TYPES OF CONNECTIVE TISSUE WITH LOCATION AND FUNCTION

TYPE OF CONNECTIVE TISSUE	LOCATION	FUNCTION
 Loose connective tissue	Deep layers of skin, blood vessels, nerves, body organs	Support, elasticity
 Dense connective tissue	Tendons, ligaments	Attaches structures to one another; provides great strength

TABLE 1-8 TYPES OF CONNECTIVE TISSUE WITH LOCATION AND FUNCTION—cont'd

TYPE OF CONNECTIVE TISSUE	LOCATION	FUNCTION
 Elastic connective tissue	Lungs, arteries, trachea, vocal cords	Provides elasticity
 Reticular connective tissue	Spleen, liver, lymph nodes	Provides internal scaffold for soft organs
 Cartilage	Ends of long bones; tip of nose; parts of larynx, trachea	Provides flexibility and support
 Bone	Bones	Protection, support, muscle attachment
 Vascular connective tissue	Within blood vessels	Transport oxygen and carbon dioxide; immune response; blood clotting

TABLE 1-8 TYPES OF CONNECTIVE TISSUE WITH LOCATION AND FUNCTION—cont'd

TYPE OF CONNECTIVE TISSUE	LOCATION	FUNCTION
 Adipose tissue	Deep layers of skin; surrounds heart and kidneys; padding around joints; paracrine hormones	Support, protection, heat conservation, energy source

Data from Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.

TABLE 1-9 TYPES OF MUSCLE TISSUE WITH LOCATION AND FUNCTION

TYPE OF MUSCLE TISSUE	LOCATION	FUNCTION
 Smooth muscle	Gastrointestinal tract, uterus, urinary bladder, blood vessels	Propulsion of materials
 Cardiac muscle	Heart	Contraction
 Skeletal muscle	Attached to bones	Movement

Data from Raven PH, Johnson GB: *Understanding biology,* ed 3, Dubuque, IA, 1995, Brown.

SUMMARY REVIEW

Cellular Functions

1. Cells become specialized through the process of differentiation, or maturation.
2. The eight specialized cellular functions are movement, conductivity, metabolic absorption, secretion, excretion, respiration, reproduction, and communication.

Structure and Function of Cellular Components

1. The eukaryotic cell consists of three general components: the plasma membrane, the cytoplasm, and the intracellular organelles.
2. The nucleus is the largest membrane-bound organelle and is usually found in the cell's center. The chief functions of the nucleus are cell division and control of genetic information.
3. Cytoplasm, or the cytoplasmic matrix, is an aqueous solution (cytosol) that fills the space between the nucleus and the plasma membrane.
4. The organelles are suspended in the cytoplasm and are enclosed in biologic membranes.
5. The endoplasmic reticulum (ER) is a network of tubular channels (cisternae) that extend throughout the outer nuclear membrane. It specializes in the synthesis and transport of protein and lipid components of most of the organelles. Importantly, the ER is responsible for protein folding and sensing cell stress.
6. The Golgi complex is a network of smooth membranes and vesicles located near the nucleus. The Golgi complex is responsible for processing and packaging proteins into secretory vesicles that break away from the Golgi complex and migrate to a variety of intracellular and extracellular destinations, including the plasma membrane.
7. Lysosomes are saclike structures that originate from the Golgi complex and contain digestive enzymes. These enzymes are responsible for digesting most cellular substances completely to their basic components, such as amino acids, fatty acids, and carbohydrates.
8. Cellular debris is encapsulated within a vesicle that reacts with a lysosome to complete its degradation, a process called autophagy. Autophagy plays a crucial role in health and disease.
9. Peroxisomes are similar to lysosomes but contain several oxidative enzymes, such as catalase and urate oxidase.
10. Mitochondria are found in great numbers in most cells and are responsible for cellular respiration and energy production. The enzymes of the respiratory chain (electron-transport chain), found in the inner membrane of the mitochondria, generate most of the cell's ATP.
11. Vaults are cytoplasmic organelles also called ribonucleoproteins. They are thought to function as cellular "trucks" carrying mRNA from the nucleus to the ribosomal sites of protein synthesis.
12. The cytoskeleton is the "bone and muscle" of the cell. The internal skeleton is composed of a network of protein filaments including microtubules and actin filaments (microfilaments).
13. The plasma membrane encloses the cell and, by controlling the movement of substances across it, exerts a powerful influence on metabolic pathways.
14. The plasma membrane is a bilayer of lipids and proteins not uniformly distributed but can separate into discrete units called microdomains.
15. Membrane functions are determined largely by proteins. These functions include (a) recognition and binding units (receptors) for substances moving in and out of the cell; (b) pores or transport channels; (c) enzymes that drive active pumps; (d) cell surface markers, such as glycoproteins; (e) cell adhesion molecules; and (f) catalysts of chemical reactions.
16. The information regarding concepts of biologic membranes has changed markedly in the last two decades.
17. A protein is made from a chain of amino acids known as polypeptides. Proteins are the major workhorses of the cell.
18. Cellular receptors are protein molecules on the plasma membrane, in the cytoplasm, or in the nucleus that are capable of recognizing and binding smaller molecules, called *ligands.*
19. The ligand-receptor complex initiates a series of protein interactions, causing adenylyl cyclase to catalyze the transformation of cellular ATP to messenger molecules that stimulate specific responses within the cell.
20. A field called *proteomics* is the study of the proteome or entire set of proteins expressed by a genome—from synthesis, translocation, and modification (e.g., folding) to their role in a staggering number of diseases.
21. The carbohydrate contained within the plasma membrane is generally bound to membrane proteins.

Cell-to-Cell Adhesions

1. Cell-to-cell adhesions are formed on plasma membranes, thereby allowing the formation of tissues and organs. Cells are held together by three different means: (a) the extracellular membrane, (b) cell adhesion molecules in the cell's plasma membrane, and (c) specialized cell junctions.
2. The extracellular matrix includes three types of protein fibers: collagen, elastin, and fibronectin. The matrix helps regulate cell growth and differentiation.
3. The basement membrane is a thin layer of connective tissue underlying the epithelium of many organs. It is also called the basal lamina.
4. The three main types of cell junctions are desmosomes, tight junctions, and gap junctions.

Cellular Communication and Signal Transduction

1. Cells communicate in three main ways: (a) they display plasma membrane–bound signaling molecules (receptors) that affect the cell itself and other cells in direct physical contact; (b) they activate receptor proteins inside the target cell, and the signal molecule has to enter the cell to bind to them; and (c) they form protein channels (gap junctions) that directly coordinate the activities of adjacent cells.

SUMMARY REVIEW—cont'd

2. Primary modes of intercellular signaling are contact-dependent, paracrine, hormonal, neurohormonal, and neurotransmitter.
3. Signal transduction involves signals or instructions from extracellular chemical messengers that are conveyed to the cell's interior for execution.
4. Signal transduction pathways (signaling cascades, relay chains) have several important functions, including physically transferring the signal around the cell, amplifying the signal, distributing the signal, and modulating the signal.
5. Two important second messenger pathways are cAMP and Ca^{++}.
6. G protein is an intermediary between the receptor and adenylyl cyclase.
7. Phospholipase C, an enzyme protein effector, is bound to the inner side of the membrane.

Cellular Metabolism

1. The chemical tasks of maintaining essential cellular functions are referred to as *cellular metabolism.* Anabolism is the energy-using process of metabolism, whereas catabolism is the energy-releasing process.
2. ATP functions as an energy-transferring molecule. Energy is stored by molecules of carbohydrate, lipid, and protein, which, when catabolized, transfer energy to ATP.
3. Oxidative phosphorylation occurs in the mitochondria and is the mechanism by which the energy produced from carbohydrates, fats, and proteins is transferred to ATP.

Membrane Transport: Cellular Intake and Output

1. Water and small, electrically uncharged molecules move through pores in the plasma membrane's lipid bilayer in the process called *passive transport.*
2. Passive transport does not require the expenditure of energy; rather, it is driven by the physical effects of osmosis, hydrostatic pressure, and diffusion.
3. Larger molecules and molecular complexes (e.g., ligand-receptor complexes) are moved into the cell by active transport, which requires expenditure of energy (by means of ATP) by the cell.
4. Endocytosis is a cellular internalizing process where a section of the plasma membrane enfolds substances from outside the cell, invaginates, and separates from the plasma membrane, forming a vesicle that moves inside the cell.
5. Endocytosis can be subdivided into four categories: (a) clathrin-mediated endocytosis, (b) caveolae-mediated endocytosis, (c) macropinocytosis, and (d) phagocytosis. Over time, however, these categories may change.
6. Two types of solutes exist in body fluids: electrolytes and nonelectrolytes. Electrolytes are electrically charged and dissociate into constituent ions when placed in solution. Nonelectrolytes do not dissociate when placed in solution.
7. Diffusion is the passive movement of a solute from an area of higher solute concentration to an area of lower solute concentration.
8. Hydrostatic pressure is the mechanical force of water pushing against cellular membranes.
9. Osmosis is the movement of water across a semipermeable membrane from a region of lower solute concentration to a region of higher solute concentration.
10. The amount of hydrostatic pressure required to oppose the osmotic movement of water is called the *osmotic pressure* of the solution.
11. The overall osmotic effect of colloids, such as plasma proteins, is called the *oncotic pressure* or *colloid osmotic pressure.*
12. Mediated transport can be passive or active. Mediated transport includes the movement of two molecules simultaneously in one direction (symport) or in opposite directions (antiport), or the movement of a single molecule in one direction (uniport).
13. Passive mediated transport is also called *facilitated diffusion.* It does not require the expenditure of metabolic energy.
14. Active mediated transport requires metabolic energy (ATP) to move molecules against the concentration gradient.
15. Active transport also occurs by endocytosis, or vesicle formation.
16. Pinocytosis is a type of endocytosis in which fluids and solute molecules are ingested through formation of small vesicles.
17. Phagocytosis is a type of endocytosis in which large particles, such as bacteria, are ingested through formation of large vesicles, called *vacuoles.*
18. All body cells are electrically polarized, with the inside of the cell more negatively charged than the outside. The difference in voltage across the plasma membrane is the resting membrane potential.
19. When an excitable (nerve or muscle) cell receives an electrochemical stimulus, cations enter the cell, causing a rapid change in the resting membrane potential known as the *action potential.* The action potential "moves" along the cell's plasma membrane and is transmitted to an adjacent cell. This is how electrochemical signals convey information from cell to cell.

Cellular Reproduction: The Cell Cycle

1. Cellular reproduction in body tissues involves mitosis (nuclear division) and cytokinesis (cytoplasmic division).
2. Only mature cells are capable of division. Maturation occurs during a stage of cellular life called *interphase* (growth phase).
3. The cell cycle is the reproductive process that begins after interphase in all tissues with cellular turnover. The four phases of the cell cycle are (a) the S phase, during which DNA synthesis takes place in the cell nucleus; (b) the G_2 phase, the period between the completion of DNA synthesis and the next phase (M); (c) the M phase, which involves both nuclear (mitotic) and cytoplasmic (cytokinetic) division; and (d) the G_1 phase (growth phase, or interphase), after which the cycle begins again.

SUMMARY REVIEW—cont'd

4. The M phase (mitosis) involves four stages: prophase, metaphase, anaphase, and telophase.
5. The mechanisms that control cell division depend on the integrity of genetic, epigenetic, and protein growth factors.
6. Cyclin–cyclin-dependent protein kinase (CDK) complexes trigger cell cycle events.

Tissues

1. Cells of one or more types are organized into tissues, and different types of tissues compose organs. Organs are organized to function as tracts or systems.
2. Specialized cells are thought to form tissue by mitosis of one or more founder cells or by migration of founder cells and their subsequent assembly at the site of tissue formation.
3. Stem cells are cells with the potential to develop into many different cell types during early development and growth.
4. The four basic types of tissues are epithelial, muscle, neural, and connective tissues.
5. Epithelial tissue covers most internal and external surfaces of the body. The functions of epithelial tissue include protection, absorption, secretion, and excretion.
6. Connective tissue binds various tissues and organs together, supporting them in their locations and serving as storage sites for excess nutrients.
7. Muscle tissue is composed of long, thin, highly contractile cells or fibers called *myocytes.* Muscle tissue that is attached to bones enables voluntary movement. Muscle tissues in internal organs enable involuntary movement, such as the heartbeat.
8. Neural tissue is composed of highly specialized cells called *neurons* that receive and transmit electrical impulses very rapidly across junctions called *synapses.*

CHAPTER OUTLINE

Injury to cells and their surrounding environment, called the extracellular matrix, leads to tissue and organ injury. Although the normal cell is restricted by a narrow range of structure and function, it can *adapt* to physiologic demands or stress to maintain a steady state called *homeostasis*. **Adaptation** is a reversible, structural, or functional response to both normal or physiologic conditions and adverse or pathologic conditions. For example, the uterus adapts to pregnancy—a normal physiologic state—by enlarging. Enlargement occurs because of an increase in the size and number of uterine cells. In an adverse condition, such as high blood pressure, myocardial cells are stimulated to enlarge by the increased work of pumping. Like most of the body's adaptive mechanisms, however, cellular adaptations to adverse conditions are usually only temporarily successful. Severe or long-term stressors overwhelm adaptive processes and cellular injury or death ensues. Altered cellular and tissue biology can result from adaptation, injury, neoplasia, accumulations, aging, or death. (Neoplasia is discussed in Chapters 12, 13, and 14.)

Knowledge of the structural and functional reactions of cells and tissues to injurious agents, including genetic defects, is key to understanding disease processes. Cellular injury can be

caused by any factor that disrupts cellular structures or deprives the cell of oxygen and nutrients required for survival. Injury may be reversible *(sublethal)* or irreversible *(lethal)* and is classified broadly as chemical, hypoxic (lack of sufficient oxygen), free radical, unintentional or intentional, and immunologic or inflammatory. Cellular injuries from various causes have different clinical and pathophysiologic manifestations. Stresses from metabolic derangements may be associated with intracellular *accumulations* and include carbohydrates, proteins, and lipids. Sites of cellular death can cause accumulations of calcium resulting in *pathologic calcification*.

Cellular death is confirmed by structural changes seen when cells are stained and examined with a microscope. The most important changes are nuclear; clearly, without a healthy nucleus, the cell cannot survive.

Cellular aging causes structural and functional changes that eventually lead to cellular death or a decreased capacity to recover from injury. Mechanisms explaining how and why cells age are not known and distinguishing between pathologic changes and physiologic changes that occur with aging is often difficult. Aging clearly causes alterations in cellular structure and function, yet *senescence*—growing old—is both inevitable and normal.

CELLULAR ADAPTATION

Cells adapt to their environment to escape and protect themselves from injury. An adapted cell is neither normal nor injured—its condition lies somewhere between these two states. Cellular adaptations, however, are a common and central part of many disease states. In the early stages of a successful adaptive response, cells may have enhanced function; thus it is hard to differentiate a pathologic response from an extreme adaptation to an excessive functional demand. The most significant adaptive changes in cells include atrophy (decrease in cell size), hypertrophy (increase in cell size), hyperplasia (increase in cell number), and metaplasia (reversible replacement of one mature cell type by another less mature cell type). Dysplasia (deranged cellular growth) is not considered a true cellular adaptation but rather an atypical hyperplasia. These changes are shown in Figure 2-1.

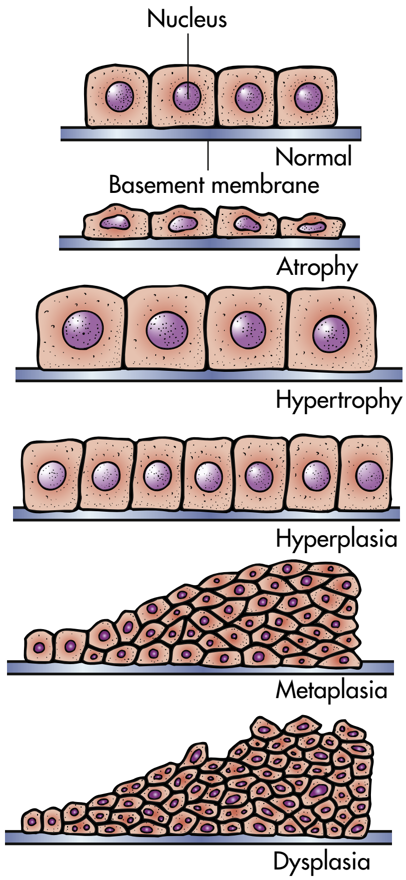

FIGURE 2-1 Adaptive Alterations in Simple Cuboidal Epithelial Cells. (From Lewis SM, Heitkemper MM, Dirksen SR: *Medical-surgical nursing: assessment and management of clinical problems,* ed 6, St Louis, 2004, Mosby.)

Atrophy

Atrophy is a decrease or shrinkage in cellular size. If atrophy occurs in a sufficient number of an organ's cells, the entire organ shrinks or becomes atrophic. Atrophy can affect any organ, but it is most common in skeletal muscle, the heart, secondary sex organs, and the brain (Figure 2-2). Atrophy can be classified as *physiologic* or *pathologic*. **Physiologic atrophy** occurs with early development. For example, the thymus gland undergoes physiologic atrophy during childhood. **Pathologic atrophy** occurs as a result of decreases in workload, use, pressure, blood supply, nutrition, hormonal stimulation, and nervous stimulation. Individuals immobilized in bed for a prolonged time exhibit a type of skeletal muscle atrophy called *disuse atrophy.* Aging causes brain cells to become atrophic and endocrine-dependent organs, such as the gonads, to shrink as hormonal stimulation decreases. Whether atrophy is caused by normal physiologic conditions or by pathologic conditions, atrophic cells exhibit the same basic changes.

The atrophic muscle cell contains less endoplasmic reticulum and fewer mitochondria and myofilaments (part of the muscle fiber that controls contraction) than does the normal cell. In muscular atrophy caused by nerve loss, oxygen consumption and amino acid uptake are rapidly reduced. The mechanisms probably include decreased protein synthesis, increased protein catabolism, or both. **Up-regulation of proteasome** (protein degrading complex) activity is characteristic of atrophic muscle changes.[1] The primary pathway of protein catabolism is the **ubiquitin-proteasome pathway.** Proteins degraded in this pathway are first conjugated to *ubiquitin* (another small protein) and then degraded by proteasomes.

Atrophy as a result of chronic malnutrition is often accompanied by a "self-eating" process called *autophagy* inducing **autophagic vacuoles.** These vacuoles are membrane-bound vesicles within the cell that contain cellular debris—small fragments of mitochondria and endoplasmic reticulum—and hydrolytic enzymes. Atrophic change causes a rapid increase in hydrolytic enzymes, which are isolated in autophagic vacuoles to prevent uncontrolled cellular destruction. Thus the vacuoles proliferate as needed to protect the uninjured organelles from the injured organelles and are eventually taken up and destroyed by lysosomes (see p. 7). Certain contents of the autophagic vacuole may resist destruction by lysosomal enzymes and persist in membrane-bound residual bodies. An example of this

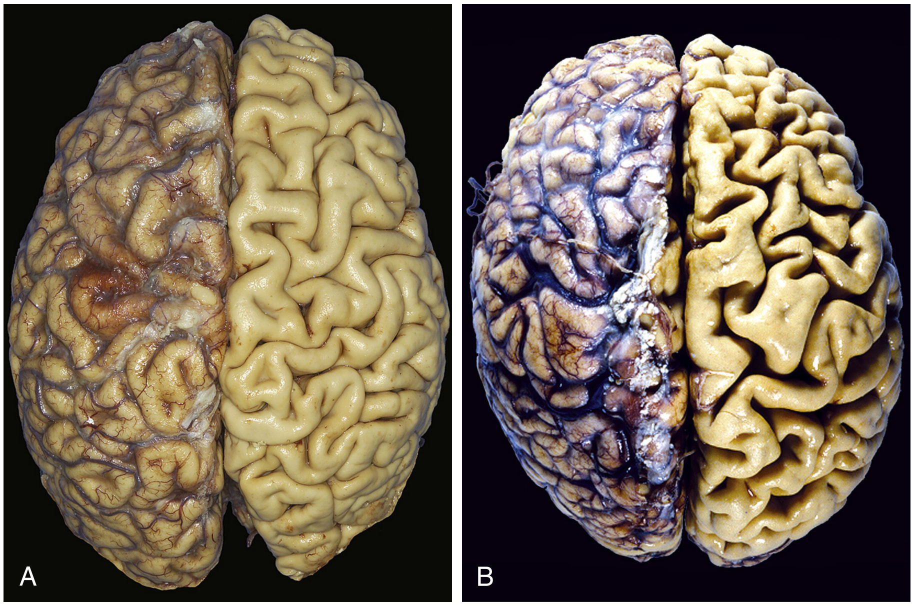

FIGURE 2-2 Atrophy. **A,** Normal brain of a young adult. **B,** Atrophy of the brain in an 82-year-old male with atherosclerotic disease. Atrophy of the brain is a result of aging and reduced blood supply. Note that loss of brain substance narrows the gyri and widens the sulci. The meninges have been stripped from the right half of each specimen to reveal the surface of the brain. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2007, Saunders.)

is granules that contain **lipofuscin,** the yellow-brown age pigment. Lipofuscin accumulates primarily in liver cells, myocardial cells, and atrophic cells.

Hypertrophy

Hypertrophy is an increase in the size of cells and consequently in the size of the affected organ. The cells of the heart and kidneys are particularly responsive to enlargement. Hypertrophy, as an adaptive response (muscular enlargement), occurs in the striated muscle cells of both the heart and skeletal muscles. Physiologic hypertrophy in skeletal muscle occurs in response to heavy work. Muscular hypertrophy tends to diminish if the excessive workload diminishes.

The triggers for hypertrophy include two types of signals: *mechanical signals,* such as stretch, and *trophic signals,* such as growth factors and vasoactive agents. After removal of one kidney, the other kidney adapts to an increased demand for work with an increase in both the size and the number of cells. The major contribution to renal enlargement is hypertrophy.

Initial enlargement of the heart is caused by dilation of the cardiac chambers, is short-lived, and is followed by increased synthesis of cardiac muscle proteins, allowing muscle fibers to do more work. The nucleus also is hypertrophic and exhibits increased synthesis of deoxyribonucleic acid (DNA). The increase in cellular size is associated with an increased accumulation of protein in the cellular components (plasma membrane, endoplasmic reticulum, myofilaments, mitochondria) and *not* with an increase in the amount of cellular fluid. With time cardiac hypertrophy is characterized by extracellular matrix remodeling and increased growth of adult myocytes. The myocytes progressively increase in size and reach a limit beyond which no further hypertrophy can occur.[2] Although hypertrophy can be classified as *physiologic* or *pathologic,* time may be the critical factor or determinant of the transition from physiologic to pathologic cardiac hypertrophy. Pathologic hypertrophy in the heart is secondary to hypertension or valvular dysfunction. Eventually, however, advanced hypertrophy can lead to myocardial failure (Figure 2-3), suggesting that restrictions in myocyte growth are critical determinants of ventricular dysfunction[2] (see Chapter 32).

With physiologic hypertrophy, preservation of myocardial structure characterizes postnatal development, moderate endurance exercise training, pregnancy, and the early phases of increased pressure and volume loading on the adult human heart. This physiologic response is temporary, however, and aging, strenuous exercise, and sustained workload or stress lead to pathologic hypertrophy with structural and functional manifestations. A variety of intermediate signal-transduction pathways involved in myocardial growth have been reported using animal models.

Data for understanding myocyte hypertrophy have advanced; however, the reason the hypertrophied heart ultimately fails is not known. The molecular correlates that define decompensated (pathologic) hypertrophy remain obscure.[2] The fetal genes present in embryonic development, α-skeletal actin and β-myosin heavy chains, have been viewed as the hallmark of pathologic hypertrophy.[3]

Historically it was thought that myocardial cells could not adapt to increased metabolic demands by mitotic division and production of new cells to share the work. This is now being challenged (see What's New? Myocardial Hypertrophy, Stem Cells, Regeneration Controversy).

Hyperplasia

Hyperplasia is an increase in the number of cells resulting from an increased rate of cellular division. Hyperplasia as a response to injury occurs when the injury has been severe and prolonged.

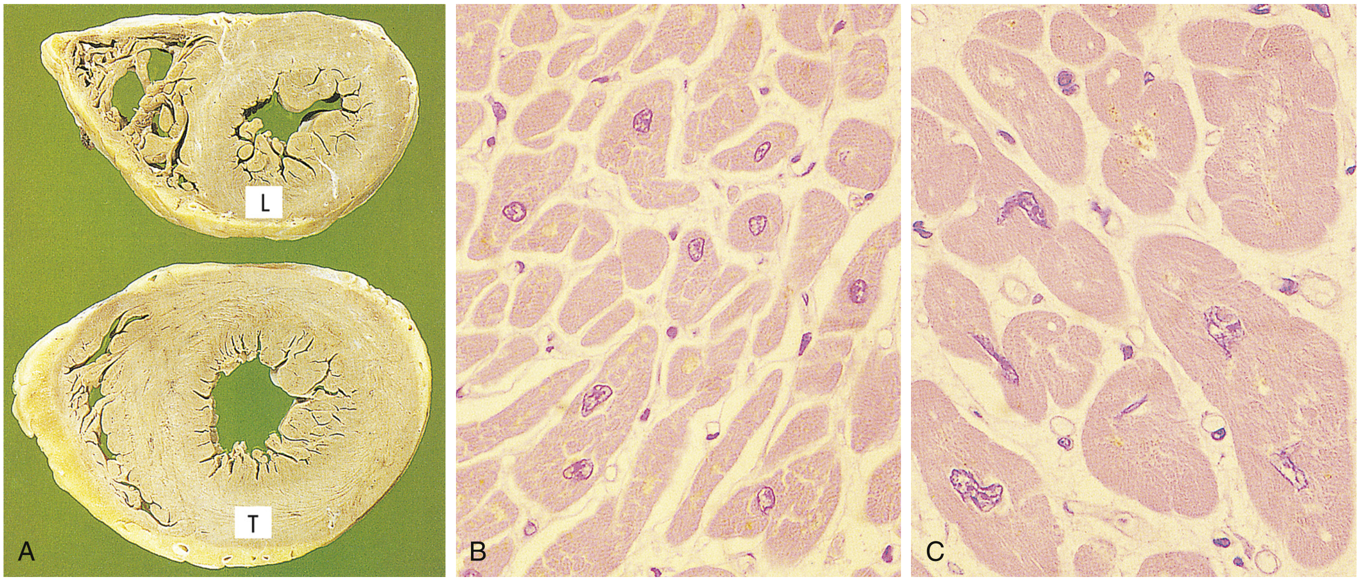

FIGURE 2-3 Hypertrophy of Cardiac Muscle in Response to Valve Disease. **A,** Transverse slices of a normal heart and a heart with hypertrophy of the left ventricle. (*L,* Normal thickness of left ventricular wall; *T,* thickened wall from heart in which severe narrowing of aortic valve caused resistance to systolic ventricular emptying.) **B,** Histology of cardiac muscle from a normal heart. **C,** Histology of cardiac muscle from a hypertrophied heart. WHAT'S NEW?

Myocardial Hypertrophy, Stem Cells, Regeneration Controversy

The human heart has been viewed as a terminally differentiated postmitotic organ where the number of cardiomyocytes is constant from birth, and these cells persist throughout the life span. The recent discovery that cardiac stem cells exist in the heart and differentiate into various cardiac cell lineages has changed the understanding of myocardial biology profoundly. So far, four potential sources of cells may account for new cardiomyocytes after birth: (1) adult cardiomyocytes may enter the cell cycle and divide, (2) bone marrow–derived cardiac stem cells or progenitor cells that have the ability to mature into cardiomyocytes may populate the heart after injury, (3) cells from the embryonic epicardium may be present, and (4) niches of cardiac or cardiac progenitor cells (CPCs) may give rise to cardiomyocytes.

From birth to adulthood and aging, the increase in myocardial mass was assumed to be regulated by a parallel increase in volume of cardiomyocytes and the changes in cell size were equal to the changes in heart weight. In the absence of cardiac disease, the number of myocytes was thought to remain constant throughout life. Hypertrophy was promoted as the exclusive mechanism used by the heart to increase its muscle mass. Myocytes increased their volume by turnover of their cytoplasmic proteins and mitochondrial organelles. Altogether, cardiomyocytes were regarded to live and function for nearly 100 years or longer. The assumption, although unstated, was that cardiomyocytes were basically immortal and died only by pathologic processes during one's life span. Myocytes, however, are formed postnatally and myocyte number decreases with aging. For example, investigators analyzed 74 normal human hearts of individuals 19 to 104 years of age and reported myocyte turnover in the female heart occurs at a rate of 10%, 14%, and 40% per year at 20, 60, and 100 years of age, respectively. The values were respectively 7%, 12%, and 32% per year in male hearts, demonstrating that myocyte growth involves a large and increasing number of cells with aging. However, the extent of myocyte turnover reported by different investigators varies substantially.

Ventricular dilation and wall thinning are the main structural aspects of heart failure. Understanding these structural aspects according to processes that modulate plasticity or regeneration and myocyte death will better define the cellular mechanisms of the failing heart. Cardiac stem cells or progenitor cells regulate myocyte turnover and this new novel information imposes a reconsideration of the mechanisms involved in myocardial aging and progression of myocardial hypertrophy to heart failure.

Data from Anversa P, Kajstura J, Leri A: Chapter 11: Cardiovascular regeneration and tissue engineering. In Bonow RO et al, editors: *Braunwald's heart disease: a textbook of cardiovascular medicine,* ed 9, St Louis, 2012, Elsevier Saunders; Leri A, Kajstura J, Amversa P: *Circ Res* 109:941–961, 2011; Kajstura J et al: *Circ Res* 107:305–315, 2010; Kajstura J et al: *Circ Res* 107:1374–1386, 2010; Olivetti G et al: *J Am Coll Cardiol* 26:1068–1079, 1995.

Loss of epithelial cells and cells of the liver and kidney triggers DNA synthesis and mitotic division. Increased cell growth is a multistep process involving the production of growth factors, which stimulate the remaining cells to synthesize new cell components and, ultimately, to divide. Hyperplasia and hypertrophy often occur together, although the specific mechanism is unknown. Both hyperplasia and hypertrophy take place if the cells are capable of synthesizing DNA.

Two types of normal, or physiologic, hyperplasia are compensatory hyperplasia and hormonal hyperplasia. **Compensatory hyperplasia** is an adaptive mechanism that enables certain organs to regenerate. For example, removal of part of the liver leads to hyperplasia of the remaining liver cells (hepatocytes) to compensate for the loss. Even with removal of 70% of the liver, regeneration is complete in about 2 weeks. The remarkable regenerating capacity of the liver was even

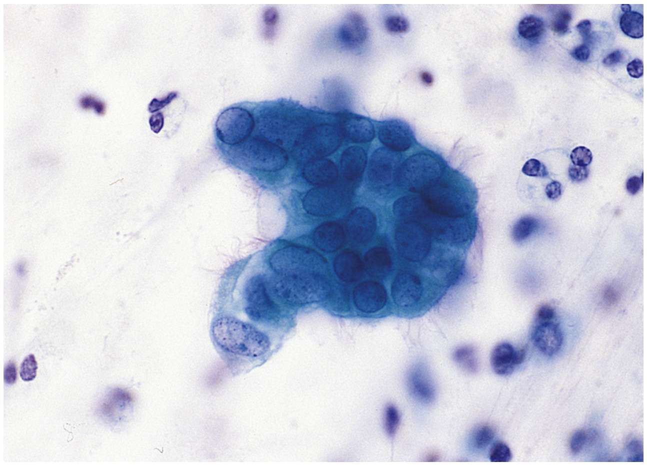

FIGURE 2-4 Hyperplasia of Bronchial Epithelium. (Bronchial Brush.) (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

noted by the ancient Greeks. A protein, **hepatocyte growth factor (HGF),** is a mediator in vitro of liver regeneration. In addition, other in vitro growth factors and cytokines (cell-signaling proteins) that increase hepatic cell regeneration include transforming growth factor-alpha (TGF-α), epidermal growth factor (EGF), interleukin-6 (IL-6), and tumor necrosis factor-alpha (TNF-α).

Not all types of mature cells have the same capacity for compensatory hyperplastic growth. Nondividing tissues contain cells that can no longer (i.e., postnatally) go through the cell cycle and undergo mitotic division. These cells include neurons and skeletal and cardiac muscle cells. Destruction of neurons in the central nervous system is usually replaced by proliferation of the glial cells, the supportive structures. Recent data, however, have demonstrated neuron development from stem cells in adult brains.[4] Mature skeletal muscle cells do not divide but have been shown to have regenerative capacity from differentiation of satellite cells that are part of the endomysial sheaths. Additionally, large injury to cardiac muscle cells is followed by scar formation. However, laboratory experiments show cardiac muscle cells may have limited regenerative capacity.

Significant compensatory hyperplasia occurs in epidermal and intestinal epithelia, hepatocytes, bone marrow cells, and fibroblasts, and some hyperplasia is noted in bone, cartilage, and smooth muscle cells. An example of compensatory hyperplasia is a **callus,** or thickening, of the skin as a result of hyperplasia of epidermal cells in response to a mechanical stimulus. Another example is the response to wound healing as part of the inflammation process (see Chapter 7).

Hormonal hyperplasia occurs chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum. If pregnancy occurs, hormonal hyperplasia, as well as hypertrophy, enables the uterus to enlarge. (Hormone function is described in Chapters 21 and 22.)

Pathologic hyperplasia is the abnormal proliferation of normal cells and can occur as a response to excessive hormonal stimulation or the effects of growth factors on target cells (Figure 2-4). Hyperplastic cells are identified by pronounced enlargement of the nucleus, clumping of chromatin, and the presence of one or more enlarged nucleoli. The most common example is pathologic hyperplasia of the endometrium, which is caused by an imbalance between estrogen and progesterone secretion with oversecretion of estrogen (see Chapter 24). Pathologic endometrial hyperplasia, which causes excessive menstrual bleeding, is under the influence of regular growth-inhibition controls. If these controls fail, hyperplastic endometrial cells can undergo malignant transformation. (Malignant cell transformation is discussed in Chapter 12.)

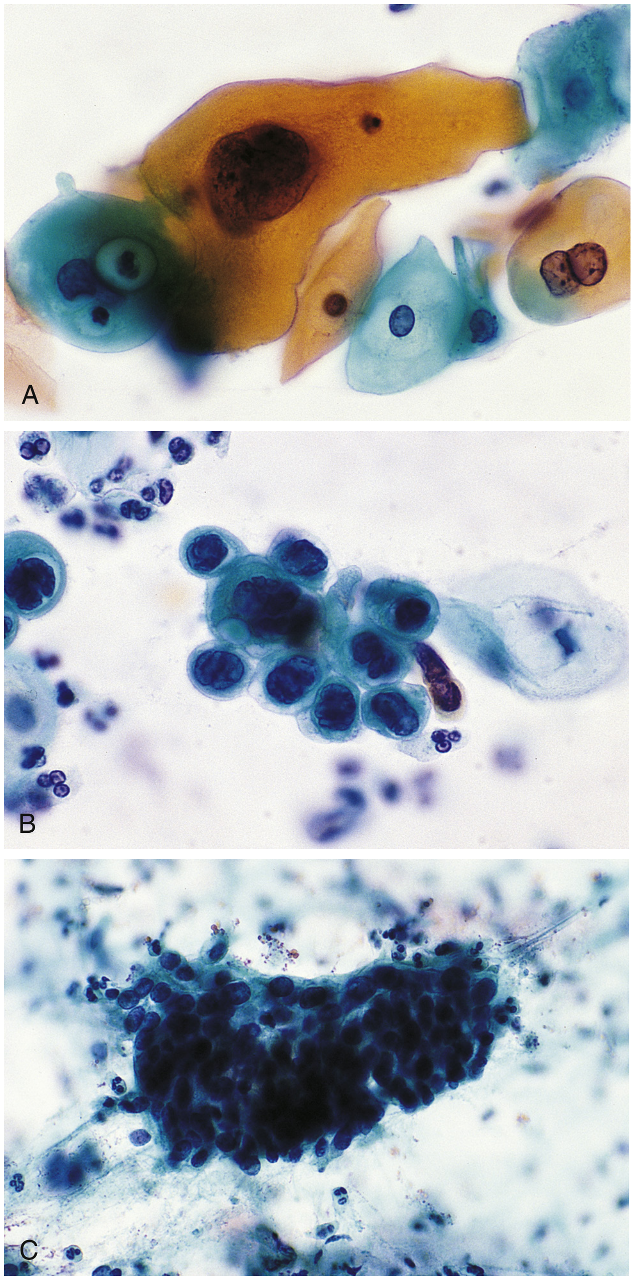

FIGURE 2-5 Dysplasia of Uterine Cervix. **A,** Mild dysplasia. **B,** Severe dysplasia. **C,** Carcinoma in situ (see Chapter 12). (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Dysplasia: Not a True Adaptive Change

Dysplasia refers to abnormal changes in the size, shape, and organization of mature cells. Dysplasia is not considered a true

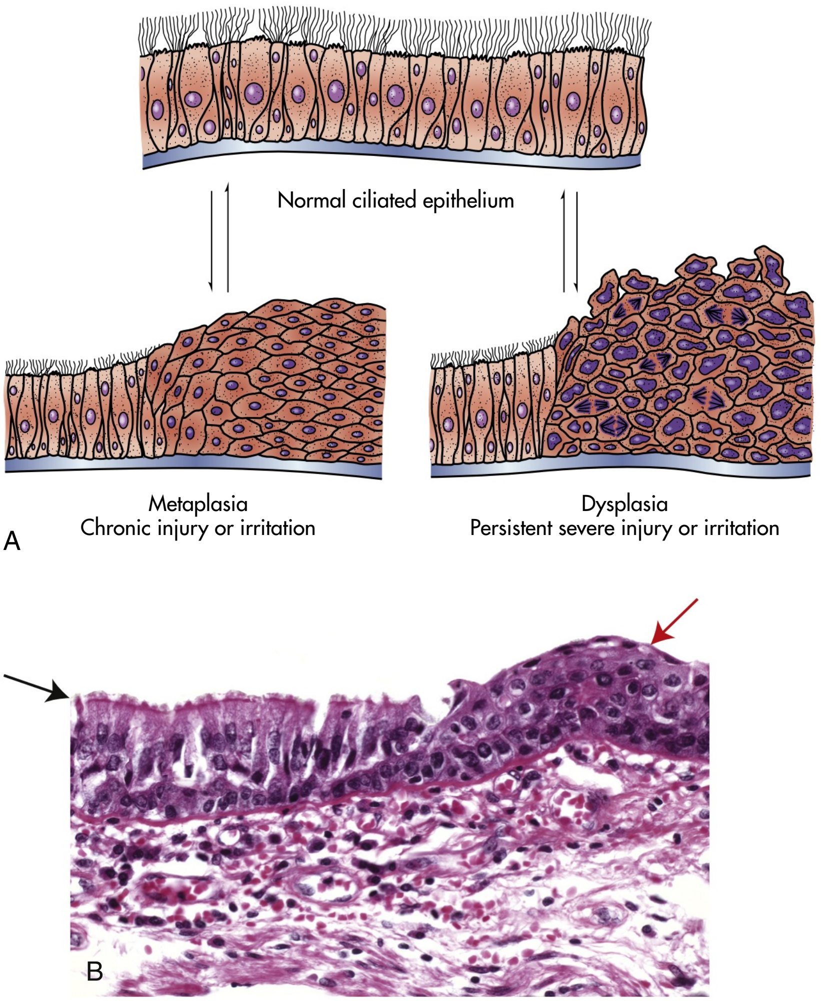

FIGURE 2-6 **Reversible Changes in Cells Lining the Bronchi. A,** Normal ciliated epithelium, metaplasia, and dysplasia. **B,** Histologic slide with upper left *(black arrow)* normal columnar epithelium and basement membrane, and upper right *(red arrow)* squamous metaplasia. (**B** from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2007, Saunders.)

adaptive process but is related to hyperplasia and is often called **atypical hyperplasia.** Dysplastic changes frequently are encountered in epithelial tissue of the cervix and respiratory tract, where they are strongly associated with common neoplastic growths and often are found adjacent to cancerous cells. Importantly, the term *dysplasia* does *not* indicate cancer and may not progress to cancer.

Dysplasia is often classified as mild, moderate, or severe; however, this subjective scheme has prompted recommendations to use either "low grade" or "high grade," for example, of the female reproductive tract (i.e., Papanicolaou [Pap] test [discussed in Chapter 24]) (Figure 2-5). Data indicate that atypical hyperplasia is a strong predictor of breast cancer development.[5,6] If the inciting stimulus is removed, dysplastic changes often are reversible.

Metaplasia

Metaplasia is the reversible replacement of one mature cell by another, sometimes less differentiated, cell type. The best example of metaplasia is replacement of normal columnar ciliated epithelial cells of the bronchial (airway) lining by stratified squamous epithelial cells (Figure 2-6). The newly formed squamous epithelial cells do not secrete mucus or have cilia, causing loss of a vital protective mechanism.

Metaplasia is thought to develop from a reprogramming of stem cells existing in most epithelia or of undifferentiated **mesenchymal** (tissue from embryonic mesoderm) **cells** present in connective tissue. These precursor cells mature along a new pathway because of signals generated by cytokines and growth factors in the cell's environment.

Bronchial metaplasia can be reversed if the inducing stimulus, usually cigarette smoking, is removed. With prolonged exposure to the inducing stimulus, however, cancerous transformation can occur.

CELLULAR INJURY

Injury to cells and to extracellular matrix (ECM) leads to injury of tissues and organs ultimately determining the structural patterns of disease. Loss of function derives from cell and ECM injury and cell death. Cellular injury occurs if the cell is unable to maintain homeostasis—a normal or adaptive steady state—in the face of injurious stimuli or stress. Injured cells may recover (**reversible injury**) or

TABLE 2-1 PROGRESSIVE TYPES OF CELL INJURY AND RESPONSES

TYPE	RESPONSES
Adaptation	Atrophy, hypertrophy, hyperplasia, metaplasia
Active cell injury	Immediate response of "entire" cell
Reversible	Loss of adenosine triphosphate (ATP), swelling of cell, detachment of ribosomes, autophagy of lysosomes
Irreversible	"Point of no return" structurally when severe vacuolization of mitochondria occurs and Ca^{++} moves into the cell, including mitochondrial membrane damage
Necrosis	Common type of cell death with severe cell swelling and breakdown of organelles
Apoptosis, a type of programmed cell death	Cellular self-destruction for elimination of unwanted cell populations
Chronic cell injury (subcellular alterations)	Persistent stimuli response may involve only specific organelles or cytoskeleton (e.g., phagocytosis of bacteria)
Accumulations or infiltrations	Water, pigments, lipids, glycogen, proteins
Pathologic calcification	Dystrophic and metastatic calcification

die (**irreversible injury**). Injurious stimuli include chemical agents, lack of sufficient oxygen (hypoxia), free radicals, infectious agents, physical and mechanical factors, immunologic reactions, genetic factors, and nutritional imbalances. Types of cellular injury and their responses are summarized in Table 2-1 and Figure 2-7.

Cell injury and cell death often result from exposure to toxic chemicals, infections, and hypoxia. (Infections are discussed in Chapter 10.) The mechanisms causing chemical and hypoxic injury are perhaps the best understood. Both of these mechanisms can lead to disruption of selective permeability (i.e., transport mechanisms) of the plasma membrane; reduction or cessation of cellular metabolism; lack of protein synthesis; damage to lysosomal membranes with leakage of destructive enzymes into the cytoplasm; enzymatic destruction of cellular organelles; cellular death (exhibited by nuclear changes); and phagocytosis of the dead cell by cellular components of the acute inflammatory response (see Chapter 7). The extent of cellular injury depends on the type, state (including level of cell differentiation and increased susceptibility to fully differentiated cells), and adaptive processes of the cell, as well as the type, severity, and duration of the injurious stimulus. Two individuals exposed to an identical stimulus may incur varying degrees of cellular injury. Modifying factors, such as nutritional status, can profoundly influence the extent of injury. The precise "point of no return" that leads to cellular death is a biochemical puzzle, and the exact mechanisms responsible for the transition from reversible to irreversible cellular damage are being debated.

General Mechanisms of Cell Injury

Cells are complex units, and therefore the mechanisms responsible for cell injury leading to necrotic cell death are numerous and interrelated and depend on a delicate balance between intracellular and extracellular events. There are, however, common biochemical themes important to cell injury and cell death regardless of the injuring agent (Table 2-2). Examples of cell injury are: (1) hypoxic injury, (2) reactive oxygen species and free radical–induced injury, and (3) chemical injury.

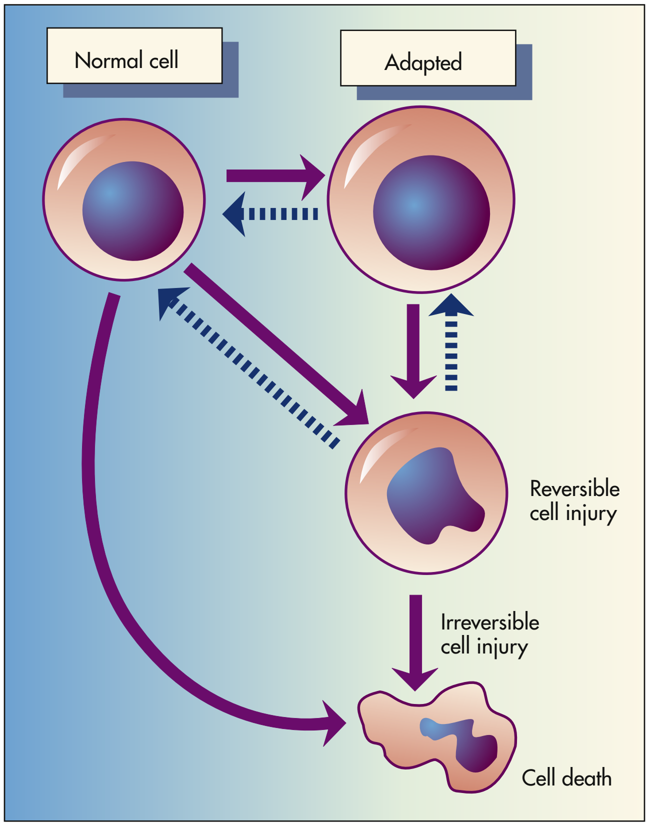

FIGURE 2-7 Cellular Injury and Responses. Depicted here is the relationship among normal, adapted (hypertrophy), and reversibly injured cells and cell death of myocardial cells.

TABLE 2-2 COMMON THEMES IN CELL INJURY AND CELL DEATH

THEME	COMMENTS
ATP depletion	Loss of mitochondrial ATP and decreased ATP synthesis; results include cellular swelling, decreased protein synthesis, decreased membrane transport, and lipogenesis, all changes that contribute to loss of integrity of plasma membrane (see text)
Oxygen and oxygen-derived free radicals	Lack of oxygen is key in progression of cell injury in ischemia (reduced blood supply); activated oxygen species (free radicals, H_2O_2, O_2^-, NO) cause destruction of cell membranes and cell structure
Intracellular calcium and loss of calcium steady state	Normally intracellular cytosolic calcium concentrations are very low; ischemia and certain chemicals cause an increase in cytosolic Ca^{++} concentrations; sustained levels of Ca^{++} continue to increase with damage to plasma membrane; Ca^{++} causes intracellular damage by activating a number of enzymes (see text)
Defects in membrane permeability	Early loss of selective membrane permeability found in all forms of cell injury (see text)

ATP, Adenosine triphosphate.

Hypoxic Injury

Hypoxia, or lack of sufficient oxygen, is the single most common cause of cellular injury (Figure 2-8). Hypoxia can result from a reduced amount of oxygen in the air, loss of hemoglobin or hemoglobin function, decreased production of red blood cells, consequences of respiratory and cardiovascular system diseases, and poisoning of the oxidative enzymes (cytochromes) within the cells. The most common cause of hypoxia is **ischemia** (reduced blood supply). Hypoxia can induce inflammation and inflamed lesions can become hypoxic (Figure 2-9).

Ischemic injury is often caused by gradual narrowing of arteries (arteriosclerosis) and complete blockage by blood clots (thrombosis). Progressive hypoxia caused by gradual arterial obstruction is better tolerated than the sudden acute **anoxia** (total lack of oxygen) caused by a sudden obstruction, such as can occur with an embolus (a blood clot or other plug in the circulation). An acute obstruction in a coronary artery can cause myocardial cell death (infarction) within minutes if the blood supply is not restored, whereas the gradual onset of ischemia usually results in myocardial adaptation. Myocardial infarction and stroke, which

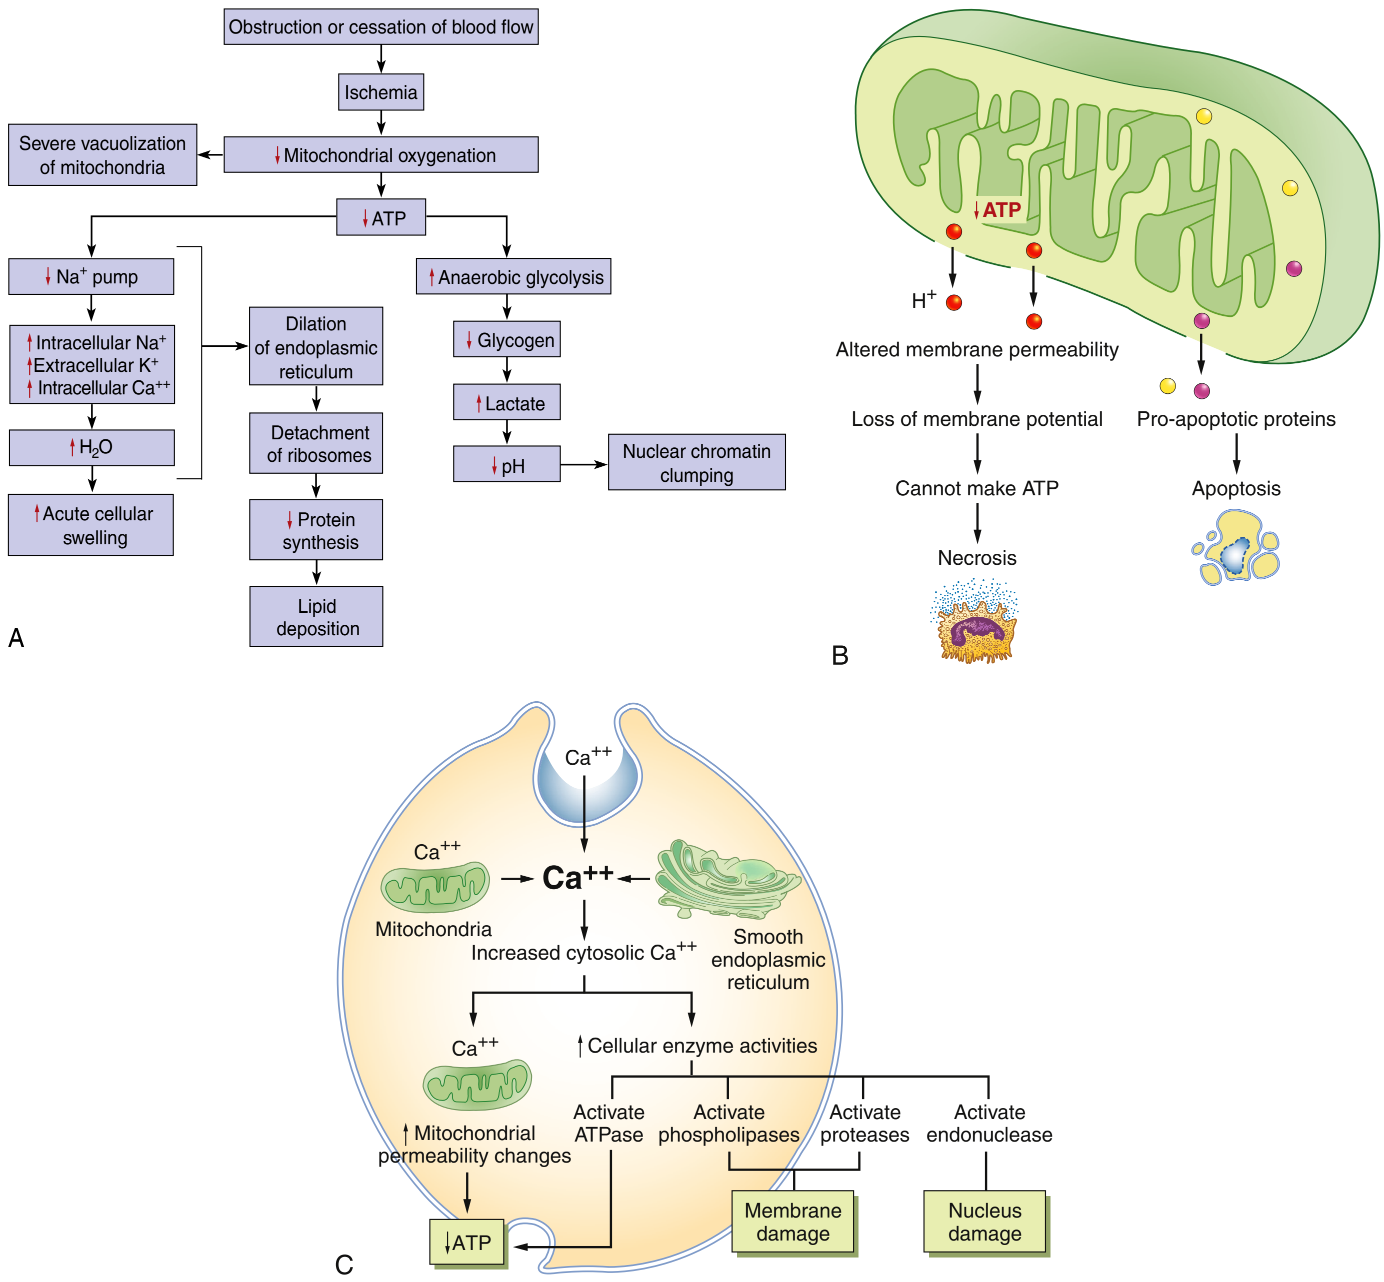

FIGURE 2-8 Hypoxic Injury Induced by Ischemia. **A,** Consequences of decreased oxygen delivery or ischemia with decreased ATP. The structural and physiologic changes are reversible if oxygen is delivered quickly. Significant decreases in ATP concentration result in cell death, mostly by necrosis. **B,** Mitochondrial damage can result in changes in membrane permeability, loss of membrane potential, and decreased ATP. Between the outer and inner membranes of the mitochondria are proteins that can activate the cell's suicide pathways, called apoptosis. **C,** Calcium ions are critical mediators of cell injury. Calcium ions are usually maintained at low concentrations in the cell's cytoplasm; thus ischemia and certain toxins can initially cause an increase in the release of Ca^{++} from intracellular stores and later an increased movement (influx) across the plasma membrane.

are common causes of death in the United States, generally result from atherosclerosis (a type of arteriosclerosis) and consequent ischemic injury. (Vascular obstruction is discussed in Chapter 32.)

Cellular responses to hypoxic injury in heart muscle have been extensively studied. Within 1 minute after blood supply to the myocardium is interrupted, the heart becomes pale and has difficulty contracting normally. Within 3 to 5 minutes the ischemic portion of the myocardium ceases to contract. The abrupt lack of contraction is caused by a rapid decrease in mitochondrial phosphorylation, which results in insufficient adenosine triphosphate (ATP) production. Lack of ATP leads to an increase in anaerobic metabolism, which generates ATP from glycogen when there is insufficient oxygen. When glycogen stores are depleted even anaerobic metabolism ceases.

A reduction in ATP levels causes the plasma membrane's sodium-potassium (Na^+-K^+) pump and sodium-calcium exchange to fail, which leads to an intracellular accumulation of sodium and calcium, resulting in cellular swelling and diffusion of potassium out of the cell. (The Na^+-K^+ pump is discussed in Chapter 1.) Because all cells are bathed in a fluid rich in calcium ions, cell membrane damage allows rapid movement of calcium intracellularly. The movement of water and ions into the cell causes early dilation of the endoplasmic reticulum. Dilation causes the ribosomes to detach from the rough endoplasmic reticulum, resulting in reduced protein synthesis. With continued hypoxia, the entire cell becomes markedly swollen, with increased concentrations of sodium, water, and chloride and decreased concentrations of potassium. These disruptions are reversible if oxygen is restored. If oxygen is not restored, however, there is **vacuolation** (formation of vacuoles or cytoplasmic small cavities) within the cytoplasm, swelling of lysosomes, and marked swelling of the mitochondria resulting from mitochondrial membrane damage. Continued hypoxic injury with accumulation of calcium subsequently activates multiple enzyme systems, including proteases, nitric oxide synthase, phospholipases, and endonuclease, resulting in cytoskeleton disruption, membrane damage, activation of inflammation, DNA

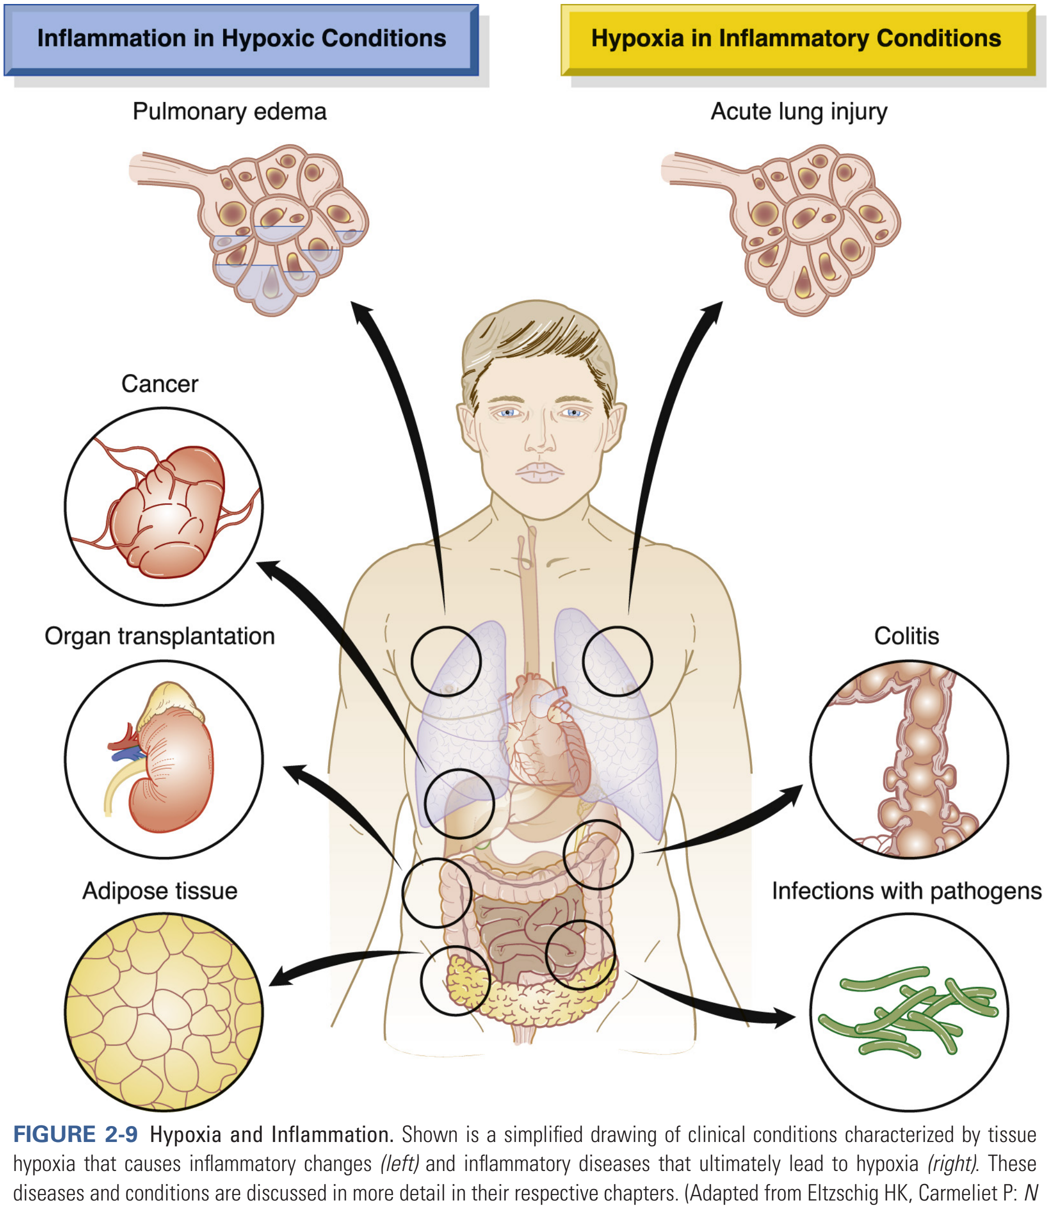

FIGURE 2-9 Hypoxia and Inflammation. Shown is a simplified drawing of clinical conditions characterized by tissue hypoxia that causes inflammatory changes *(left)* and inflammatory diseases that ultimately lead to hypoxia *(right)*. These diseases and conditions are discussed in more detail in their respective chapters. (Adapted from Eltzschig HK, Carmeliet P: *N Engl J Med* 364:656–665, 2011.)

and chromatin degradation, ATP depletion, and eventual cell death (see Figures 2-8 and 2-23 [p. 86]). Structurally, with plasma membrane damage, extracellular calcium readily moves into the cell and intracellular calcium stores are released.

Intracellular calcium results in the activation of enzymes that can further damage membranes, proteins, ATP, and nucleic acids. The increased permeability of the membrane causes continued loss of proteins, essential coenzymes, and ribonucleic acids. In addition, the substrates necessary to reconstitute ATP are lost. Increased intracellular calcium levels activate cell enzymes (caspases) that promote cell death by apoptosis (see Figure 2-26 [p. 89]). Continued ischemia causes irreversible injury that is associated structurally with severe swelling of the mitochondria, severe damage to plasma membranes, and swelling of lysosomes.

Acid hydrolases from leaking lysosomes are activated in the reduced pH of the injured cell and they digest cytoplasmic and nuclear components. Leakage of intracellular enzymes into the peripheral circulation provides a diagnostic tool for detecting tissue-specific cellular injury and death using blood samples; for example, the contractile protein troponin from cardiac muscle is found after myocardial injury and liver transaminases are found after hepatic injury.

Restoration of oxygen, however, can cause additional injury called **reperfusion (reoxygenation) injury.** Reperfusion injury results from the generation of highly reactive oxygen intermediates (oxidative stress), including hydroxyl radical (OH•), superoxide $O_2^{\bar{}}$, and hydrogen peroxide (H_2O_2) (see p. 59). These radicals can all cause further membrane damage and mitochondrial calcium overload. The white blood cells (neutrophils) are especially affected with reperfusion injury, including neutrophil adhesion to the endothelium.

Reperfusion is a serious complication and an important mechanism of injury in instances of tissue transplantation and in myocardial, hepatic, intestinal, cerebral, renal, and other ischemic syndromes, including stroke.[7] Xanthine dehydrogenase, an enzyme that normally uses oxidized nicotinamide adenine dinucleotide (NAD^+) as an electron acceptor, is converted during reperfusion with oxygen to xanthine oxidase. During the ischemic period, excessive ATP consumption leads to the accumulation of the purine catabolites hypoxanthine and

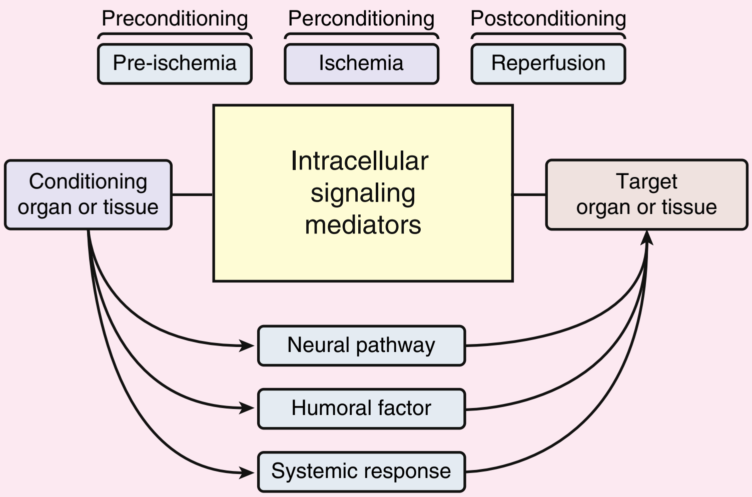
WHAT'S NEW?

Cardioprotection for Ischemia-Reperfusion Injury

Coronary heart disease (CHD) is the leading cause of morbidity and mortality worldwide. Despite optimal therapy and an amazing amount of research, individuals with CHD still suffer significant morbidity and mortality. Therefore, to improve individual outcomes novel treatment strategies for protecting the heart against the detrimental effects of acute ischemia-reperfusion injury (IRI), the major pathologic consequence of CHD, are required. Cardioprotection can occur by signaling pathways initiated before or at the beginning of sustained ischemia, called *preconditioning* (PC), and/or cardioprotection at the very start of reperfusion, called postconditioning (see figure below). *Perconditioning* is a term sometimes used for the period of ischemia.

Murray and colleagues first described ischemic preconditioning (IPC) in which the application of short cycles of nonlethal ischemia and reperfusion to the canine heart reduced subsequent myocardial infarct size (IS). The problem with this strategy is the requirement for the intervention to be applied before the ischemic event, which in the case of an acute myocardial infarction (MI) is impossible to predict. However, the introduction of ischemic postconditioning in 2003, whereby the process of myocardial reperfusion is interrupted by several short-lived episodes of ischemia, overcomes this problem and can be applied at the onset of myocardial reperfusion in individuals presenting with an acute MI. Yet, both IPC and ischemic postconditioning require an intervention to be applied to the heart directly that is not feasible in all clinical settings. Therefore, remote ischemic conditioning (RIC) may provide a noninvasive endogenous therapeutic strategy (for example, with a blood pressure cuff) for protecting the heart against acute IRI. Remote ischemic conditioning is the cardioprotective effect elicited from applying one or more cycles of nonlethal ischemia reperfusion to an organ or tissue remote from the heart. Furthermore, experimental studies found that it was possible to protect non-cardiac organs and tissues from acute IRI. Thus, RIC represents a form of systemic protection against acute IRI. Recently, it was discovered that the RIC stimulus could be noninvasively induced using a standard blood pressure cuff placed on the upper arm or leg. Importantly, the timing of the RIC stimulus can accommodate most clinical settings of acute IRI (see figure below).

Remote Ischemic Conditioning



Data from Kharbanda RK et al: *Circulation* 106:2881–2883, 2002; Lim SY, Hausenloy DJ: *Front Physiol* 3:27, 2012.

xanthine, which upon subsequent reperfusion and influx of oxygen are metabolized by xanthine oxidase to make *massive* amounts of superoxide and hydrogen peroxide. These radicals can all cause membrane damage and mitochondrial calcium overload.[3] Cardiac ischemia and reperfusion injury cause excessive reactive oxygen species (ROS) and calcium overload of the mitochondria. These changes presumably lead to the opening of a large conductance pore on the mitochondrial membrane called the *mitochondrial permeability transition pore* (MPTP) with massive escape of ATP and solutes leading to cell death activation (apoptosis).[8] Cardioprotection from ischemia/reperfusion injury is an important focus of much research (see What's New? Cardioprotection for Ischemia-Reperfusion Injury). Other potential and current treatments include use of antioxidants, blockage of inflammatory mediators, and inhibition of apoptotic pathways.

Free Radicals and Reactive Oxygen Species—Oxidative Stress

An important mechanism of membrane damage is injury induced by free radicals, especially by excess ROS called **oxidative stress** (Figure 2-10). Oxidative stress occurs when *excess*

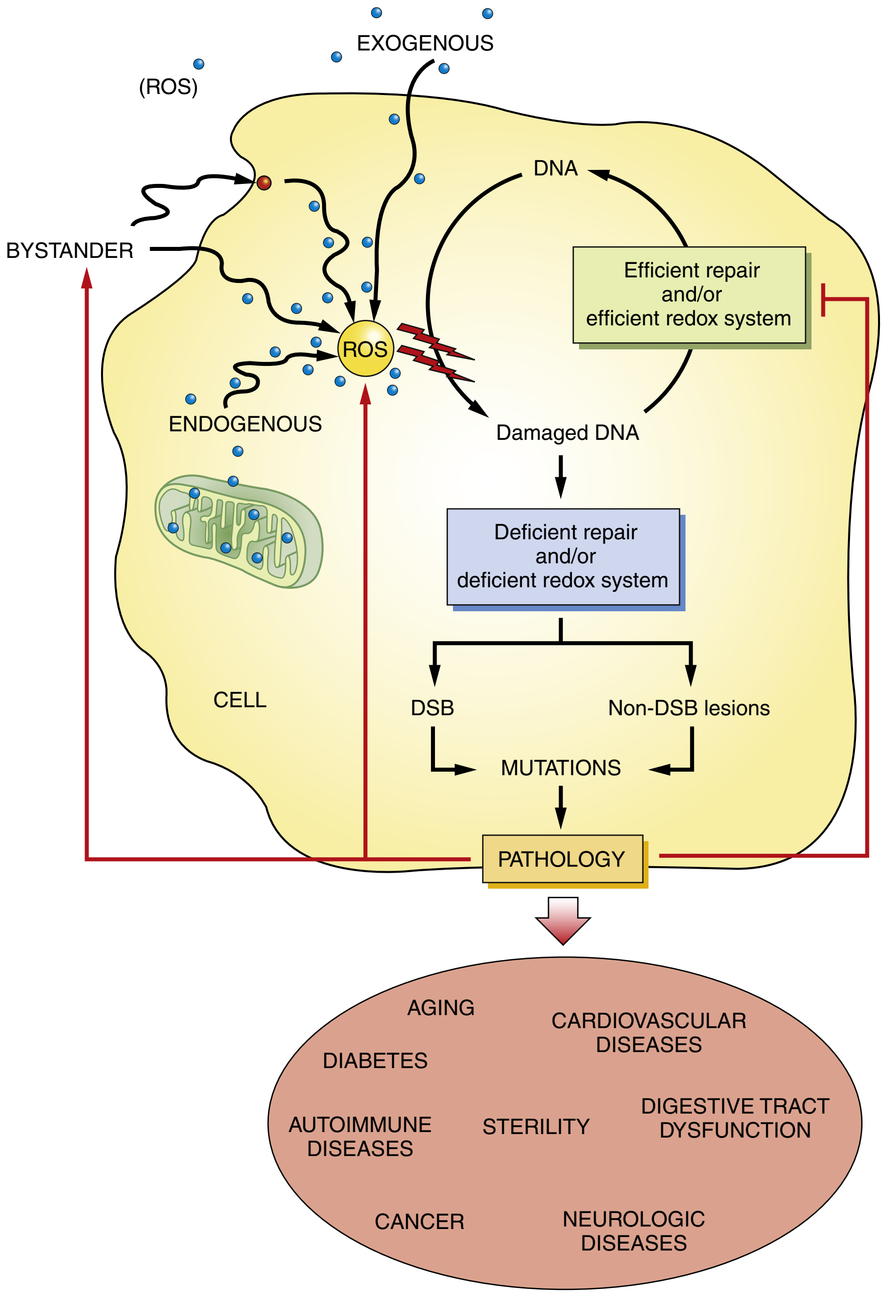


FIGURE 2-10 Oxidative Stress in Human Pathogenesis. Reactive oxygen species *(ROS)* have a role in a wide variety of diseases and age-related diseases including cancer, neurologic disease, type 2 diabetes, autoimmune and cardiovascular diseases, infertility, and normal aging. Chronic exposure to ROS and decreased DNA repair can result in persistent DNA mutations. Accumulation of DNA lesions can lead to DNA double strand breaks *(DSB)* and disease onset/progression. Diseased cells can in turn develop ROS and decrease the efficiency of the DNA repair mechanism. (Adapted from Sedelnikova OA et al: *Mutat Res* 704:152–159, 2010.)

ROS overwhelms endogenous antioxidant systems (Box 2-1). A **free radical** is an electrically uncharged atom or group of atoms having an unpaired electron. Having one unpaired electron makes the molecule unstable; thus to stabilize, it gives up an electron to another molecule or steals one. Therefore, it is capable of injurious chemical bond formation with proteins, lipids, and carbohydrates—key molecules in membranes and nucleic acids. Free radicals are difficult to control and initiate chain reactions. Emerging data indicate that ROS play major roles in the initiation and progression of cardiovascular alterations associated with hypertension, hyperlipidemia, diabetes mellitus, ischemic heart disease, chronic heart failure, and sleep apnea.[9,10] ROS generation is thought to lead to vascular endothelial injury and consequently atherosclerosis. Up-regulation of adhesion molecule production in the endothelium can be accomplished by ROS, which diminishes nitric oxide (NO) synthase activity and promotes NO breakdown. This disturbance of the vascular environment presumably causes a reduction of endothelial-dependent vasodilation.[11] Such reduction in endothelium-dependent vasodilation has been demonstrated through intra-arterial infusion of vasoactive agents. Specific mechanisms by which vascular endothelial dysfunction may lead to adverse cardiovascular events include vasoconstriction, vascular smooth muscle proliferation, hypercoagulability, and thrombosis.[12]

ROS produced by migrating inflammatory cells (e.g., neutrophils), as well as vascular cells (endothelial cells, vascular smooth muscle cells, and adventitial fibroblasts), have distinct effects on each cell type.[13] These cell effects are shown in Figure 2-11. When inflammatory responses also are activated, there is consequent activation of endothelial cells, leukocytes, and platelets. These activated cells express adhesion molecules and proinflammatory cytokines that may further exacerbate inflammatory responses and cause endothelial cell injury and dysfunction, promoting the development of cardiovascular morbidities.[14]

Free radicals may be initiated within cells by (1) the absorption of extreme energy sources (e.g., ultraviolet light, x-rays); (2) the occurrence of endogenous reactions, such as redox reactions in which oxygen is reduced to water, as evident in systems involved in electron and oxygen transport (all biologic membranes contain redox systems important for cellular defense, for example, inflammation, iron uptake, growth and proliferation, and signal transduction) (Figure 2-12); or (3) the enzymatic metabolism of exogenous chemicals or drugs (e.g., chloromethyl [$CC1_3^{\bullet}$], a product of carbon tetrachloride [CCl_4]). Table 2-3 describes the most significant free radicals.

Although wide-ranging effects can occur from these reactive species, three are particularly important in regard to cell injury: (1) peroxidation of lipids; (2) alterations of proteins causing fragmentation of polypeptide chains; and (3) alterations of DNA, including breakage of single strands. **Lipid peroxidation** is the destruction of unsaturated fatty acids. Fatty acids of lipids in membranes possess double bonds between some of the carbon atoms. Such bonds are vulnerable to attack by oxygen-derived free radicals, especially OH·. The lipid-radical interactions themselves yield peroxides. The peroxides instigate a chain reaction resulting in membrane, organelle, and cellular destruction.

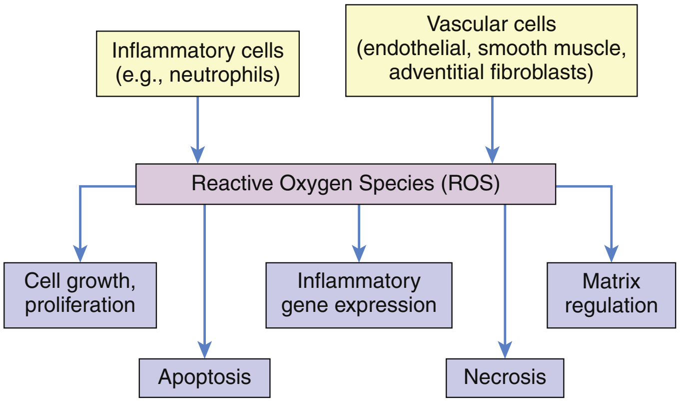

FIGURE 2-11 ROS Can Cause Distinct Functional Effects Depending on Cell Type. All cells are capable of making reactive oxygen species (ROS). Emphasis has been on inflammatory and vascular cells because of their widespread disease-causing effect. Some examples include angiotensin II, which can induce vascular smooth muscle cells (VSMCs) to hypertrophy; NAD(P)H oxidase–derived ROS has been implicated in the growth response; H_2O_2 has been shown to induce proliferation and migration of endothelial cells; ROS act as mediators of vascular endothelial growth factor, thus modulating angiogenesis; endothelial injury or exposure to O_2^- and H_2O_2 induces apoptosis of endothelial cells. Activity of the extracellular matrix by matrix metalloproteinases (MMPs) can be modulated by ROS. Cytokines play a significant role in the progression of vascular lesions. An important mechanism by which cytokine gene expression is increased is the activation of nuclear factor-κβ (NF-κβ). NF-κβ is a ROS-sensitive transcription factor and has a role in the expression of proinflammatory genes. (Data from Beutler TM, Krauskopf A, Ruegg UT: *News Physiol Sci* 19:120–123, 2004; Dröge W: *Physiol Rev* 82:47–95, 2002; Valko M et al: *Int J Biochem Cell Biol* 39[1]:44–84, 2007.) (Also see Box 2-1.)

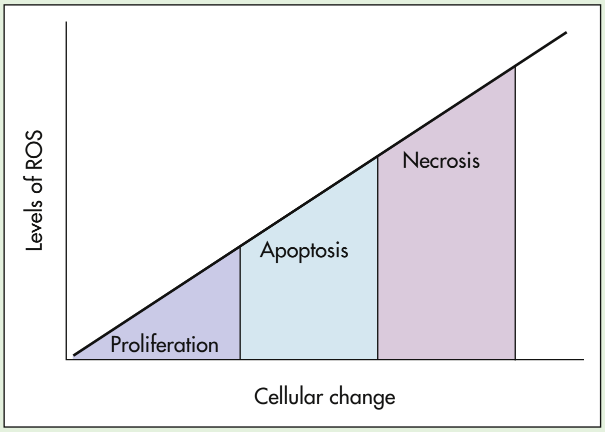
BOX 2-1 ROS AND PROLIFERATION, APOPTOSIS, AND NECROSIS



Cellular effects of reactive oxygen species (ROS) may depend on *concentration levels*. At low concentrations, ROS appear to exert a beneficial growth-stimulatory effect on a wide variety of cells and microorganisms. For example, bacteria such as *Escherichia coli* and *Salmonella typhimurium* need O_2^- for growth. Certain human cell lines also have shown this dependency in vitro. Yet when ROS levels increase, other signaling pathways may be activated that lead to apoptosis. When ROS levels rise even higher, a cell may die a sudden necrotic death. The apoptosis and necrosis modes are thought to be caused by oxidative stress. Thus the signaling functions of ROS are now appreciated.

Data from Beutler TM, Krauskopf A, Ruegg UT: *News Physiol Sci* 19:120–123, 2004; Valko M et al: *Int J Biochem Cell Biol* 39(1):44–84, 2007.

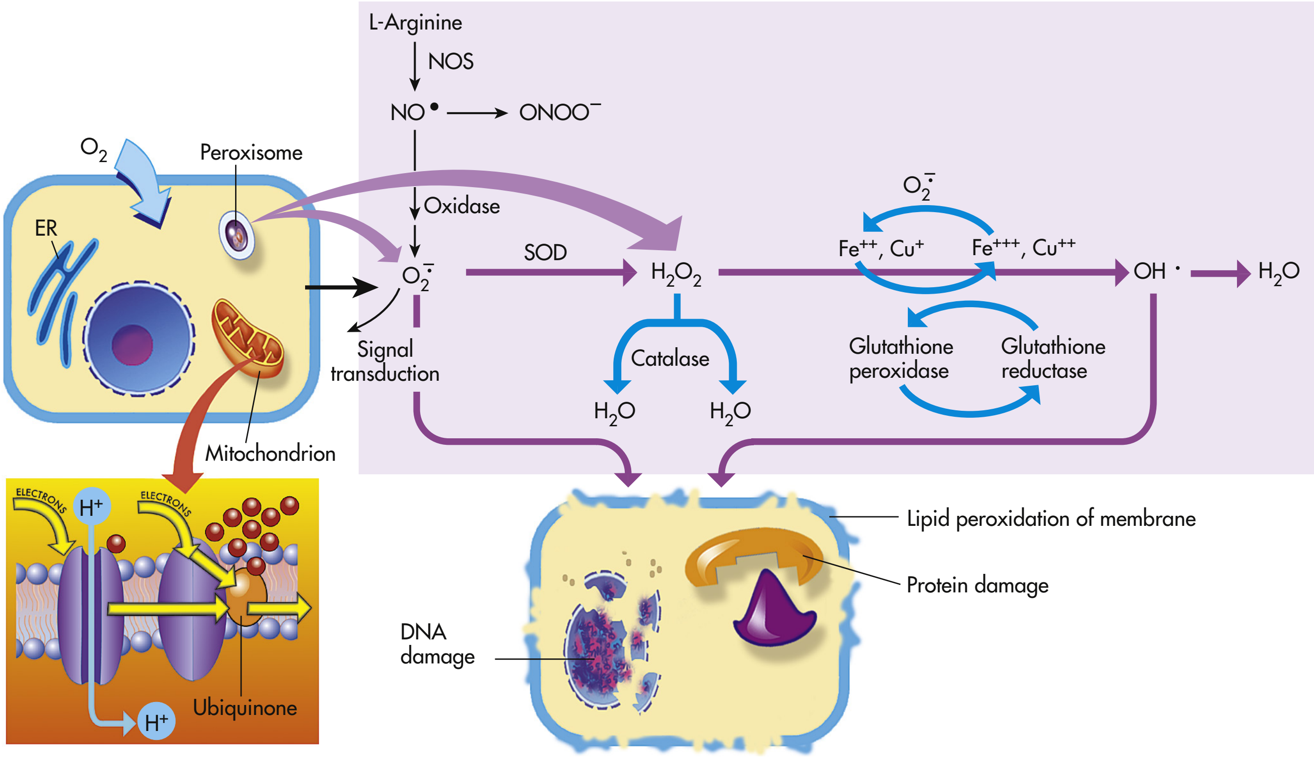


FIGURE 2-12 **Generation of Reactive Oxygen Species (ROS) and Antioxidant Mechanisms in Biologic Systems.** Mitochondria have four sites of entry for electrons coming into the electron-transport system: one for reduced nicotinamide adenine dinucleotide (NADH) and three for the reduced form of flavin adenine dinucleotide ($FADH_2$). These pathways meet at the small, lipophilic molecule ubiquinone (coenzyme Q), at the beginning of the common electron-transport pathway. Ubiquinone transfers electrons in the inner membrane, ultimately enabling their interaction with O_2 and H_2 to yield H_2O. In so doing, the transport allows free energy change and the synthesis of 1 mol of adenosine triphosphate (ATP). With the transport of electrons, free radicals are generated within the mitochondria. ROS (H_2O_2, OH•, and O_2^- and nitric oxide [NO]) act as physiologic modulators of some mitochondrial functions but also may cause cell damage. O_2 is converted to superoxide (O_2^-) by oxidative enzymes in the mitochondria, endoplasmic reticulum (ER), plasma membrane, peroxisomes, and cytosol. O_2 is converted to H_2O_2 by superoxide dismutase (SOD) and further to OH• by the Cu^{++}/Fe^{++} Fenton reaction. Superoxide catalyzes the reduction of Fe^{++} to Fe^{+++}, thus increasing OH• formation by the Fenton reaction. H_2O_2 is also derived from oxidases in peroxisomes. The NO• (radical) is produced by the oxidation of one of the terminal guanido-nitrogen atoms of l-arginine. Depending on the microenvironment, NO can be converted to other reactive nitrogen species including the highly reactive peroxynitrate ($ONOO^-$). Both OH• and $ONOO^-$ are very reactive and can modify cellular macromolecules and cause toxicity. The less reactive molecules O_2^- and H_2O_2 can serve as cellular signaling molecules. The major antioxidant enzymes include SOD, catalase, and glutathione peroxidase. (Data from Dröge W: *Physiol Rev* 82:47–95, 2002; Buetler TM, Krauskopf A, Ruegg UT: *News Physiol Sci* 19:120–123, 2004.)

Because of the increased understanding of free radicals, a growing number of diseases and disorders have been linked either directly or indirectly to these reactive species (Box 2-2).

The body can sometimes rid itself of free radicals. The oxygen free radical superoxide may spontaneously decay into oxygen and hydrogen peroxide. Table 2-4 summarizes other methods that contribute to inactivation or termination of free radicals. The toxicity of certain drugs and chemicals can be attributed to either the conversion of these chemicals to free radicals or the formation of oxygen-derived metabolites.[7] This process is discussed in Chemical Injury.

Mitochondria and ROS

During normal metabolism, the mitochondria are the greatest source and target of ROS. Usually ROS are reduced by intracellular antioxidant enzymes, including superoxide dismutase (SOD), glutathione peroxidase, and catalase, as well as antioxidant molecules, such as glutathione and vitamin E. These ROS, however, contribute to mitochondria dysfunction and are related to many human diseases and aging. In pathologic conditions, the large numbers of ROS overwhelm the balance by antioxidants. This inefficiency of antioxidants is even more serious in mitochondria because mitochondria in most cells lack catalase.[15] Consequently, the excessive production of hydrogen peroxide and eventually hydroxyl radicals (OH•) in mitochondria will damage lipid, proteins, and **mitochondrial DNA (mtDNA),** which then causes cells to die.[15-18] Mitochondrial oxidative stress has been implicated in heart disease, Alzheimer disease, Parkinson disease, prion diseases, and amyotrophic lateral sclerosis (ALS), as well as aging itself.[19-23] Accumulating evidence shows ROS important for cell proliferation and survival.[20] Dysfunction of autophagy may result in abnormal mitochondrial function

TABLE 2-3 BIOLOGICALLY RELEVANT FREE RADICALS

FREE RADICAL	COMMENTS
Reactive oxygen species (ROS) Superoxide O_2^- $O_2 \rightarrow$ oxidase O_2^-	Generated either (1) directly during autooxidation in mitochondria, or (2) enzymatically by enzymes in the cytoplasm, such as xanthine oxidase or cytochrome P-450; once produced, it can be inactivated spontaneously or more rapidly by the enzyme superoxide dismutase (SOD): $O_2^- + O_2^- + 2H^+ \rightarrow$ SOD H_2O_2 + O_2^- O_2^-, a signaling molecule in growing or differentiating tissue, including hypertrophy, can alter cellular responses to growth factors and vasoconstrictor hormones; increasing levels of O_2^- may lead to apoptosis (see Figure 2-11)
Hydrogen peroxide (H_2O_2) $O_2^- + O_2^- + 2H \rightarrow$ SOD $H_2O_2 + O_2$ *or* Oxidases present in peroxisomes O_2 peroxisome $O_2^- \rightarrow$ SOD H_2O_2	Generated by SOD or directly by oxidases in intracellular peroxisomes; SOD is considered an antioxidant because it converts superoxide to $H_2O_2^{\cdot}$, catalase (another antioxidant) can then decompose H_2O_2 to O_2 + H_2O; H_2O_2 can serve as a cellular signaling molecule
Hydroxyl radicals (OH•) $H_2O \rightarrow H\bullet + OH\bullet$ *or* $Fe^{++} + H_2O_2 \rightarrow Fe^{+++} + OH\bullet + OH^-$ *or* $H_2O_2 + O_2^- \rightarrow OH\bullet + OH^- + O_2$ Nitric oxide (NO)	Generated by the hydrolysis of water caused by ionizing radiation or by interaction with metals—especially iron (Fe) and copper (Cu); iron is important in toxic oxygen injury because it is required for maximal oxidative cell damage; OH• is highly reactive and can modify cellular macromolecules and cause toxicity
$NO\bullet + O_2^- \rightarrow ONOO^- + H+$ ↑↓ $OH\bullet + NO_2$ ONOOH $\rightarrow NO_3^-$	NO by itself is an important mediator that can act as a free radical; it can be converted to another radical—peroxynitrite anion (ONOO–), as well as $NO_2\bullet$ and NO_3^-; NO is formed in neuronal cells, where it modulates neurotransmission; in endothelial cells as a modulator of vessel relaxation; and in neutrophils and macrophages as a factor in vessel relaxation and inactivation of pathogens

TABLE 2-4 METHODS CONTRIBUTING TO INACTIVATION OR TERMINATION OF FREE RADICALS

METHOD	PROCESS
Antioxidants	Endogenous or exogenous; either blocks synthesis or inactivates (e.g., scavenges) free radicals; includes vitamin E, vitamin C, cysteine, glutathione, albumin, ceruloplasmin, transferrin
Enzymes	Superoxide dismutase,* which converts superoxide to H_2O_2; catalase* (in peroxisomes) decomposes H_2O_2; glutathione peroxidase* decomposes OH• and H_2O_2

*These enzymes are important in modulating the cellular destructive effects of free radicals, also released in inflammation.

and oxidative or nitrative (i.e., reactive nitrogen species) stress. Emerging investigations have provided new understanding of how autophagy of mitochondria (also known as mitophagy) is controlled, and the impact of autophagic dysfunction on cellular oxidative stress. Impaired mitochondrial function, oxidative stress, accumulation of protein aggregates, and autophagic stress are common in many diseases.[24] Additionally, investigators are trying to identify the polypeptides (i.e., proteomes) directly involved in diseases associated with mitochondrial dysfunction.

Chemical Injury

Mechanisms

Chemical injury begins with a biochemical interaction between a toxic substance and the cell's plasma membrane, which is

ultimately damaged, leading to increased permeability. Not all the mechanisms causing chemically induced membrane destruction are known; however, the two general mechanisms include (1) direct toxicity by combining with a molecular component of the cell membrane or organelles and (2) reactive free radicals and lipid peroxidation.

Because it has been investigated extensively, carbon tetrachloride (CCl_4) injury is a useful example of chemical injury. Carbon tetrachloride, an agent formerly used in dry cleaning, harms cells because an enzyme system (P-450) in the smooth endoplasmic reticulum of liver cells converts it into chloromethyl ($CC1_3^{\bullet}$), a highly toxic free radical.

In CCl_4 injury, newly formed $CC1_3^{\bullet}$ rapidly destroys the endoplasmic reticulum of the liver cell by way of lipid peroxidation breaking down the reticulum's lipid component. The lipid molecules accumulate within the cytoplasm, starting within cisternae of the endoplasmic reticulum (Figure 2-13). Fatty liver develops because CCl_4 poisoning blocks the synthesis of **lipid-acceptor proteins (apoproteins)** that normally bind with triglycerides to form lipoproteins, which are transported out of the cell. Blockage of triglyceride (lipoprotein) secretion begins 10 to 15 minutes after CCl_4 exposure. Fat droplets that accumulate in cisternae of the endoplasmic reticulum combine to form larger droplets and fill vacuoles, which in turn fill the entire cytoplasm. Approximately 10 to 12 hours later the liver appears grossly enlarged and pale because of the accumulation of fat. (Accumulation of fat is discussed further on p. 84.)

During this process cellular swelling progresses because of alterations in the selective permeability of the plasma membrane. Cellular swelling becomes severe when the plasma membrane loses its ability to prevent the passive inward diffusion of sodium ions, water, and calcium. The most serious consequence of plasma membrane damage is, as in hypoxic injury, to the mitochondria. An influx of calcium ions from the extracellular compartment activates multiple enzyme systems resulting in cytoskeleton disruption, membrane damage, activation of inflammation, and eventually DNA degradation. Calcium ion accumulation in the mitochondria causes the mitochondria to swell, an occurrence that is associated with irreversible cellular injury. The injured mitochondria can no longer generate ATP, but they do continue to accumulate calcium ions. The influx of calcium into the mitochondria interferes with oxidative metabolism (by uncoupling oxidative phosphorylation).

Decreasing cellular pH (caused by the loss of oxidative phosphorylation and ATP-stimulating glycolysis), together with fluid and electrolyte imbalances (increased levels of sodium, calcium, and water and decreased concentration of potassium), leads to lysosomal membrane injury, causing a leakage of lysosomal enzymes into the cytoplasm. Enzymatic digestion of cellular organelles, including the nucleus and nucleolus, ensues, halting synthesis of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). The leakage of lysosomal enzymes apparently occurs late in chemical injury, well after irreversible lipid accumulation, mitochondrial swelling, and ATP loss.

Chemical Agents Including Drugs

Numerous chemical agents cause cellular injury. Minute amounts of some, such as arsenic and cyanide, can rapidly destroy enough cells to cause death of the individual. Long-term exposure to air pollutants, insecticides, and herbicides can cause cellular injury (Figure 2-14). Carbon monoxide, carbon tetrachloride, and social drugs, such as alcohol, can significantly alter cellular function and injure cellular structures. Over-the-counter and prescribed drugs also may cause cellular injury, sometimes leading to death. The leading cause of child poisoning is medications (see What's New? The Percentage of Child Medication–Related Poisoning Deaths Is Increasing). Acetaminophen (known as paracetamol outside the United States), commonly used as an analgesic, is one of the most common causes of poisoning

WHAT'S NEW?

The Percentage of Child Medication–Related Poisoning Deaths Is Increasing

Today, the leading cause of child poisoning is medications. Each year, more than 500,000 children, ages 5 and younger, experience a potential poisoning related to medications. More than 60,000 children are treated in emergency departments because of accidental medication exposure or overdose. One of every 150 2-year-olds is being sent to the emergency department for an unintentional medication overdose. Among children younger than age 5, 95% of emergency room visits are caused by unsupervised accidental ingestions and about 5% from dosing errors made by clinicians.

Importantly, investigators analyzed records from the American Association of Poison Control Centers' National Poison Data System (NPDS), an electronic database of all calls to the 61 poison control centers across the United States. Their analysis included all calls for children age 5 years or younger who were seen in a hospital emergency department between 2001 and 2008 for either unintentional self-exposure to a single drug (prescription or over-the-counter [OTC]) or unintentional therapeutic error for a single drug (prescription or OTC). The number of such calls during this 8-year period totaled 453,559. Medication-related poisoning deaths among children 5 years and younger now most frequently involve exposures to opioid analgesics and cardiovascular medications. About half of all poisoning-related deaths involve analgesics, antihistamines, and sedatives.

Development of new medications also has led to more of them being available in American homes. With aging, more adults are taking OTC and prescription medications as well as multiple medications. Oxycodone, morphine, and methadone prescriptions have increased between 159% and 559%, depending on the drug; the number of prescribed cardiovascular drugs (e.g., metoprolol) has increased about fivefold. Additionally, more medications, such as those utilized for attention-deficit disorder and diabetes, are being prescribed to younger adults and children.

How can we increase the safety of children exposed to so many medications? Safe storage is the *most* important solution and safe dosing from clinicians will reduce dosing errors. Additionally, improvements are continuing through improved packaging and labeling of medications as well as education of parents and consumers on dosing information.

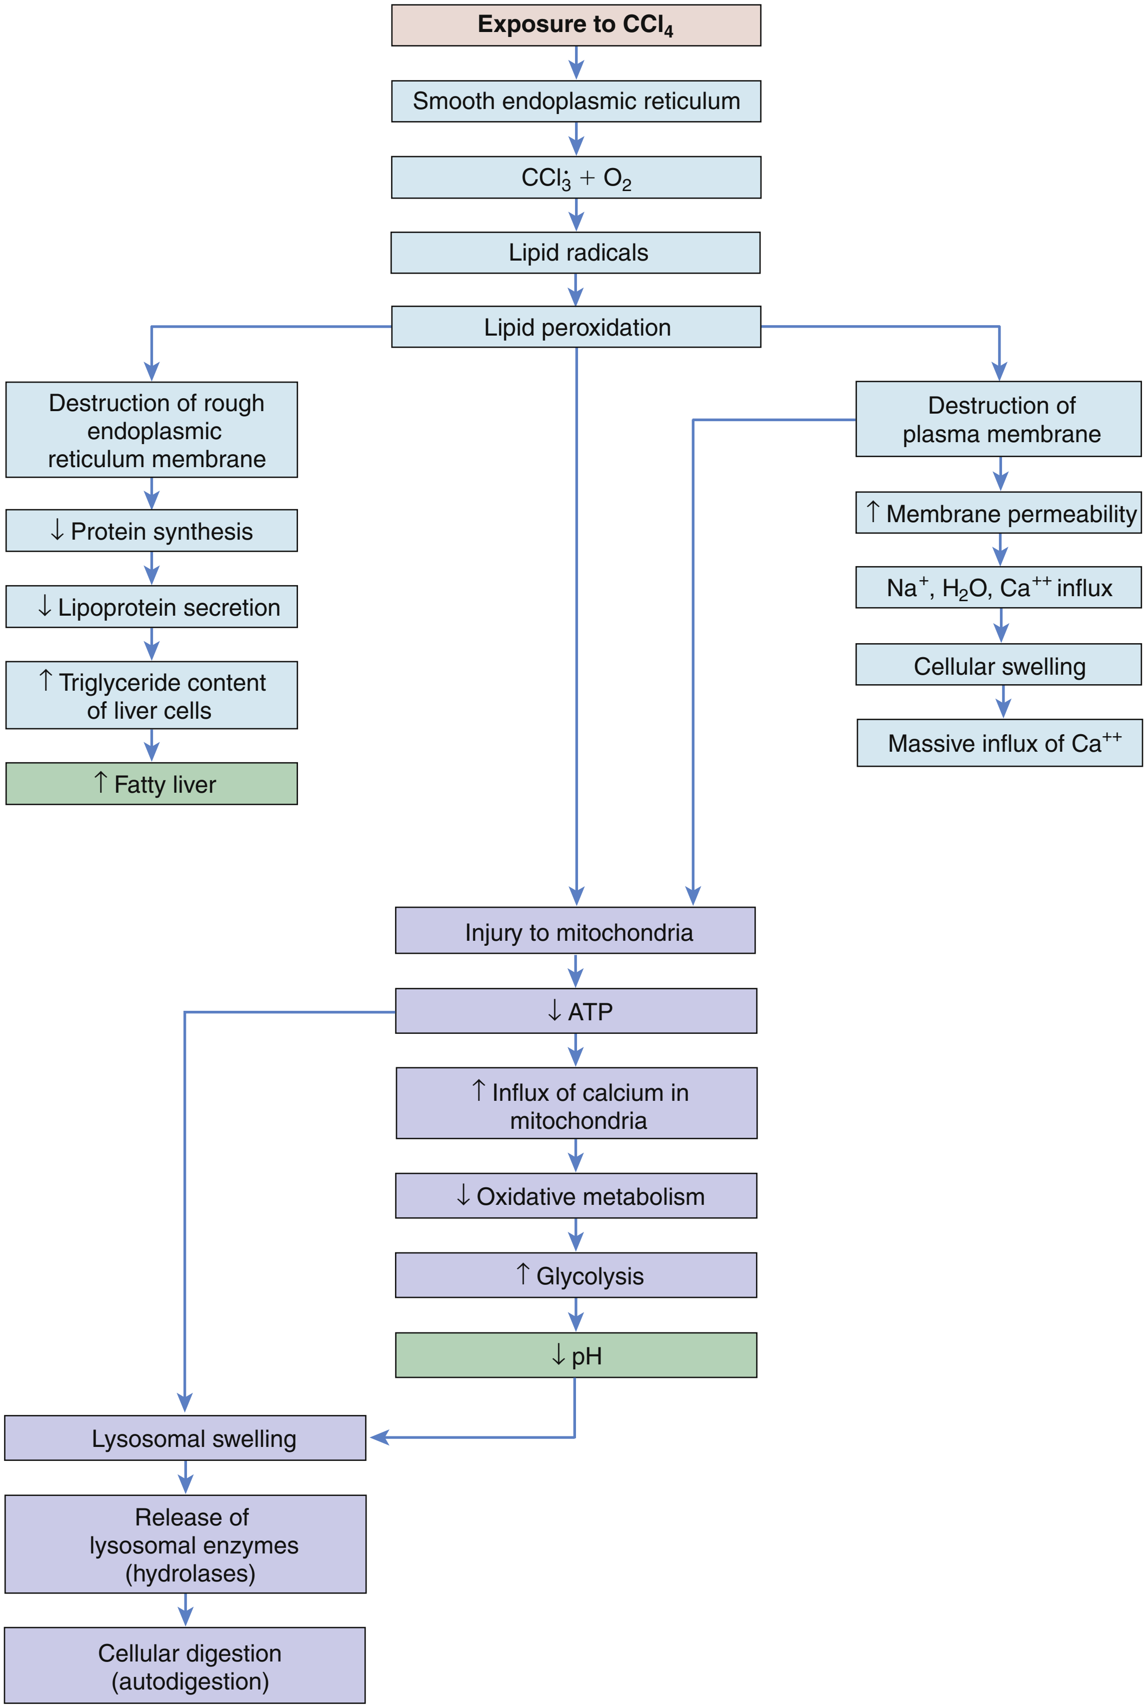

FIGURE 2-13 Chemical Injury of Liver Cells Induced by Carbon Tetrachloride (CCl_4) Poisoning. *Light blue boxes* are mechanisms unique to chemical injury; *purple boxes* involve hypoxic injury. *Green boxes* are clinical manifestations.

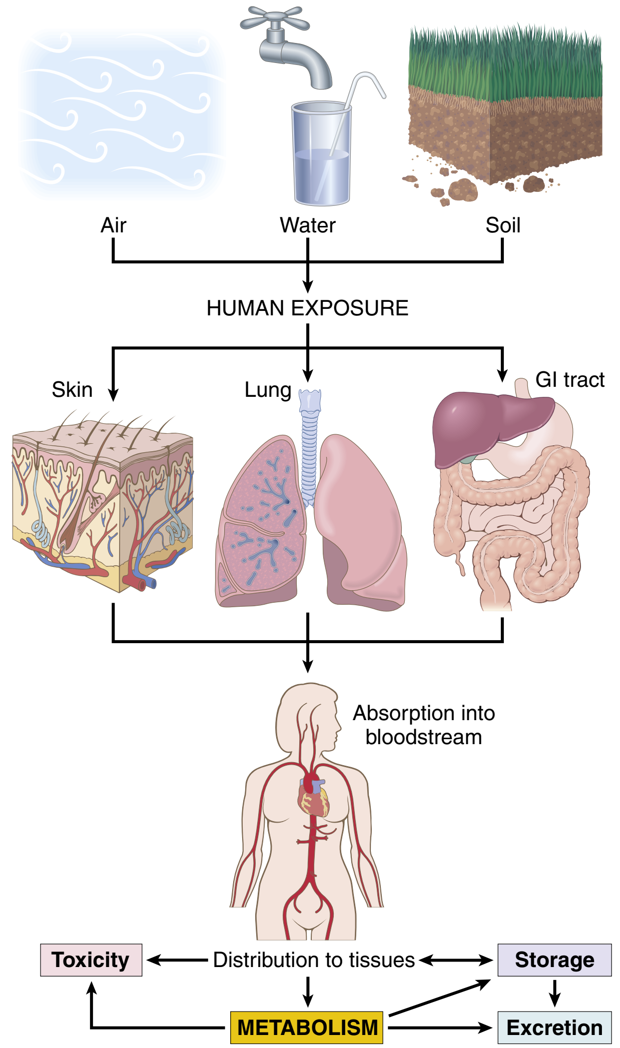

FIGURE 2-14 **Human Exposure to Pollutants.** Pollutants contained in air, water, and soil are absorbed through the lungs, gastrointestinal tract, and skin. In the body they may act at the site of absorption but are generally transported through the bloodstream to various organs where they can be stored or metabolized. Metabolism of xenobiotics may result in the formation of water-soluble compounds that are excreted, or a toxic metabolite may be created by activation of the agent. (From Kumar V et al, editors: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Saunders.)

worldwide. Drug-induced acute liver failure accounts for about 20% of liver failure in children and a higher percentage in adults[25] (see What's New? in Chapter 41). Accidental or suicidal poisonings by chemical agents cause numerous deaths. The injurious effects of some of these agents—lead, carbon monoxide, ethyl alcohol, and mercury—exemplify common cellular injuries.

Lead. **Lead** is a heavy toxic metal ubiquitous in older homes, the environment, and the workplace. In the United States, despite efforts to reduce exposure by passing government regulations, discontinuing the production of leaded gasoline, and banning the use of lead paint, excessive lead exposure still persists in homes, the environment, and the workplace for many people and lead toxicity is still a primary hazard to children (see What's New? Low Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention). Lead exposure also remains an important safety and health concern worldwide. On a scale unprecedented in decades, for example, lead-contaminated gold ore in Nigeria caused significant childhood poisoning and deaths.[26] Worrisome is lead exposure to the fetus during pregnancy because the developing nervous system is especially vulnerable. Compared to adults, developing fetuses and young children absorb lead more easily;[27] however, the exact transport mechanisms have not yet been elucidated. Exposure to lead during neurologic development has significant effects on neurobehavioral and intellectual performance, resulting in learning disorders, hyperactivity, and attention problems.[27]

The most common source of childhood lead exposure is old paint containing lead. Homes built before 1978 are likely to contain lead paint.[28] Lead-based paint has a sweet taste and is often ingested by children when they have access to surfaces painted with it. Children also may play in lead-contaminated soil. Other sources of lead in daily life include toys, jewelry, imported candies, foods, supplements, cosmetics (tiro, surma, kajal in Asia and kohl in the Middle East),[29] dust and soil found in inner-city urban and possibly rural areas, debris from household renovations, baby formula mixed with lead-contaminated tap water, newsprint, water that flows through lead pipes, hair dyes, food stored in soldered tin cans or eaten off of pottery made with lead-based glazes, and contamination from leaded gasoline. If nutrition is compromised, especially if dietary intake of iron, calcium, zinc, and vitamin D is insufficient, lead's toxic effects are enhanced.

Occupational exposure is a common cause of lead poisoning in adults. Approximately 95% of all elevated blood lead levels (BLLs) reported among adults in the United States are work related.[30,31] Industries with the highest number of lead-exposed workers are battery manufacturing, secondary smelting and

WHAT'S NEW?

Low Level Lead Exposure Harms Children: A Renewed Call for Primary Prevention

An advisory committee of the CDC recently suggested that the current threshold for harmful lead exposure in children should be cut in half because even lower levels cause irreversible harm. The report noted that studies have found reduced intelligence quotients (IQs) and behavioral problems in children with exposure levels less than 10 mcg/dl and that such low levels have effects on cardiovascular, endocrine, and immunologic systems. Based on these data, the panel recommended reducing the threshold for harmful levels of lead in the blood to 5 mcg/dl. Despite progress in reducing blood lead levels (BLLs), racial and income disparities persist. An internal review process from both the Centers for Disease Control and Prevention and the U.S. Department of Health and Human Services will determine how to implement any accepted recommendations. This is a very important process because BLLs appear to be irreversible, underscoring the need for primary prevention.

Data from Advisory Committee on Childhood Lead Poisoning Prevention of the Centers for Disease Control and Prevention: *Low level lead exposure harms children: a renewed call for primary prevention,* 2012. Available at www.cdc.gov/nceh/lead/ACCLPP/Final_Document_030712.pdf. Accessed September 24, 2012.

refining of nonferrous metals, and painting and paper hanging. The most common nonoccupational exposures of lead are shooting firearms, remodeling buildings, renovating, painting, possessing retained bullets in the body (gunshot wounds, especially retained bullet in joints), and lead casting.[31]

The organ systems affected by lead include the nervous, hematopoietic (tissues that produce blood cells), reproductive, gastrointestinal, cardiovascular, and musculoskeletal systems as well as the kidneys.

PATHOPHYSIOLOGY. Exposure occurs through inhalation, ingestion, and uncommonly skin contact. Lead is taken in through direct contact with the mouth, nose, and eyes (i.e., mucous membranes); and through cuts in the skin. Tetraethyl lead, still used in aviation fuel, can pass through skin but inorganic lead, found in the most common sources of paint, food, and consumer products, is only minimally absorbable through skin.[32,33] Absorption of inorganic lead is primarily from ingestion and inhalation.[32] In adults, 95% of inhaled lead dust passes into the bloodstream and 35% to 40% is deposited in the lungs.[32] Usually about 15% of ingested lead is absorbed, but these rates are higher in children, pregnant women, and those with deficiencies in calcium, zinc, or iron.[34] The main tissues that store lead are the blood, soft tissues, and bone. The persistence of lead or half-life in these tissues is weeks for blood, months for soft tissue, and years for bone.[34] In adults, 94% of absorbed lead is deposited in the bones and teeth. Children store about 70% of absorbed lead in their bones and teeth; thus, other tissues in children are more greatly affected compared to adults.[35] The estimated half-life of lead in bone is 20 to 30 years, and lead can move from bone to the bloodstream years after the initial exposure.[33] Lead can be reintroduced continuously to the blood from bone remodeling.[35] Other tissues can store lead including the brain, spleen, kidneys, liver, and lungs, however, not at the levels found in blood, bone, and teeth.[36]

A primary cause of lead's toxicity is its ability to bind to sulfhydryl groups found on many enzymes.[37] Lead can mimic other metals (calcium, iron, zinc) in biologic processes because it acts as a cofactor in several enzymatic reactions.[36] Lead's role as a cofactor interferes with the enzyme's ability to catalyze reactions. A primary cause of pathology is lead's interference with a main enzyme called δ-aminolevulinic acid dehydratase, or ALAD, important in the synthesis of heme in hemoglobin.[33] Lead can interfere with another heme enzyme called ferrochelatase. Ferrochelatase catalyzes the reaction of protoporphyrin and Fe^+ to form heme. Interference with the formation of heme causes the production of zinc protoporphyrin and the development of anemia. A significant manifestation of lead toxicity is anemia caused by lysis of red blood cells (hemolysis). Lead interferes with the release of glutamate, a neurotransmitter involved in many functions, including learning, by blocking *N*-methyl-D-aspartate (NMDA) receptors.[38] Overall, lead interferes with mitochondrial oxidative phosphorylation, ATPases, and calcium-dependent messengers; increases intracellular oxidation; and results in cell death by apoptosis. Lead appears to have its greatest effects during the later stages of brain development, possibly by altering development of synaptic connections (i.e., trimming/pruning) and causing neuronal death (apoptosis).[27] Alterations in calcium concentration may play a crucial role in the interference with neurotransmitters, which may cause hyperactive behavior and proliferation of capillaries of the white matter and intercerebral arteries.[27,39]

CLINICAL MANIFESTATIONS. Lead affects all body systems and especially the nervous, cardiovascular, reproductive, and immune systems as well as the bones, kidneys, and teeth. Hearing loss, tooth decay, and cataracts have been linked to lead exposure.[40,41] High and low levels of lead can damage the kidneys causing nephropathy and proximal tubular dysfunction. Lead poisoning can interfere with excretion of urate and predispose to gout. Cardiovascular alterations include hypertension, coronary heart disease, heart rate disturbances, and death from stroke.[42] Reproductive changes from lead exposure include alterations in sperm physiology and anatomy. High blood levels of lead in pregnant women are associated with miscarriage, premature birth, low birth weight, and impaired childhood development. Lead can pass through the placenta and contaminate breast milk.[36] Lead affects both the central and peripheral nervous systems. In adults the effects of lead occur primarily in the peripheral nervous system, whereas in children the effects are mostly in the central nervous system.[43] Lead interferes with normal brain and nervous system development in children. In a child's developing brain, lead can cause interference with synapse development (specifically neurochemical development including neurotransmitters) and the organization of ion channels.[44] Overall, lead causes loss of neurons, alterations in neuronal transmission, and decreases in neuronal growth.[37] Lead also has been linked to learning disabilities in young children. Other manifestations of brain involvement include convulsions and delirium, irritability, and, with peripheral nerve involvement, wrist, finger, and sometimes foot paralysis. Renal lesions can cause tubular dysfunction resulting in glycosuria (glucose in the urine), aminoaciduria (amino acids in the urine), and hyperphosphaturia (excess phosphate in the urine). Gastrointestinal symptoms are less severe and include nausea, loss of appetite, weight loss, and abdominal cramping.

EVALUATION, PREVENTION, AND TREATMENT. Diagnosis involves the medical history and clinical signs and determination of routes of exposure. The main method of evaluation is laboratory analysis of the blood lead level (BLL). The current acceptable BLL in healthy persons with excessive exposure to environmental sources of lead is less than 10 micrograms/deciliter (mcg/dl) for children and less than 25 mcg/dl for adults. In 2012 there was a recommendation to reduce the value for children to 5 mcg/dl. Because 95% to 99% of lead in blood is sequestered in red blood cells, lead needs to be measured in whole blood, not serum.[45] Lead in bones may be measured noninvasively by K x-ray fluorescence (KXRF); however; this method is not widely available.

The most important strategy for lowering exposures to lead is prevention. Prevention methods include individual and family, preventive medicine, and public health. There is an urgent need to focus on preventive strategies, especially for fetal development and the developing child. The key for adults is prevention of exposures at the workplace and home. The main methods of treatment are removal of the source of exposure and, for those

with high blood levels, chelation therapy. Additionally, treatment may include correcting deficiencies of iron, calcium, and zinc; irrigating the bowel; removing strategic bullets or shrapnel; and administering medications for control of seizures.

Carbon Monoxide. Gaseous substances can be classified according to their ability to asphyxiate (interrupt respiration) or irritate. Toxic asphyxiants, such as carbon monoxide, hydrogen cyanide, and hydrogen sulfide, directly interfere with cellular respiration. Carbon monoxide is widely available.

Carbon monoxide (CO), a gas, is odorless, colorless, and undetectable unless it is mixed with a visible or odorous pollutant. It is produced by the incomplete combustion of such fuels as gasoline. In dense urban environments, CO produced by incomplete combustion from motor vehicles increases air pollution. CO is a leading cause of unintentional poisoning deaths in the United States with more than 50,000 emergency department visits per year (68,316 exposures reported between 2000 and 2009) and about 500 deaths per year.[46] Those who (1) breathe air polluted by gasoline engines or defective furnaces and appliances; (2) work in occupations such as coal mining, firefighting, welding,[47] or engine repair; and (3) smoke cigarettes, cigars, or pipes are at risk for CO exposure. At highest risk for CO poisoning are unborn babies, infants, and people with chronic heart disease, respiratory disease, and anemia. Fatalities are highest for those 65 years and older.

The pathophysiology of carbon monoxide poisoning is not completely understood. Although CO is a chemical agent, the ultimate injury it produces is a hypoxic injury, namely, oxygen deprivation. It directly reduces the oxygen-carrying capacity of blood and promotes tissue hypoxia because it shifts the oxyhemoglobin curve to the left (see Chapter 34). Normally, oxygen molecules are carried to tissues bound to hemoglobin in red blood cells (see Chapter 31). Because CO's affinity for hemoglobin is 200 times greater than that of oxygen, it quickly binds with the hemoglobin, preventing oxygen molecules from doing so. Minute amounts of CO can produce significant percentages of **carboxyhemoglobin** (carbon monoxide bound with hemoglobin, COHb). CO also is an anesthetic agent and causes loss of airway capacity in animal studies. Other mechanisms may include disruption of cellular oxidative processes, binding to myoglobin and hepatic cytochromes, and lipid peroxidation of brain lipids.[48]

Although COHb levels on hospital admission may not reflect the severity of the CO poisoning, minor doses may be asymptomatic and include headache, giddiness, tinnitus (ringing in the ears), nausea, weakness, and vomiting. Higher doses may appear as confusion, poor concentration, loss of short-term memory, seizures, and loss of consciousness. Poor outcomes are noted with individuals older than 35 years, exposure greater than 24 hours, acidosis, and loss of consciousness.[48]

Ethanol. Alcohol *(ethanol)* is the number one mood-altering drug used in the United States. It is estimated there are more than 10 million chronic alcoholics in the United States. Alcohol contributes to more than 100,000 deaths annually with 50% of these deaths from drunk driving accidents, alcohol-related homicides, and suicides.[49] A blood alcohol concentration of 80 mg/dl is the legal definition of drunk driving in the United States. This level of alcohol in an average person may be reached after consumption of three drinks (three 12-ounce bottles of beer, 15 ounces of wine, and 4 to 5 ounces of distilled liquor). The effects of alcohol vary by age, gender, and percentage body fat; the rate of metabolism affects the blood alcohol level. Importantly, alcohol-related problems include family violence and workplace disabilities. Because alcohol is not only a psychoactive drug but also a food, it is considered part of the basic food supply in many societies.

A large intake of alcohol has enormous effects on nutritional status. Major nutritional deficiencies include magnesium, vitamin B_6, thiamine, and phosphorus. Chronic intake of alcohol and vitamin deficiencies may adversely affect the brain and peripheral nerves (e.g., Wernicke encephalopathy, peripheral neuropathy, Korsakoff pyschosis). Folic acid deficiency is a common problem in chronic alcoholic populations. Ethanol alters folic acid (folate) homeostasis by decreasing intestinal absorption of folate, increases liver retention of folate, and increases the loss of folate through urinary and fecal excretion.[25] Folic acid deficiency becomes especially serious in pregnant women who consume alcohol and may contribute to fetal alcohol syndrome (see p. 68).

Most of the alcohol in blood is metabolized to *acetaldehyde* in the liver by three enzyme systems: alcohol dehydrogenase (ADH), the microsomal ethanol-oxidizing system (MEOS; CYP2E1), and catalase (Figure 2-15).

The major pathway involves ADH, an enzyme located in the cytosol of hepatocytes. The microsomal ethanol-oxidizing system (MEOS) depends on cytochrome P-450 (CYP2E1), an enzyme needed for cellular oxidation. Activation of CYP2E1 requires a high ethanol concentration and thus is thought to be important in the accelerated ethanol metabolism (i.e., tolerance) noted in persons with chronic alcoholism. Acetaldehyde has many toxic tissue effects and is responsible for some of the acute effects of alcohol and for development of oral cancers.[50]

After ingestion, alcohol is absorbed, unaltered, into the stomach and small intestine from which it is transported to the liver. Fatty foods and milk slow absorption. Alcohol then is distributed to all tissues and fluids of the body in direct proportion to the blood concentration. Individuals differ in their capability to metabolize alcohol. Genetic differences in metabolism of liver alcohol, including aldehyde dehydrogenases, have been identified. People with chronic alcoholism develop certain levels of tolerance because of enzyme induction, leading to an increased rate of metabolism (e.g., P-450).

Studies conducted since 1997 have contributed to our understanding of the association between alcohol consumption and cardiovascular disease. Consistent results validate the so-called *J-shaped inverse association* between alcohol and cardiovascular disease mortality and morbidity. That is, moderate drinkers exhibit a decreased risk compared with both heavy drinkers and nondrinkers. Surprisingly, consistent epidemiologic studies show that daily light to moderate alcohol intake reduces the risk of coronary heart disease (CHD) as compared with those who do not drink alcoholic beverages at all. The suggested mechanisms for cardioprotection include increased levels of high-density lipoprotein–cholesterol (HDL-C), prevention of clot formation, reduced platelet aggregation, and increased clot degradation (fibrinolysis). Alcohol also may increase insulin sensitivity.[51] Limited data suggest that the level for optimal

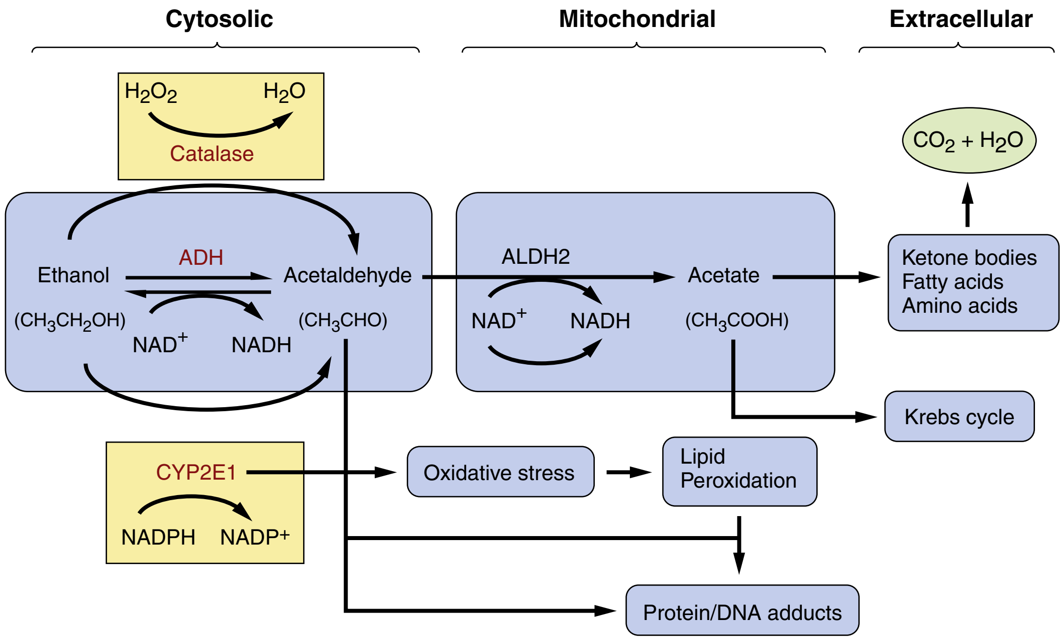

FIGURE 2-15 **Ethanol Metabolism Pathway.** Ethanol is metabolized into acetaldehyde through the cytosolic enzyme alcohol dehydrogenase (ADH), the microsomal enzyme cytochrome P-450 2E1 (CYP2E1), and the peroxisomal enzyme catalase. The ADH enzyme reaction is the main ethanol metabolic pathway involving an intermediate carrier of electrons, namely, nicotinamide adenine dinucleotide (NAD^+), which is reduced by two electrons to form NADH. Acetaldehyde is metabolized mainly by aldehyde dehydrogenase 2 (ALDH2) in the mitochondria to acetate and NADH before being cleared into the systemic circulation. (Adapted from Zhang Y, Ren J: *Pharmacol Ther* 132[1]:86–92, 2011.)

benefit may be slightly lower for women; therefore, the American Heart Association recommends no more than two drinks per day for men and one drink per day for women. Individuals who do not consume alcohol should not be encouraged to start regular drinking.

The major effects of *acute alcoholism* (drunkenness) involve the central nervous system (CNS). Alcohol intoxication causes CNS depression. Depending on the amount consumed, depression is associated with sedation, drowsiness, loss of motor coordination, delirium, altered behavior, loss of consciousness, and, with toxic amounts (300 to 400 mg/dl), lethal coma or respiratory arrest because of medullary center depression. Much investigation is under way to determine the extent of the relationship between alcohol level and snoring and obstructive sleep apnea (cessation of breathing).[52,53] Acute alcoholism may induce reversible hepatic and gastric changes.

Chronic alcoholism causes structural alterations in practically all organs and tissues in the body, especially the liver and stomach. The most significant alterations occur in the liver, a condition called alcohol-induced liver disease (ALD). ALD includes fatty liver, alcoholic hepatitis, and cirrhosis. ALD may eventually develop into hepatocellular carcinoma. Reactive oxygen and nitrogen species (ROS/RNS) and dysregulated redox signaling pathways are associated with alcohol consumption and provide insight into the molecular basis of hepatic cell dysfunction, destruction, and remodeled tissue or fibrosis.[54] Oxidative stress is associated with cell membrane phospholipid depletion, which alters the fluidity and function of cell membranes as well as intercellular transport. The initial liver histologic changes are characterized by accumulation of inflammatory cells and matrix deposition around the portal vein.[55] With ALD and hepatitis C virus (HCV), liver fibrosis is defined as the abnormal accumulation of extracellular matrix (ECM).[56,57] Inflammation plays a crucial role in ALD.[57]

Cirrhosis is associated with portal hypertension and an increased risk for hepatocellular carcinoma.[49] Acute gastritis is a direct toxic effect and chronic use can lead to acute and chronic pancreatitis. Oxidative stress is associated with cell membrane phospholipid depletion, which alters the fluidity and function of cell membranes as well as intercellular transport. Chronic alcoholism is related to several disorders, including injury to the myocardium (alcoholic cardiomyopathy), increased tendency to hypertension, and regressive changes in skeletal muscle (see Chapter 35). Ethanol is implicated in the onset of a variety of immune defects, including effects on the production of cytokines involved in inflammatory responses.

The activation of methionine, an essential amino acid, to *S*-adenosyl-l-methionine (SAMe) is decreased in those with alcoholism.[58] Oxidative stress is associated with phospholipid depletion. The replacement of polyenylphosphatidylcholine (PPC) has been studied in both baboons and para-null mice.[58]

Prenatal alcohol exposure causes **fetal alcohol syndrome (FAS).** Alcohol crosses the placenta, reaching the fetus rapidly.[59] Research has demonstrated an unimpeded bidirectional movement of alcohol between the fetus and the mother. The fetus may completely depend on maternal hepatic detoxification because the activity of alcohol dehydrogenase (ADH) in fetal liver is less than 10% of that of the adult liver. Additionally, the amniotic fluid acts as a reservoir for alcohol, prolonging fetal exposure.[59] The specific mechanisms of injury are unknown; however, acetaldehyde can alter fetal development by disrupting

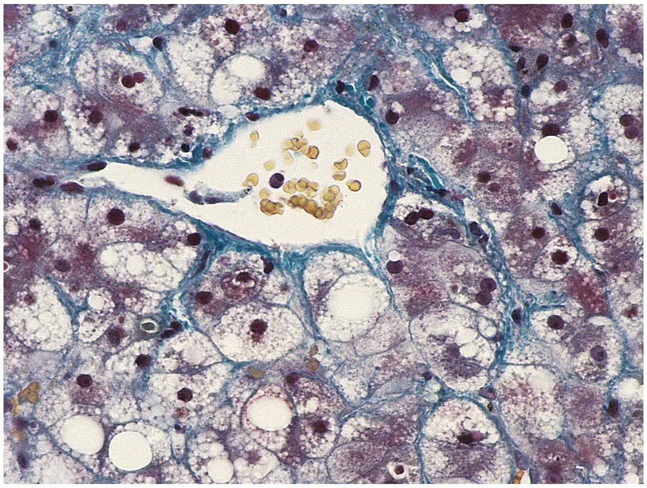

FIGURE 2-16 Alcoholic Hepatitis. Chicken-wire fibrosis extending between hepatocytes. (Mallory trichrome stain.) (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

differentiation and growth; DNA and protein synthesis; modification of carbohydrates, proteins, and fats; and the flow of nutrients across the placenta.[59,60] Additionally, alcohol may cause fetal disturbances, even preconceptual effects, epigenetically.[61]

FAS can lead to growth retardation, cognitive impairment, facial anomalies, and ocular disturbances.[62] In some cases, full-blown FAS may not be indicated but CNS defects may *still* be present and are classified as alcohol-related birth defects (ARBDs) and alcohol-related neurodevelopmental disorders (ARNDs).

Autopsies of children with FAS have revealed widespread severe damage, including failure of certain brain regions to develop, malformations of brain tissue, and failure of certain cells to migrate to their necessary location during development. Imaging studies reveal that in addition to an overall reduction in brain size, the corpus callosum is reduced in size or missing, the cerebellum is significantly reduced in size, and the basal ganglia and caudate nucleus are significantly reduced.

Additionally, ethanol has been shown to increase apoptotic cell death.[63] Whatever the cause, people with chronic alcoholism have a significantly shortened life span related mainly to damage to the liver, stomach, brain, and heart (Figure 2-16).

Mercury. Mercury has been used medically and commercially for centuries.[64] In the past it was a common component in medications. Mercury is still present in some thermometers and blood pressure cuffs and in batteries, switches, and fluorescent light bulbs. Large amounts of mercury exist as part of the electrodes formed in the electrolytic production of chlorine and sodium hydroxide from saline. Today people are exposed to mercury from two major sources: fish consumption and dental amalgams. Since 2001 no vaccine contains **thimerosal** (a preservative in multidose vials of vaccines containing ethyl mercury) except inactivated influenza vaccines. All of these uses give rise to possible accidental and occupational exposures.[64]

Dental Amalgams. Dental amalgams have been used for more than 150 years. They are believed to be more durable and easier to use than other types of fillings, as well as being relatively inexpensive. Amalgams consist of about 50% mercury amalgamated or combined with other metals, such as silver and copper. The controversies and heated debates concerning amalgams peaked in the 1970s with the discovery that amalgams can release mercury vapors into the mouth in concentrations that are higher than those deemed safe by occupational health guidelines.

Since then it was realized that the actual inhaled dose was small because of the small volume of the oral cavity.[64] Yet, brain, blood, and urinary mercury concentrations correlate with the number of amalgam surfaces present in a person. Removal of amalgam fillings also can cause temporary elevations in blood mercury concentration because the removal transiently increases the amount of mercury vapor inhaled.

Current health risk concerns arise from claims that long-term exposure to low concentrations of mercury vapor either causes or worsens degenerative diseases, such as amyotrophic lateral sclerosis, Alzheimer disease, multiple sclerosis, and Parkinson disease. Concern about the effect of mercury vapor in relation to Alzheimer disease was intensified for a time after a report that the brains of individuals with Alzheimer disease had elevated mercury concentrations. Several epidemiologic investigations, however, failed to provide evidence of a role of dental amalgams in these degenerative diseases; these include a long-term Swedish study, an ongoing Swedish study, and a study of 129 nuns 75 to 102 years of age. Recently, a randomized prospective trial of 507 children failed to show exposure to mercury from amalgams is linked to neurobehavioral or neurologic effects.[65] A difficult problem is that mercury can inhibit various biochemical processes in vitro without having the same effects in vivo. Thus, at present it is unknown whether removal of amalgams reduces risk of certain diseases, especially because removal itself affects blood concentrations of mercury vapor, which will rise before they eventually decline, thereby adding to the controversy.

Fish Consumption. The major source of exposure to methyl mercury is the consumption of fish and sea mammals. Clinical reports of mercury poisoning from fish consumption are those from Japan in the 1950s and 1960s. Environmental Protection Agency (EPA) guidelines are derived from reports of neuropsychologic changes noted in the Faeroe Islands study, in which subjects had been inadvertently exposed to methyl mercury mainly from whale consumption. A similar study in the United States shows methyl mercury levels to be slightly higher than the EPA guideline for safe consumption.[64] The health risk posed by exposure to mercury from fish consumption is being debated. The U.S. Food and Drug Administration (FDA) has, however, recommended that pregnant women, nursing mothers, and young children avoid eating fish with a high mercury content (>1 part per million [ppm]), such as shark, swordfish, tile fish, king mackerel, and whale meat.[64] Other advocates, however, have published more extensive lists including fish with the lowest levels, e.g., blue crab, croaker, fish sticks, flounder, haddock, trout, salmon (wild), and shrimp.[66]

Social or Street Drugs. The social or "recreational" use of psychoactive drugs is widespread in many parts of the world. Most popular and dangerous are the drugs methamphetamine ("meth"), marijuana, cocaine, and heroin. Although the prevalence of cocaine use in the general population decreased

TABLE 2-5 SOCIAL OR STREET DRUGS AND THEIR EFFECTS

TYPE OF DRUG	DESCRIPTION AND EFFECTS
Marijuana	Active substance: δ-9-tetrahydrocannabinol (THC), found in resin of the *Cannabis sativa* plant With smoking (e.g., "joints"), about 50% is absorbed through the lungs; when ingested, only 10% is absorbed; with heavy use the following adverse effects have been reported: alterations of sensory perceptions, cognitive and psychomotor impairment (e.g., inability to judge time, speed, distance); smoking 3 or 4/day is similar to smoking 20 cigarettes/day in regard to frequency of chronic bronchitis and may contribute to lung cancer; data, from animal studies only, indicate reproductive changes including reduced fertility, decreased sperm motility, and decreased circulatory testosterone level; fetal abnormalities including low birth weight and increased frequency of childhood leukemia; increased frequency of infectious illness is thought to be the result of depressed cell-mediated and humoral immunity
Methamphetamine (meth)	Amine derivation of amphetamine ($C_{10}H_{15}N$) used as crystalline hydrochloride CNS stimulant; in large doses causes irritability, aggressive (violent) behavior, anxiety, excitement, auditory hallucinations, and paranoia (delusions and psychosis); mood changes are common and the abuser can swiftly change from friendly to hostile; paranoiac swings can result in suspiciousness, hyperactive behavior, and dramatic mood swings Appeals to abusers because body's metabolism is increased and produces euphoria, alertness, and perception of increased energy Stages: Low intensity: user is not psychologically addicted and uses methamphetamine by swallowing or snorting Binge and high intensity: user has psychologic addiction and smokes or injects to achieve a faster, stronger high Tweaking: most dangerous stage; user is continually under the influence, not sleeping for 3 to 15 days, extremely irritated, and paranoid
Cocaine and crack	Extracted from the leaves of the coca plant and sold as a water-soluble powder (cocaine hydrochloride) liberally diluted with talcum powder or other white powders; extraction of pure alkaloid from cocaine hydrochloride is "free-base" called crack because it "cracks" when heated Crack is more potent than cocaine; cocaine is widely used as an anesthetic, usually in procedures involving the oral cavity; it is a potent CNS stimulant, blocking reuptake of the neurotransmitters norepinephrine, dopamine, and serotonin; also increases synthesis of norepinephrine and dopamine; dopamine induces a sense of euphoria, and norepinephrine causes adrenergic potentiation, including hypertension, tachycardia, and vasoconstriction; cocaine can therefore cause severe coronary artery narrowing and ischemia; not clear why cocaine increases thrombus formation; other cardiovascular effects include arrhythmias, sudden death, dilated cardiomyopathy, rupture of descending aorta (i.e., secondary to hypertension); effects on the fetus include premature labor, retarded fetal development, stillbirth, hyperirritability
Heroin	Opiate closely related to morphine, methadone, and codeine Highly addictive, and withdrawal causes intense fear ("I'll die without it"); sold "cut" with similar-looking white powder; dissolved in water it is often highly contaminated; feeling of tranquility and sedation lasts only a few hours and thus encourages repeated intravenous or subcutaneous injections; acts on the receptors enkephalins, endorphins, and dynorphins, which are widely distributed throughout the body with high affinity for the CNS; effects can include infectious complications, especially *Staphylococcus aureus,* granulomas of the lung, septic embolism, and pulmonary edema—in addition, viral infections from casual exchange of needles and HIV; sudden death is related to overdosage secondary to respiratory depression, decreased cardiac output, and severe pulmonary edema

Data from Cotran RS, Kumar V, Collins T: *Robbins pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders; Nahas G, Sutin K, Bennett WM: *N Engl J Med* 343(7):514, 2000.
CNS, Central nervous system; *HIV,* human immunodeficiency virus.

in 1986, morbidity and mortality related to cocaine increased sharply in the 1990s. Illicit use of drugs is a prevalent risk behavior among adolescents. Table 2-5 summarizes the effects of these drugs.

Unintentional and Intentional Injuries

Unintentional and intentional injuries are an important health problem in the United States. Death due to injury is significantly more common for men than women; the overall rate for men is 84.38/100,000 vs. 34.31/100,000 for women. Significant racial differences exist in the death rate, too: whites at 59.59/100,000, blacks at 65.15/100,000, and other racial groups at a combined rate of 35.12/100,000. A bimodal age distribution for injury-related deaths also has been noted, with peaks in the young adult and older adult groups. Unintentional injury is the leading cause of death for people between the ages of 1 and 34 years, with intentional injury (suicide, homicide) ranking between the second and fourth leading causes of death in this age group (see Table 2-6). Firearm injury in the United States has averaged 32,300 deaths annually between 1980 and 2007.[67] Firearm injury is the second leading cause of injury after motor vehicle crashes.[67] There are an average of five nonfatal firearm injuries for every two firearm deaths; in 2008 there were 78,622 nonfatal firearm injuries in the United States.[68] Of those injuries, 73% were the result of interpersonal violence.[67] Among the leading causes of death for ages 15 to 24, homicide ranks second and suicide ranks third with the number of firearm-related homicides and suicides outnumbering the next leading causes of death (i.e., cancer, heart disease, congenital disorders, cerebrovascular, influenza and pneumonia, and combined [complicated pregnancy, HIV, and septicemia]).[67] Unintentional injury ranks fifth in the United States for cause of death including falls, motor vehicle traffic deaths, and poisonings.[69] Deaths from all causes and deaths from injuries compares the United States with summary estimates of mortality for WHO member states for the year 2008 (Figure 2-17). The more common terms used to describe and classify unintentional and intentional injuries and brief descriptions of important features of these are discussed in Table 2-6.

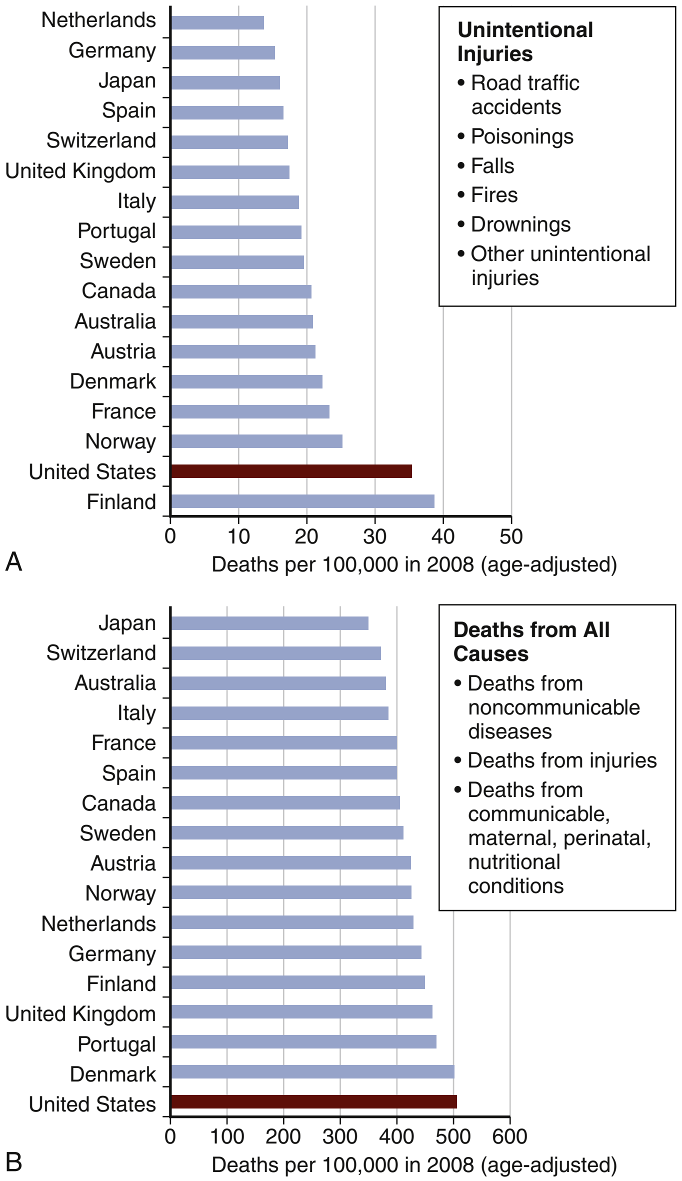

FIGURE 2-17 Global Health Data for Deaths from Unintentional Injury and from All Causes. Summary estimates of mortality for WHO member states for the year 2008. The age-adjusted death rates and the relative ranking of countries in relation to others vary from year to year. **A,** Unintentional injuries and **B,** death from all causes. (Data from World Health Statistics, 2011. World Health Organization, World Press, Geneva, Switzerland.)

Additionally, each year many unnecessary deaths occur in hospitals as a result of errors by healthcare professionals (see below). An accurate account is a tremendous challenge because of disagreements over reported statistics.[70] Statistics on nonfatal injuries are harder to document accurately, but they are known to be a significant cause of morbidity and disability and to cost society billions of dollars annually (see p. 70).

Injury from Errors in Health Care

Errors in health care (collectively called medical errors) are an unintended event, no matter how trivial or commonplace. They are errors that could or did harm individuals. A number of global and regional initiatives have been instituted to improve the safety of care, for example, the WHO 2008 Safe Surgery Saves Lives campaign extended the concept of a checklist,[71] and researchers from the United States found that it can reduce mortality and morbidity.[72] The use of the checklist strategy has exploded into many facets of patient care and now a call for it in nonsurgical, interventional specialties, for example, endoscopy, cardiac catherization and interventional radiology.[73] During the years 1999 to 2009, rates of death from complications of medical and surgical care declined among all age groups for persons ≧45 years. The *rate* of decline was lower among adults from 45 to 64 years compared with the rates of decline for all older age groups.[74]

Although progress is being made, medical errors are a concern as a cause of death and injury in the United States.[75] Studies have shown that in a single month an estimated 1.5% of Medicare beneficiaries experienced an event that contributed to their deaths, which projects to 15,000 individuals. An additional 13.5% of Medicare beneficiaries experienced events during their hospital stays that resulted in temporary harm.[76] According to the Institute of Medicine (IOM), many of the errors in health care result from a culture and system that is fragmented, and remedy of this major problem will require extensive foundation or infrastructure building. Errors involve medicines, surgery, diagnosis (i.e., wrong, overdiagnosis [is widespread in the United States, as well as overtreatment], underdiagnosis), equipment, and laboratory reports.[77] A 2006 follow-up to the IOM 1999 study found that medication errors are among the most common medical mistakes, harming at least 1.5 million people every year. According to this study, 400,000 preventable drug-related injuries occur each year in hospitals, 800,000 in long-term care settings, and approximately 530,000 among Medicare recipients in outpatient clinics.[78] Errors can occur anywhere in the healthcare system including hospitals, clinics, outpatient surgery centers, physician offices, nurse practitioner offices, pharmacies, and an individual's home. Errors in health care are associated with inexperienced physicians and nurses, new procedures, start of new clinician rotations, extremes of age, and complex care and urgent care. Additionally, financial incentives may be one reason.[79] Contributors to the problem are documentation errors, illegible handwriting, inadequate nurse-to-patient ratios, similarly named medications, and poor communication (language barriers). *The Joint Commission's Annual Report on Quality and Safety 2007* found that inadequate communication between healthcare providers, or between providers and the individual and family members, was the main cause of more than half of the serious adverse events in accredited hospitals.[80] Actions by patients also may contribute significantly to medical errors.[81]

More is known about errors in hospitals than in other healthcare delivery settings. Medication-related error has been studied for several reasons: (1) it is the most common type of error, (2) substantial numbers of people are affected, and (3) it accounts for a large increase in healthcare costs. Medication errors are methodologically easier to study because the drug-prescribing process provides documentation of medical decisions, administration of drugs is recorded, supplying drugs are documented, and deaths attributable to medication errors are recorded on death certificates.

TABLE 2-6 **UNINTENTIONAL AND INTENTIONAL INJURIES**

TYPE OF INJURY	DESCRIPTION
Blunt-Force Injuries	Mechanical injury to body resulting in tearing, shearing, or crushing; most common type of injury seen in healthcare settings; caused by blows or impacts; motor vehicle accidents and falls most common cause (see photo)
	*Contusion (bruise):* Bleeding into skin or underlying tissues; initial color will be red-purple, then blue-black, then yellow-brown or green; duration of bruise depends on extent, location, and degree of vascularization; bruising of soft tissue may be confined to deeper structures; *hematoma* is collection of blood in soft tissue; *subdural hematoma* is blood between inner surface of dura mater and surface of brain; can result from blows, falls, or sudden acceleration/deceleration of head as occurs in *shaken baby syndrome; epidural hematoma* is collection of blood between inner surface of skull and dura; is most often associated with a skull fracture
	Laceration: Tear or rip resulting when tensile strength of skin or tissue is exceeded; is ragged and irregular with abraded edges; an extreme example is *avulsion,* where a wide area of tissue is pulled away; lacerations of internal organs are common in blunt-force injuries; lacerations of liver, spleen, kidneys, and bowel occur from blows to abdomen; thoracic aorta may be lacerated in sudden deceleration accidents; severe blows or impacts to chest may rupture heart with lacerations of atria or ventricles
	Fracture: Blunt-force blows or impacts can cause bone to break or shatter (see Chapter 44)
Sharp-Force Injuries	Cutting and piercing injuries accounted for 2734 deaths in 2007; men have a higher rate (1.37/100,000) than women (0.44/100,000); differences by race are whites 0.71/100,000, blacks 2.12/100,000, and other groups 0.80/100,000
	*Incised wound:* Wound that is *longer* than it is *deep;* wound can be straight or jagged with sharp, distinct edges without abrasion; usually produces significant external bleeding with little internal hemorrhage; these wounds are noted in sharp-force injury suicides; in addition to a deep, lethal cut, there will be superficial incisions in same area called *hesitation marks* (see photo)
	Stab wound: Penetrating sharp-force injury that is *deeper* than it is *long;* if a sharp instrument is used, depths of wound are clean and distinct but can be abraded if object is inserted deeply and wider portion (e.g., hilt of a knife) impacts skin; depending on size and location of wound, external bleeding may be surprisingly small; after an initial spurt of blood, even if a major vessel or heart is struck, wound may be almost completely closed by tissue pressure, thus allowing only a trickle of visible blood despite copious internal bleeding
	Puncture wound: Instruments or objects with sharp points but without sharp edges produce puncture wounds; classic example is wound of foot after stepping on a nail; wounds are prone to infection, have abrasion of edges, and can be very deep
	Chopping wound: Heavy, edged instruments (axes, hatchets, propeller blades) produce wounds with a combination of sharp- and blunt-force characteristics

TABLE 2-6 UNINTENTIONAL AND INTENTIONAL INJURIES—cont'd

TYPE OF INJURY	DESCRIPTION
Gunshot Wounds	Accounted for more than 31,224 deaths in the United States in 2007; men more likely to die than women (18.16 vs. 2.73/100,000); black men between ages of 15 and 24 have greatest death rate (86.95/100,000); gunshot wounds are either penetrating (bullet remains in body) or perforating (bullet exits body); bullet also can fragment; most important factors or appearances are whether it is an entrance or exit wound and range of fire *Entrance wound:* All wounds share some common features; overall appearance is most affected by range of fire
	*Contact range entrance wound:* Distinctive type of wound when gun is held so muzzle rests on or presses into skin surface; there is searing of edges of wound from flame and soot or smoke on edges of wound in addition to hole; hard contact wounds of head cause severe tearing and disruption of tissue (because of thin layer of skin and muscle overlying bone); wound is gaping and jagged, known as *blow back;* can produce a patterned abrasion that mirrors weapon used (see photo)
	*Intermediate (distance) range entrance wound:* Surrounded by gunpowder tattooing or stippling; *tattooing* results from fragments of burning or unburned pieces of gunpowder exiting barrel and forcefully striking skin; *stippling* results when gunpowder abrades but does not penetrate skin (see photo) *Indeterminate range entrance wound:* Occurs when flame, soot, or gunpowder does not reach skin surface but bullet does; *indeterminate* is used rather than *distant* because appearance may be same regardless of distance; for example, if an individual is shot at close range through multiple layers of clothing the wound may look the same as if the shooting occurred at a distance *Exit wound:* Has the same appearance regardless of range of fire; most important factors are speed of projectile and degree of deformation; size cannot be used to determine if hole is an exit or entrance wound; usually has clean edges that can often be reapproximated to cover defect; skin is one of toughest structures for a bullet to penetrate; thus it is not uncommon for a bullet to pass entirely through body but stopped just beneath skin on "exit" side
	Wounding potential of bullets: Most damage done by a bullet is a result of amount of energy transferred to tissue impacted; speed of bullet has much greater effect than increased size; some bullets are designed to expand or fragment when striking an object, for example, *hollow-point* ammunition; lethality of a wound depends on what structures are damaged; wounds of brain may not be lethal; however, they are usually immediately incapacitating and lead to significant long-term disability; a person with a "lethal" injury (wound of heart or aorta) also may not be immediately incapacitated

The IOM report has galvanized a national movement to improve client safety and eliminate healthcare errors. "Errors and excess mortality can be eliminated but only if concern and attention is shifted away from individuals and toward the error-prone systems in which clinicians work."[82]

Asphyxial Injuries

Asphyxial injuries are caused by a failure of cells to receive or use oxygen. Deprivation of oxygen may be partial *(hypoxia)* or total *(anoxia)*. Asphyxial injuries can be grouped into four general categories: suffocation, strangulation, chemical asphyxiants, and drowning.

Suffocation. **Suffocation,** or oxygen failing to reach the blood, can result from a lack of oxygen in the environment (entrapment in an enclosed space or filling the environment with a suffocating gas) or blockage of the external airways. Classic examples of these types of asphyxial injuries are a child who is trapped in an abandoned refrigerator or a person who commits suicide by putting a plastic bag over the head. A reduction in the ambient oxygen level to 16% (normal is 21%) is immediately dangerous. If the level is below 5%, death can ensue within a matter of minutes. The diagnosis of these types of asphyxial injuries depends on the history of the injury, because there will be no specific physical findings.

Diagnosis and treatment in **choking asphyxiation** (obstruction of the internal airways) depend on locating and removing the obstructing material. Injury or disease also may cause swelling of the soft tissues of the airway, leading to partial or complete obstruction and subsequent asphyxiation. Suffocation also may result from compression of the chest or abdomen (mechanical or compressional asphyxia), preventing normal respiratory movements. Usual signs and symptoms include florid facial congestion and petechiae (pinpoint hemorrhages) of the eyes and face.

Strangulation. **Strangulation** is caused by compression and closure of the blood vessels and air passages resulting from external pressure on the neck. This causes cerebral hypoxia or anoxia secondary to the alteration or cessation of blood flow to and from the brain. It is important to remember that the amount of force needed to close the jugular veins (2 kg [4.5 lb]) or carotid arteries (5 kg [11 lb]) is significantly less than that required to crush the trachea (15 kg [33 lb]). It is the alteration of cerebral blood flow in most types of strangulation that causes injury or death—not the lack of airflow. With complete blockage of the carotid arteries, unconsciousness can occur within 10 to 15 seconds.

A noose is placed around the neck, and the weight of the body is used to cause constriction of the noose and compression of the neck in **hanging strangulations.** The body does not need to be completely suspended to produce severe injury or death. Depending on the type of ligature used, there usually is a distinct mark on the neck, an inverted V with the base of the V pointing toward the point of suspension. Internal injuries of the neck are actually quite rare in hangings, and only in judicial hangings, in which the body is weighted and dropped, is significant soft tissue or cervical spinal trauma seen. Petechiae of the eyes or face may be seen, but they are rare.

In **ligature strangulation,** the mark on the neck is horizontal, without the inverted V pattern seen in hangings. Petechiae may be more common because intermittent opening and closure of the blood vessels may occur as a result of the victim's struggles. Internal injuries of the neck are rare.

Variable amounts of external trauma on the neck with contusions and abrasions are noted in **manual strangulation** caused either by the assailant or by the victim clawing at one's own neck in an attempt to remove the assailant's hands. Internal damage can be quite severe, with bruising of deep structures and even fractures of the hyoid bone and tracheal and cricoid cartilages. Petechiae are common.

Chemical Asphyxiants. **Chemical asphyxiants** either prevent the delivery of oxygen to the tissues or block its use. Carbon monoxide is the most common chemical asphyxiant (see p. 67). **Cyanide** acts as an asphyxiant by combining with the ferric iron atom in cytochrome oxidase, thereby blocking the intracellular use of oxygen. A victim of cyanide poisoning has the same cherry-red appearance as a carbon monoxide intoxication victim because cyanide blocks the use of circulating oxyhemoglobin. An odor of bitter almonds also may be detected. (The ability to smell cyanide is a genetic trait that is absent in a significant portion of the general population.) **Hydrogen sulfide (sewer gas)** is a chemical asphyxiant in which victims of hydrogen cyanide poisoning may have brown-tinged blood in addition to the nonspecific signs of asphyxiation.

Drowning. **Drowning** is an alteration of oxygen delivery to tissues resulting from the breathing in of fluid, usually water. Each year there are thousands of drowning deaths in the United States. Although research done in the 1940s and 1950s indicated that changes in blood electrolyte levels and volume as a result of absorption of fluid from the lungs may be an important factor in some drownings, the major mechanism of injury is hypoxemia (low blood oxygen levels). Even in freshwater drownings, where large amounts of water can pass through the alveolar-capillary interface, there is no evidence that increases in blood volume cause significant electrolyte disturbances or hemolysis, or that the amount of fluid loading is beyond the compensatory capabilities of the kidneys and heart. Airway obstruction is the more important pathologic abnormality, underscored by the fact that in up to 15% of drownings, little or no water enters the lungs because of vagal nerve–mediated laryngospasms. This phenomenon is called *dry-lung drowning*.

No matter what mechanism is involved, cerebral hypoxia leads to unconsciousness in a matter of minutes. Whether this progresses to death depends on a number of factors, including the age and health of the individual. One of the most important factors is the temperature of the water. Irreversible injury develops much more rapidly in warm water than it does in cold water. Submersion times of up to 1 hour with subsequent survival have been reported in children retrieved from very cold water. Complete submersion is not necessary for a person to drown. An incapacitated or helpless individual (such as a person with epilepsy or alcoholism, or an infant) may drown in only a few inches of water.

It is important to remember that there are no specific or diagnostic findings to *prove* that a person recovered from the

water is actually a drowning victim. In cases in which water has entered the lung, there may be large amounts of foam coming from the nose and mouth, although this also can be seen in certain types of drug overdoses. A body recovered from water with signs of prolonged immersion could just as easily be a victim of some other type of injury who has been put in the water to obscure the actual cause of death. When working with a living victim recovered from water, it is essential to keep in mind that an underlying condition may have led to the person's becoming incapacitated and submersed—a condition that also may need to be treated or corrected while correcting hypoxemia and dealing with its sequelae.

Infectious Injury

The pathogenicity (virulence) of microorganisms lies in their ability to survive and proliferate in the human body, where they injure cells and tissues. The disease-producing potential of a microorganism depends on its ability to (1) invade and destroy cells, (2) produce toxins, and (3) produce damaging hypersensitivity reactions (see Chapter 9 for further discussion).

Immunologic and Inflammatory Injury

Cellular membranes are injured by direct contact with cellular and chemical components of the immune and inflammatory responses, such as phagocytic cells (lymphocytes, macrophages) and substances such as histamine, antibodies, lymphokines, complement, and proteases (see Chapter 7). Complement is responsible for many of the membrane alterations that occur during immunologic injury. Membrane alterations are associated with rapid leakage of potassium (K^+) out of the cell and rapid influx of water. Antibodies can interfere with membrane function by binding to and occupying receptor molecules on the plasma membrane. This type of injury is found in certain forms of diabetes mellitus and in myasthenia gravis. Antibodies also can block or destroy cellular junctions, interfering with intercellular communication (see Chapters 8 and 9).

Injurious Genetic/Epigenetic Factors

Genetic disorders may be the result of genetic factors that alter the cell's nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms. For example, enzymatic genetic defects can lead to abnormalities in membrane transport. Genetic disorders can cause structural alterations of the red blood cell (for example, sickle cell anemia). (Mechanisms causing genetic abnormalities are discussed in Unit II.) Certain human diseases, for example, cancer, can occur because of misregulation of gene expression linked to alterations of epigenetic patterning (see Chapters 6, 12, and 13).

Injurious Nutritional Imbalances

Essential nutrients—proteins, carbohydrates, lipids (fats), vitamins, and minerals—are required for cells to function normally. If these nutrients are not consumed in the diet and transported to the body's cells or if excessive amounts of nutrients are consumed and transported, pathophysiologic cellular effects develop.

Proteins, which consist of chains of amino acids, are the major structural units of the cell and participate in many enzymatic and hormonal functions. Protein deficiency causes a decrease in the intestinal mucosal mass, decreasing the absorptive function. The integrity of the pancreas is also affected, resulting in diminished exocrine secretion. With starvation or malnutrition, the lowered levels of plasma proteins, particularly albumin, cause fluid to move into the interstitium (edema). Protein-calorie malnutrition (PCM) is the predominant worldwide type of malnutrition. Malnourished children are very susceptible to disease and often die of infectious diseases. Even with adequate protein intake, cellular injury can occur if amino acid transport mechanisms fail or are defective. In Fanconi syndrome, for example, renal tubular cells may contain accumulated protein droplets that have been absorbed but cannot be transported.

Glucose is the major carbohydrate obtained from the breakdown of starch (see Chapter 1). **Hyperglycemia** (excessive glucose in the blood) caused by excessive carbohydrate intake may lead to obesity. Deficiencies of glucose result from starvation or from lack of use, as in diabetes. In both conditions the body compensates by metabolizing fat (lipids). (For details on diabetes, see Chapter 22.)

In lipid deficiency, or **hypolipidemia,** the body compensates by mobilizing fatty acids from adipose tissue. This causes an increase in the production and circulation of ketone bodies, which are acidic byproducts of lipid metabolism. The excretion of ketone bodies results in loss of water and electrolytes and causes dehydration and thirst. Severe increases in the concentration of ketone bodies cause ketoacidosis, coma, and death. **Hyperlipidemia,** or an increase in the levels of lipoproteins in the blood, results in deposits of fat in the heart, liver, and muscle.

Vitamins are not sources of energy but are necessary for maintaining normal cellular functions. Adequate vitamin intake is necessary because most vitamins are not synthesized by the body. Research from the 1990s resulted in the identification of 13 vitamins as being essential for humans. These include 8 B vitamins (thiamine, niacin, riboflavin, folate, vitamin B_6, vitamin B_{12}, biotin, and pantothenic acid), vitamin C or ascorbic acid, and the fat-soluble vitamins A, D, E, and K. (Minerals are discussed in Chapter 3.) Vitamins are involved in numerous reactions, including metabolism of visual pigments (vitamin A), calcium and phosphate metabolism (vitamin D), prothrombin synthesis (vitamin K), and antioxidation reactions (vitamins E and C). Pyridoxal (vitamin B_6) affects amino acid transfer reactions; flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and nicotinamide adenine dinucleotide (NAD) help transfer electrons in various reactions (see Chapter 1).

Injurious Physical Agents

Injurious physical agents include temperature extremes, atmospheric pressure changes, radiation, illumination, mechanical factors, noise, and prolonged vibration. Physical injury can result from excessive exposure to many environmental agents, as well as to agents used for the diagnosis and treatment of illness.

Temperature Extremes and Climate Change

Much research is occurring to elucidate linkages between climate change and epidemics. Climate change is affecting human health including: (1) an increase in heat- and pollution-related

deaths with cardiovascular, cerebrovascular, and respiratory diseases; (2) an increase in gastroenteritis and infectious disease epidemics because of water and food contamination as a result of flooding, lack of clean water, and sewage treatment; (3) an increase in vector-borne infectious diseases (for example, malaria, West Nile virus infection, hantavirus pulmonary syndrome); and (4) an increase in the number of people affected by malnutrition because of food crop disruptions.[49,83,84] Climate change is just one of several factors impacting the incidence of disease. Chilling or freezing of cells causes **hypothermic injury.** Hypothermia has proved to be strongly injurious to a variety of cells. *Accidental hypothermia* is an unintentional drop in core body temperature below 35° C (95° F). At these temperatures, the compensatory mechanisms that conserve temperature start to fail. **Primary accidental hypothermia** is the physiologic result of a previously healthy person to the changes that occur with cold. The mortality rate is higher in those who develop **secondary hypothermia** as a consequence of a serious systemic disorder, for example, endocrine disorders. Primary accidental hypothermia is a worldwide problem with most cases evident in the winter months. Surprisingly, however, it commonly occurs in warmer regions. The highest risks are to the elderly and neonates. The elderly have diminished thermal perception and regulation and are susceptible because of increased likelihood of immobility, impaired nutritional status, the presence of coexisting diseases, and the impact of economic factors. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and lack of shivering and other behavioral responses. Individuals at increased risks for hypothermia include those with occupations or hobbies that have extensive cold weather exposure, such as people in the military, hunters, sailors, skiers, swimmers, and climbers. Prolonged exposure to low ambient temperature is a common risk factor found in homeless persons. Some causes of secondary hypothermia include hypothyroidism, hypoglycemia, adrenal insufficiency, metabolic alterations associated with uremia, neurologic injury, extensive burns, acute myocardial infarction (can be reversed with resuscitation), skin diseases, and hepatic failure.[85]

Submersion in cold water can induce a high incidence of cardiac arrhythmias in healthy volunteers.[86] Immersion in cold water is a common cause of death in children and in adults.[87] Deaths caused by cold water have historically been ascribed to hypothermia; however, reports of two newer antagonistic responses are emerging—they are called the *cold shock response* and the *diving response* (see What's New? Cold Water Immersion and Cold Shock Response and the Diving Response).

Hypothermic injury has long been attributed to disturbances of cellular ion balance or homeostasis, especially of sodium balance (i.e., increased intracellular sodium levels). Hypothermia increases the level of intracellular Ca^{++} by slowing Na^+-K^+-ATPase pump activity, leading to Na^+ accumulation intracellularly.[88] In recent years, however, a role for ROS has gained importance.[89] In animal studies, hypothermia resulted in cell damage caused by formation of ROS.[90,91] Hypothermic perfusion of the heart increased superoxide

WHAT'S NEW?

Cold Water Immersion and Cold Shock Response and the Diving Response

Submersion and breath-holding in cold water can activate two antagonistic responses called the *cold-shock response* and the *diving response*. The cold-shock response triggers tachycardia from activation of the sympathetic nervous system. Sympathetic activation affects the sinoatrial (SA) and atrioventricular (AV) nodes of the heart and the myocardium. The release of breath-holding may be involved, with many arrhythmias occurring within 10 seconds of stopping breath-holding. Paradoxically, the diving response promotes a parasympathetically mediated brachycardia. The simultaneous activation of both the sympathetic and parasympathetic branches of the autonomic nervous system is sometimes called "autonomic conflict."

Certain individuals may have vulnerable risk factors including ischemic heart disease, myocardial hypertrophy, acquired (drug-induced) long QT syndrome (LQTS), QT interval mismatch to heart rate, atherosclerosis, and conduction pathologies (e.g., LQTS). There is a strong association between sudden cardiac arrest and swimming in children with LQTS. Certain drugs also may prolong QT interval (e.g., antihistamines, antibiotics, class Ia anti-arrhythmics, gastrointestinal prokinetics, and antipsychotics). The actual number of immersion-related deaths because of "autonomic conflict" is unknown and may be undiagnosed because of drowning.

Data from Patton JF et al: *Brain Res Brain Res Rev* 49:399–404, 2010; Tipton MJ et al: *Aviat Space Environ Med* 81:399–404, 2010; Shattock MJ, Tipton MJ: *J Physiol,* April 2012. [Epub ahead of print.]

(O_2^-) concentration (see Table 2-3); in turn, O_2^- reacted with nitric oxide (NO) to form another radical peroxynitrate anion ($ONOO^-$).[88] In some cell types, such as hepatocytes and liver endothelial cells, hypothermia can cause pronounced cell injury mediated by ROS. During the body's exposure to cold, injury is inhibited by hypoxia and by a number of antioxidants, especially iron chelators.

Indirect forms of injury occur because of changes in small blood vessels (the microcirculation). Slow chilling can cause vasoconstriction followed by paralysis of vasomotor control, resulting in vasodilation and increased membrane permeability causing cellular and tissue swelling. With an abrupt drop in temperature, vasoconstriction and increased viscosity of the blood cause ischemic injury—infarction and necrosis (cellular death) in affected tissues. With continued exposure to freezing temperatures, vasodilation produces severe swelling that causes degenerative changes in the myelin sheath that surrounds peripheral nerves, resulting in sensory and motor disturbances. Thrombosis also can occur and may lead to gangrene of the affected part. (Gangrene is discussed on p. 91.) These conditions often are called *frostbite*.

Therapeutically, hypothermia is widely used to protect cells and tissues against injurious processes. Therapeutic hypothermia (TH) has been used clinically to preserve the heart during surgery and to preserve organs before transplantation.[92] TH in animals to protect the heart against acute infarction has had positive results; however, studies in humans are limited.

Hyperthermia is an uncontrolled increase in body temperature that exceeds the body's ability to lose heat. **Hyperthermic**

injury (injury caused by excessive heat) is common and varies depending on the nature, intensity, and extent of the injury. Three types of hyperthermic injury include heat cramps, heat exhaustion (illness), and heat stroke. (For more detail see Chapter 16.)

Heat cramps (cramping of voluntary muscles) are usually a result of vigorous exercise that causes a loss of salt and water as a consequence of sweat. Treatment is salt replacement.

Heat exhaustion occurs when sufficient salt and water loss results in hemoconcentration. Hypotension occurs secondary to fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse. Collapsing results from a failure of the cardiovascular system to compensate for hypovolemia. Heat exhaustion is probably the most common heat-related injury.

Heat stroke is a life-threatening condition associated with high environmental temperatures and humidity. Core body temperature rises as a result of thermoregulatory failures. Clinically, a rectal temperature of 106° F (41° C) is considered a life-threatening sign. Generalized peripheral vasodilation and decreased circulating blood volume are significant. At risk are older adults, athletes, military recruits, and people with cardiovascular disorders.

Malignant hyperthermia occurs in individuals with an inherited disorder (e.g., ryanodine receptor intracellular calcium release channel) of skeletal muscle sarcoplasmic reticulum in response to inhalational anesthetics or to succinylcholine.[93] This rare condition is often fatal. The condition includes elevated temperature, increased muscle metabolism, muscle rigidity, rhabdomyolysis, acidosis, and cardiovascular alterations within minutes.

Drug-induced hyperthermia has become increasingly common because of the increase in abuse of psychotropic drugs and illicit drugs. Examples of drugs include amphetamines, cocaine, phencyclidine (PCP), methylenedioxymethamphetamine (MDMA; ecstasy), lysergic acid diethylamide (LSD), salicylates, lithium, anticholinergics, and sympathomimetics.

Neuroleptic malignant syndrome is hyperthermia caused by the administration of neuroleptic drugs (antipsychotics, phenothiazines, haloperidol, prochlorperazine, metoclopramide) or the withdrawal of dopaminergic drugs and is characterized by lead-pipe muscle rigidity, autonomic dysregulation, hyperthermia, and extrapyramidal side effects.[94]

Burns are caused by local heat injury. A *full-thickness burn* is an open wound involving skin layers—epidermis, dermis, and subcutaneous layers—and causing extensive loss of fluids and plasma proteins. Cellular regeneration is not possible; therefore, skin from a donor or from the host must be grafted to the site. *Partial-thickness burns* result in reddening of the area as a result of dilation of small blood vessels and increased permeability of cellular membranes, with loss of protein-rich fluid, resulting in the typical “burn blister.” In surface epithelial cells, membrane permeability increases, causing both cytoplasmic and nuclear swelling. Temperature-sensitive enzymes within certain cells respond to heat by increasing cellular metabolism, with detrimental effects. Intense heat also damages the vascular endothelium and causes coagulation of the blood vessels. (Burns are discussed further in Chapter 48.)

Epidemiologic investigators have reported a positive relationship between overheating in infants (that is, overdressing infants in the winter) and the prevalence of sudden infant deaths. Studies suggest interactions between body temperature and respiratory responses to hypoxia or increased carbon dioxide concentration (hypercapnia). The hypoxia/*hypo*thermia interaction depresses breathing, reducing the ventilatory response to hypercapnia. The effects of *hyper*thermia seem to be a significant problem only when it accompanies an infection and fever and alters or depresses the breathing responses. (Temperature changes are also discussed in Chapter 16.) Recent recommendations to reduce the risk of all sleep-related infant deaths include positioning the infant supine, using a firm sleep surface, breast-feeding, room-sharing without bed-sharing, performing routine immunizations, considering use of a pacifier, and avoiding soft bedding, overheating, and exposure to tobacco smoke, alcohol, and illicit drugs. *(Policy Statement—Sudden Infant Death Syndrome and Other Sleep-Related Infant Deaths: Expansion of Recommendations for a Safe Infant Sleeping Environment).*[95]

Changes in Atmospheric Pressure

Sudden increases or decreases in atmospheric pressure cause **blast injury,** which can be transmitted by either air (air blast) or water (immersion blast). With sudden increases in pressure, tissue injury is caused by compressive waves of air impingeing on the body, followed by a sudden wave of decreased pressure. The pressure changes may collapse the thorax, rupture internal solid organs, and cause widespread hemorrhage. In increased pressure caused by immersion blast, water pressure is applied suddenly to all sides of the body, forcing the body up out of water. The positive pressure compresses the abdomen and ruptures hollow internal organs, such as the spleen, kidneys, and liver.

Decompression Sickness. **Decompression sickness (DCS)** (diver disease, the bends, or caisson disease) is a condition arising with sudden decreases in pressure; carbon dioxide and nitrogen that are normally dissolved in the blood come out of solution and form tiny bubbles called *gas emboli.* Deep-sea divers and underwater construction workers who return to the surface too quickly develop decompression sickness. Oxygen is quickly redissolved, but nitrogen bubbles may persist and obstruct blood vessels. Ischemia resulting from gas emboli causes cellular hypoxia, particularly in the muscles, joints, and tendons. Emboli and interstitial gas accumulate around the joints and skeletal muscles, causing the individual to bend in pain. Tissues of the heart and brain also may be affected by emboli, causing necrosis. The gases can be promptly redissolved in blood by raising the atmospheric pressure. This is accomplished by placing the individual in a decompression chamber and increasing the pressure until it approximates pressure at the depth to which the diver had descended. This redissolves the gas bubbles in the blood. Pressure is then decreased gradually until it equals pressure at the surface of the water. This slows the release of gas bubbles out of solution.

Nitrogen concentrations can have a crippling anesthetic effect on the brain. This narcosis has been referred to as “rapture of the deep,” where both physical and cognitive abilities

may be seriously impaired.[96] Thus, when diving to great depths, both the volume of nitrogen and the volume of oxygen must be decreased. This is accomplished by the addition of an "inert" gas (one that has no metabolic activity within the body). It has been suggested that problems associated with deep, long-duration dives could be avoided by replacing the nitrogen in a diver's gas supply with helium, an inert gas and nature's second lightest gas.[97] Helium's great advantage is that it does not lead to nitrogen narcosis—it is less soluble in blood and fat than nitrogen.

Decompression sickness can happen with very rapid ascent to high altitude in an aircraft that is not properly pressurized.[98] Although decompression sickness is not a concern when people ascend slowly (e.g., on foot) to a low atmospheric pressure environment, such as altitudes above 10,000 feet, there is a significant decrease in available oxygen because of decreased partial pressure of the inspired gases. The hypoxemia that occurs may result in pathologic conditions unique to the hypoxic environment at high altitude.

High Altitude Illness: HAPE, HACE, AMS. High altitude illness, in the form of high altitude pulmonary edema (HAPE) or high altitude cerebral edema (HACE), is potentially fatal. Both conditions, in addition to a less serious, more common form, are known as acute mountain sickness (AMS). Several factors, including rate of ascent to altitude, final altitude reached, altitude at which a person sleeps, and individual physiologic differences, are believed to influence development of these conditions.[99] Additional risk factors include certain preexisting cardiopulmonary conditions, residence at low altitude, prior history of high altitude illness, and the level of exertion at altitude.[100]

Acute mountain sickness (AMS) is defined as the presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude, and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude, dizziness, and difficulty sleeping.[101] Symptoms are usually most noticeable during the first few days at altitude, but may reappear on further ascent to a higher altitude. AMS is usually a relatively benign, self-limited condition and does not include abnormal neurologic symptoms or signs. An increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, indicates transition to **high altitude cerebral edema (HACE).** HACE is a clinical diagnosis defined as the onset of ataxia, altered consciousness (including confusion, impaired mentation, stupor, and coma), and severe lassitude. Severe headache, nausea, and vomiting are frequently present. In both AMS and HACE, headache is most likely initially produced by hypoxemia-induced cerebral vasodilation and a significant increase in blood flow. In addition, recent magnetic resonance imaging (MRI) studies suggest that in persons ascending to high altitudes and suffering moderate to severe AMS, some degree of cerebral edema occurs. However, in milder forms of AMS (a subjective distinction), brain edema is present in some MRI studies, but not in all.[101] The cerebral edema may be either cytotoxic or vasogenic in nature (see Chapter 17).

As potentially lethal as HACE can be, HAPE is actually thought to account for most deaths from high altitude illness.[101]

High altitude pulmonary edema (HAPE) is a noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure. The incidence of HAPE also is related to rate of ascent, the ultimate altitude reached, and individual susceptibility. Victims of HAPE have a relatively exaggerated pulmonary hypertensive response on ascent to altitude as a result of augmented hypoxic pulmonary vasoconstriction. Heightened sympathetic nervous system activity, vascular endothelial dysfunction, and hypoxemia resulting from a suboptimal ventilatory response to hypoxia are responsible for the pulmonary vasoconstriction and subsequent pulmonary hypertension. Recent evidence suggests HAPE-prone individuals are characterized by a genetic defect in the transepithelial sodium and water transport mechanism that may impair alveolar fluid clearance.[102] Persons with congenital or acquired pulmonary circulation abnormalities are more susceptible to HAPE, supporting the suggestion that edema results from overperfusion in a restricted pulmonary vascular bed. Another proposed explanation for elevated pulmonary capillary pressure is uneven hypoxic pulmonary vasoconstriction.[103] It is now generally accepted that HAPE is initiated as a noninflammatory unidirectional dysfunction of the alveolar-capillary barrier that is essentially a form of hydrostatic pulmonary edema (i.e., there is an increase in pulmonary capillary pressure, but no elevation in left atrial pressure) (see Chapter 35).

Ionizing Radiation

Ionizing radiation (IR) is any form of radiation capable of removing orbital electrons from atoms, resulting in the production of negatively charged free electrons and positively charged ionized atoms. Ionizing radiation is emitted by x-rays, γ-rays, and alpha and beta particles (which are emitted from atomic nuclei in the process of radioactive decay) and from neutrons, deuterons, protons, and pions. Ionizing radiation of three types (x-radiation, gamma radiation, and neutrons) was classified as a carcinogen in 2004.

An important source of exposure to ionizing radiation is the environment. This source includes emission from radioactive material inside the body, cosmic rays from outer space, and radiation emitted from such substances as soil and building materials. Environmental radioactivity is emitted primarily by uranium, thorium, and potassium. Other sources are from medical procedures (e.g., x-rays, computed tomography [CT] scans) used for medical diagnosis and treatment, uranium and thorium mines, nuclear weapons, and nuclear reactors that generate electricity. Medical radiation now comprises about 48% to 50% of the per capita radiation doses compared with 15% in the 1980s; since 1980 medical radiation exposure has increased 600% in the U.S. population (Figure 2-18). Table 2-7 includes types of ionizing radiation and their magnitude of tissue penetration.

Cellular damage from IR in the absence of effective repair involves two types of damage: (1) deterministic and (2) stochastic. *Deterministic effects* are thought to occur above a threshold dose and have dose-related increasing risks. Deterministic effects include induced dermatitis, erythema, and generation of cataracts. Recent human and lab studies suggest a lower dose

	Early 1980s	2006
Collective effective dose (person-Sv)	835,000	1,870,000
Effective dose per individual in the U.S. population (mSv)	3.6	6.2

FIGURE 2-18 **Ionizing Radiation Exposure of the Population of the United States.** (National Council on Radiation Protection & Measurements: *Ionizing radiation exposure of the population of the United States, NCRP report 160,* Bethesda, MD: Author.)

TABLE 2-7 TYPES OF IONIZING RADIATION AND THEIR TISSUE PENETRATION

TYPE	TISSUE PENETRATION
X-rays	High
Gamma (γ) rays	High
Beta (β) particles	Low
Alpha (α) particles	Very low
Protons	Intermediate between α and β
Neutrons	High

Data from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.

(0.5 gray [Gy]) than previously reported (2 Gy for acute radiation, 4 Gy fractionated doses) or no threshold for cataracts.[104] *Stochastic effects* include cell generation or hereditary effects and cancer. Although not completely clear, the probability of a stochastic effect increases with dose probably with no threshold (an assumption based on molecular studies, because a very small x-ray dose can cause a base change in DNA), but importantly, the severity of the outcome is *not* related to dose but rather the entire tissue and stress response (see below).[105,106] Historically, radiation dose–related cancer risks at low doses were estimated from data of the atomic-bomb survivors and of individuals treated with moderate- to high-dose radiation.[106] The effects of low doses were mathematically extrapolated from high doses. After review from national and international expert committees and publications from 2005 to 2008, the available biologic and biophysical data support a linear no-threshold risk model for cancer.[106] Additionally, this understanding combined with an uncertain dose and dose rate effectiveness factor for extrapolation from high doses is considered a conservative estimate for radiation protection for low doses and low dose rates.[106] Complicating these standards, however, has been the emerging data from radiobiology suggesting a much more complex understanding regarding low dose and low dose rates because of nontargeted effects of low dose radiation (e.g., effects in nonirradiated cells near and distant from irradiated cells.[107] The **nontargeted effects** of ionizing radiation include bystander effects and genomic instability. **Bystander effects,** or effects on cells not directly in the radiated field, are affected by the radiation and show high levels of mutations, chromosomal aberrations, and membrane signaling changes leading to what some call "horizontal transmission." **Genomic instability** is where generations of cells derived from an irradiated progenitor cell appear normal but time-lethal (i.e., irreversible) and nonlethal mutations appear in distant progeny, sometimes called "vertical transmission."[108] Importantly, a new paradigm shift of the effects of IR or radiobiology is occurring. These effects represent a tissue response or cell stress response from IR. The current theory that all radiation damage results from energy deposition in those cells' DNA was challenged by four key lines of evidence reported from 1986 to 1996 and includes: (1) new lethal mutations could occur in cells that had recovered from irradiation and continued dividing for several generations,[109] (2) a delayed appearance of new chromosome aberrations was demonstrated in bone marrow stem cell lines from irradiated stem cells,[110] (3) a very low dose exposure of alpha radiation resulted in more cells with chromosome damage than would have been predicted mathematically,[111] and (4) the cell medium from irradiated cells was found to cause similar levels of clonogenic genomic instability and cell death as cells *directly* irradiated.[112] Thus, from newer evidence are

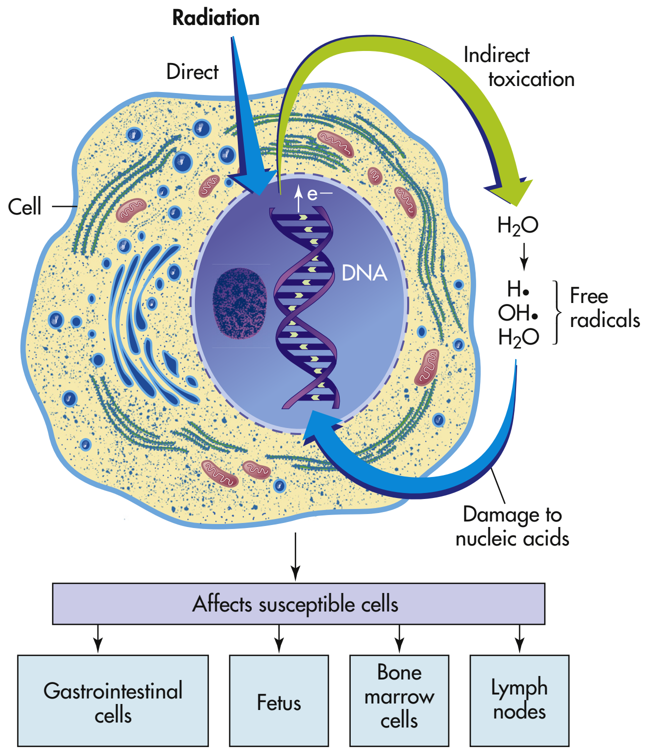

FIGURE 2-19 **Cellular Damage Caused by Ionizing Radiation.** Radiation can damage macromolecules in two ways: (1) directly, in which the micromolecules are ionized; and (2) indirectly, in which water is ionized and produces free radicals that in turn damage macromolecules. Cells that are particularly susceptible to damage are those of the gastrointestinal tract, bone marrow, lymph nodes, fetus, and ovarian follicles (also see Chapter 19).

radiobiologic understandings for low dose radiation, yet many biologic questions remain.[108] Importantly, many teams of investigators studying radiation effects have consisted of both physicists *and* biologists. Additionally, much research is now involved concerning the effects of radiation on epigenetics and the entire tissue and organismic "stress" response, including the role of the microenvironment.

Ionizing radiation (IR; x-radiation and γ-rays) causes a large spectrum of genetic changes including gene mutations, mini–satellite mutations (altered numbers of tandem repeats of DNA sequences), micronucleus formation (sign of chromosome damage or loss), chromosomal aberrations (structural or number), ploidy changes (number of sets of chromosomes), DNA strand breaks, and chromosomal instability. DNA may be damaged *directly* or *indirectly* by interaction with reactive products (i.e., free electrons, hydroxyl radicals, hydrogen free radicals) from the degradation of water (Figure 2-19). Because IR has many multicellular effects, their interactions with the cells and cellular products that comprise the microenvironment will affect tissue and determine the overall response.[113] Epigenetic mechanisms (a change in gene *expression* and not in the DNA sequence) that damage genes are involved in radiation-induced tumor formation. These mechanisms include genomic instability; mutations by irradiation of the cytoplasm (includes ROS, inflammatory cell signaling pathways, extracellular matrix alterations); "bystander effects" induction of genetic damage in innocent or cells not *directly* irradiated, possibly through cellular gap junctions; and persistent signaling pathways (see Chapter 13).

All phases of the cell cycle can be affected by ionizing radiation. Sensitivity of the cell appears to be greatest in G_2, that gap of the cell just before mitosis; irradiation during this phase retards the onset of cell division. Radio-resistance is greatest in the latter part of the S phase. At the time of therapeutic irradiation those cells in the most sensitive parts of the cell cycle will be killed. Those cells in the radio-resistant part of the cell cycle will continue to proliferate and repopulate the tumor—requiring more radiation for a therapeutic effect or cell killing. Irradiation during mitosis induces chromosomal aberrations. Membrane molecules and enzymes also are damaged by radiation (see Chapter 13).

Not all cells and tissues have the same sensitivity to radiation, although all cells can be affected. Radiosensitivity depends partly on the rate of mitosis and cellular maturity. Because fetal cells both are immature and are undergoing rapid cycling, the fetus is at great risk for injury caused by ionizing radiation. Particularly vulnerable are embryonic germ cells, which are precursors of ova and sperm. Throughout life, cells of the bone marrow, intestinal mucosa, testicular seminiferous epithelium, and ovarian follicles are susceptible to injury because they are always undergoing mitosis, which ensures the presence of vulnerable, immature daughter cells. Exposure to x-radiation and γ-radiation is most strongly correlated with leukemia and cancers of the thyroid, breast, and lung; these correlates have been reported at absorbed low levels, less than 0.2 gray Gy. The risk of developing these cancers may to some extent depend on age at exposure. The Life Span Study, which had a wide range in age at exposure and a wide dose range (from less than 0.005 Gy to 2-4 Gy), was evidence of a linear dose response for all solid tumors with significant radiation-associated excess risks observed in most, but not all, types of solid tumors. In utero radiation exposure from the bombings was associated with an increased adult-onset risk of solid tumors.[114] The studies of diagnostic x-rays in utero and risk of pediatric leukemia and other cancers are characterized by uncertainties, especially a lack of dose measurement data.[106] Ultrasound replaced abdominal x-rays and measurements of the pelvis several decades ago in pregnant women; however, there recently have been reports of increasing levels of radiologic imaging in pregnant women.[115] Many organizations have specific papers on safety and imaging pregnant women, including the American College of Radiology, American Congress of Obstetricians and Gynecologists, and internationally, for example, Health & Safety Executive from Great Britain and the International Commission on Radiological Protection Publication (ICRP). Radiation exposure to children may increase the incidence of lymphomas, leukemias, melanomas, breast cancers, and others. The increased frequency of pediatric CT exams in the United States is mainly because of the increased use of fast helical CT, which reduces the need for sedation.[116]

Radiation-induced cancers are found in the "cancer-prone" ages (usually 50 to 80 years of age), independent of age at exposure; therefore, the latency period between radiation exposure and the potential appearance of a cancer decreases significantly

with increasing age at exposure.[117] From these effects, more recent analyses of cancer incidence among atomic-bomb (A-bomb) survivors suggest that the lifetime risk of radiation-induced cancer is not so different for exposure at age 5 years vs. exposure at age 55 years.[114,118]

Studies of A-bomb survivors have found increased mortality from noncancer diseases.[119] The majority of radiation-induced noncancer deaths are cardiovascular problems (i.e., myocardial infarction and stroke). Individuals exposed to radiation at less than 40 years of age revealed an excess relative risk of myocardial infarction of 0.25. In addition, radiation exposure was significantly related to hypertension and elevated total cholesterol level. Risk estimates for heart disease and stroke indicated higher susceptibility in women.[120] Studies of the late effects of radiation in A-bomb survivors reveal elevated levels of mediators of inflammation (interleukin-6 [IL-6] and C-reactive protein [CRP]). Persistent elevations were documented of leukocyte counts, erythrocyte sedimentation rates, immunoglobulins, and sialic acid with radiation exposure. Also elevated were other inflammatory markers (tumor necrosis factor-alpha [TNF-α], IL-10, immunoglobulin [Ig], IgM, IgA, and interferon-gamma [IFN-γ]). The elevations of autoantibodies and T-cell–immune alterations is important because they may activate prolonged inflammation, which is a key contributor to cardiovascular effects.[120] The bone marrow and thymus gland are both radiosensitive, and documented immunologic effects measured from 40 to 50 years after radiation exposure suggest permanent genetic damage to lymphocyte progenitor cells.[120] A recent meta-analysis supports an association between circulatory disease mortality and low and moderate doses of ionizing radiation.[121] In Japanese atomic-bomb survivors, respiratory and digestive diseases also were increased.[119]

The effects of ionizing radiation may be acute or delayed. Acute effects of high doses, such as skin redness, skin damage, or chromosomal aberrations, occur within hours, days, or months. The delayed effects of low doses may not be evident for years.

Illumination and Luminance: Light Is Electromagnetic Radiation

Light is electromagnetic radiation visible in the adult human eye in the range of 380 to 780 nanometers (nm). All radiations like light carry energy, with the shorter wavelengths being the most energetic.[122] Luminance (radiance, measured in watts per square meter per steradian, W m^{-2} sr^{-1}), formerly called brightness, is measured in candela per square meter (cd/m^2) and illuminance (irradiance, W/m^2) is the light flux density on a receiving surface measured in lux. Consequently, the smaller the emitting surface the more concentrated the flux in the viewing direction and the higher the luminance.[122] The optical system images everything on the retina, a highly specialized sense organ, and most relevant for retinal illumination is the luminance of the viewed objects. The mechanisms of light-induced damage include (1) heat or thermal damage; (2) photochemical damage, thought to come mainly from oxidative stress by forming ROS, known as photosensitizers; and (3) thermoacoustic damage from light (e.g., laser) pulses shorter than ≈1 ns.[122-125] Thermal damage occurs from absorption of heat. The absorption rate (W/m^3) is the important factor for causing damage of the radiant energy (heat). The depth of penetration of the radiant energy depends on the incident wavelength and the primary absorbers—melanin and hemoglobin or oxyhemoglobin.[122] Photochemical damage occurs at short visible wavelengths and for exposure longer than ≈1 ns; it is thought to be the result of light absorption to the chromophore, the most sensitive molecule that absorbs the radiation (light leads to the production of ROS and oxidative stress; the retina is very sensitive to oxidative stress).[122] Thermoacoustic (photomechanical) damage occurs with light pulses shorter than ≈1 ns and when the light energy is deposited faster than mechanical relaxation can occur. Tissue is disrupted by shear forces or cavitation (i.e., production of a cavity). Photomechanical damage can be produced from sources such as intense pulsed lasers.[122]

Ocular exposures are accidental and intended (for example, in ophthalmic applications). Adherence to standards for ocular safety is a main concern for protection of the eye from laser exposures and light exposures from ophthalmic instruments. Additionally, to improve the energy performances of artificial light sources and to protect the environment, new light sources are available, such as compact fluorescent lamps or light-emitting diodes (LEDs). The potential risks of these new light sources need safety evaluation to determine health risks, especially hazards to the eye (see What's New? Health Risks Related to Use of LED Lighting Systems).

Focused light rays can increase oxidative stress, which can be prevented by a wide array of retinal antioxidant mechanisms.[126] Antioxidant mechanisms can, however, be overwhelmed by excessive light exposure, particularly of short-wavelength, high-frequency blue light, and of ultraviolet light. Since fluorescent lighting was introduced to the workplace, complaints of headaches, eyestrain, and eye discomfort have increased.[66] The

WHAT'S NEW?

Health Risks Related to Use of LED Lighting Systems

The number of light-emitting diodes (LEDs) is increasing in the marketplace because they produce light with low energy consumption. In the European Union, LEDs will become the major domestic sources of light by 2016. Therefore, safety standards, especially for exposures to children, need careful study. Rodent studies may not be the best models because rodents are mostly nocturnal and have rod-rich retina without macula. The French Agency for Food, Environmental and Occupational Health & Safety (ANSES) recommends that consumer information about health risks from LED lighting systems be made available immediately after conclusive testing. ANSES recommends (1) avoiding the use of light sources emitting cold-white light (light with a strong blue component) in places frequented by children or in the objects children use (e.g., toys, electronic devices, game consoles, joysticks, night lights); (2) ensuring high-quality controls from manufacturers of LEDs and qualifying their products according to different risk groups; and (3) using a clear labeling system for consumers with a mandatory label of the photobiologic safety information with risk groups listed on the packaging for all types of lighting. White LEDs expose the retina to violet, indigo, and blue light at higher levels than in previous light sources. This is the first time that the population will be exposed to substantial amounts of blue light.

Data from Behar-Cohen F et al: *Prog Retinal Eye Res* 30:239–257, 2011.

rapid modulation of light from fluorescent lamps is responsible for eyestrain and headaches. The modulation can be reduced by wearing tinted glasses. The shorter wavelengths in radiant energy in environmental lighting influence the absorption, scattering, and fluorescence, thus obscuring vision.[127]

Vision is obstructed at night by decreased illumination and by disabling glare from oncoming vehicle headlights. High-intensity discharge (HID) headlamps project light farther down roads, thus improving the driver's safety. However, oncoming glare, which is proportional to headlamp brightness, is *not* good for any drivers of oncoming vehicles and even worse for older drivers.[128] Older drivers experience more intraocular light scattering, increased glare sensitivity, and longer recovery time in reaction to photo stress.[129]

Mechanical Stresses

Mechanical stimulation of body tissues and cells is constant. These stresses and strains are from the external environment and internal physiologic conditions. For example, gravity as an external force and the pumping of the heart as an internal force are continual. Mechanical stimuli can cause cells to respond in a variety of ways, for example, **compression** is a perpendicular-acting force, **tension** is a stretching force, and **torsion** is a twisting force. Fluid **shear forces** or layers rubbing against each other, for example, endothelial cells can activate hormone release and intracellular signaling, as well as stiffen the cells by inducing rearrangement of the cytoskeleton. Mechanical compression of chondrocytes can modulate proteoglycan synthesis, and tensile stretching of cell structures can alter cell motility and orientation. Mechanical signals or signaling, called **mechanotransduction,** are eventually converted to biologic and chemical responses in the cell. Understanding molecular mechanisms driving cell shape changes is an important topic in cell and tissue structure. For example, achieving cell division successfully has led to the study of cytokinesis as a function of mechanical factors.[130]

Acutely mechanical forces elicit adaptive responses (to rapidly alter function) chronically; however, the responses may induce tissue remodeling to accommodate load-bearing capabilities.[131] When the mechanical forces exceed unknown thresholds, injury results.[131] Injury can initiate more reparative responses, transient or continuous dysfunction, or progressive degenerative changes that incorporate nearby and surrounding tissue. Cellularly, the structural responses to deformation and strain (e.g., biomechanical) are causing investigators to focus on the cell membrane. Disruption of cell membranes, or mechanoporation, is central to the biologic progression. Mechanical injury can progress to cell death involving both cell necrosis and delayed apoptosis.[131] The heterogeneous distribution of atherosclerosis in the vasculature is possibly related to biomechanical factors; that is, certain arteries (e.g., coronary and carotid arteries) are more susceptible to plaque formation than others.[132] Biomechanical forces probably are not systemic and vary with location. Mechanical stimuli include *shear forces* because of blood flow, **strain** from pressure distention of the vessel walls, and strain from **tethering** to a surrounding tissue area (e.g., the heart).[132]

The major focus of occupational biomechanics is the response of tissue to mechanical stress, especially the prevention of overexertion disorders of the lower back and upper extremities. Many mechanical stresses can cause overt injuries (e.g., a head injury when a worker is struck in the head with a dropped object). Most stresses, however, are subtle and can cause *accumulative* injuries and disorders. Table 2-8 summarizes common types of occupational mechanical stresses and associated types of injury. More realistic mechanical models of living cells will contribute greatly to the study of mechanotransduction in humans.

Noise

Noise is sound that has the potential for inflicting harm to the body. The most common pathophysiologic effect of noise is hearing impairment. Noise trauma can be caused by acute loud noise, as well as by the cumulative effects of various intensities, frequencies, and durations of noise. Common irritating noise is caused by numerous sources, including lawn care machinery; wood and metal working with electrical equipment; gun target practice; hunting; snowmobiles; outboard motors; chain saws; and high-decibel, low-frequency speakers. According to the National Institutes of Health, more than 10 million Americans suffer some permanent noise-associated hearing loss, and

TABLE 2-8 COMMON TYPES OF OCCUPATIONAL MECHANICAL STRESSES AND ASSOCIATED TYPES OF INJURY

MECHANICAL STRESSES	TYPE OF INJURY
Forceful exertions (e.g., lifting, pushing, pulling of heavy loads)	Low back pain
Awkward trunk postures (e.g., flexion, lateral bending, axial twisting, prolonged sitting)	Low back pain
Whole body vibration (e.g., vibrating seat or platform)	Low back pain; bone deformities; alterations in nerve conduction (carpal tunnel syndrome)
Repetitive or prolonged exposure (e.g., to any of the above)	Low back pain; numbness and tingling of wrists and hands
Extreme reaching Low temperatures (e.g., exposure to cold air, tools, materials) Vibration (segmental and whole) Forceful exertions (e.g., friction, balance, posture, pace, use of heavy objects) Ulnar deviation of the wrist	Trauma disorders of upper arms (synovitis, Raynaud phenomenon, bursitis, tendinitis)
Repetitive functions (e.g., walking, climbing stairs, carrying, shoveling, pushing, lifting objects, computer use)	Localized and/or whole body fatigue (shortness of breath, general weakness, hypoxic injury)

20 million are exposed to hazardous noise in work environments.[133] The largest increase in hearing loss from noise occurs in people 45 to 64 years old. Noise pollution is now considered a public health threat. Some evidence exists that noise in hospitals is associated with negative outcomes in patients, both psychologically and physiologically.[134]

Two types of hearing loss are associated with noise: (1) acoustic trauma, or instantaneous damage caused by a single sharply rising wave of sound (e.g., gunfire); and (2) noise-induced hearing loss, the more common type, which is the result of prolonged exposure to intense sound (e.g., noise associated with the workplace and leisure-time activities). Acoustic trauma can rupture the eardrum, displace the ossicles of the middle ear, and damage the organ of Corti in the inner ear.

If the offending noise has not been too loud or the exposure to it too long, hearing will return to its original level, a type of hearing loss called a *temporary threshold shift* (TTS). If the noise is louder than a certain value or the exposure time is long, the hearing threshold never returns to its original value, causing a *permanent threshold shift* (PTS). Structural changes associated with TTS, although not fully established, include intracellular changes in the sensory cells (hair cells) and swelling of the auditory nerve endings. With PTS, cochlear blood flow may be impaired and hair cells are damaged with each exposure. Noise-induced hearing loss is gradual and painless. Symptoms of noise-induced hearing loss include loudness recruitment and tinnitus. In loudness recruitment, soft sounds are not heard but loud sounds are heard normally. Tinnitus is a constant high-pitched ringing that annoys the individual and contributes to loss of sleep. The Occupational Safety and Health Administration (OSHA) requires industries to protect workers when the exposure is over an 8-hour period and averages 85 decibels.

MANIFESTATIONS OF CELLULAR INJURY

Cellular Manifestations: Accumulations

An important manifestation of cell injury is the resultant metabolic disturbances of intracellular accumulation of abnormal amounts of various substances. **Cellular accumulations,** also known as **infiltrations,** occur as a result of not only sublethal injury sustained by cells but also normal (but inefficient) cell function. Two categories of substances can cause accumulations: (1) *a normal cellular substance,* such as water, proteins, lipids, and carbohydrate excesses; or (2) an *abnormal substance,* either endogenous, such as a product of abnormal metabolism or synthesis, or exogenous, for example, infectious agents or a mineral. These products can accumulate transiently or permanently and can be toxic or harmless. Most accumulations are attributed to four types of mechanisms, all abnormal (Figure 2-20). Abnormal accumulations of these substances can occur in the cytoplasm (frequently in the lysosomes) or in the nucleus if (1) the normal, endogenous substance is produced in excess or at an increased rate; (2) an abnormal substance, often the result of a mutated gene, accumulates because of defects in protein folding, transport, or abnormal degradation; (3) an endogenous substance (normal or abnormal) is not effectively catabolized, usually because of lack of a vital lysosomal enzyme; or (4) harmful exogenous materials,

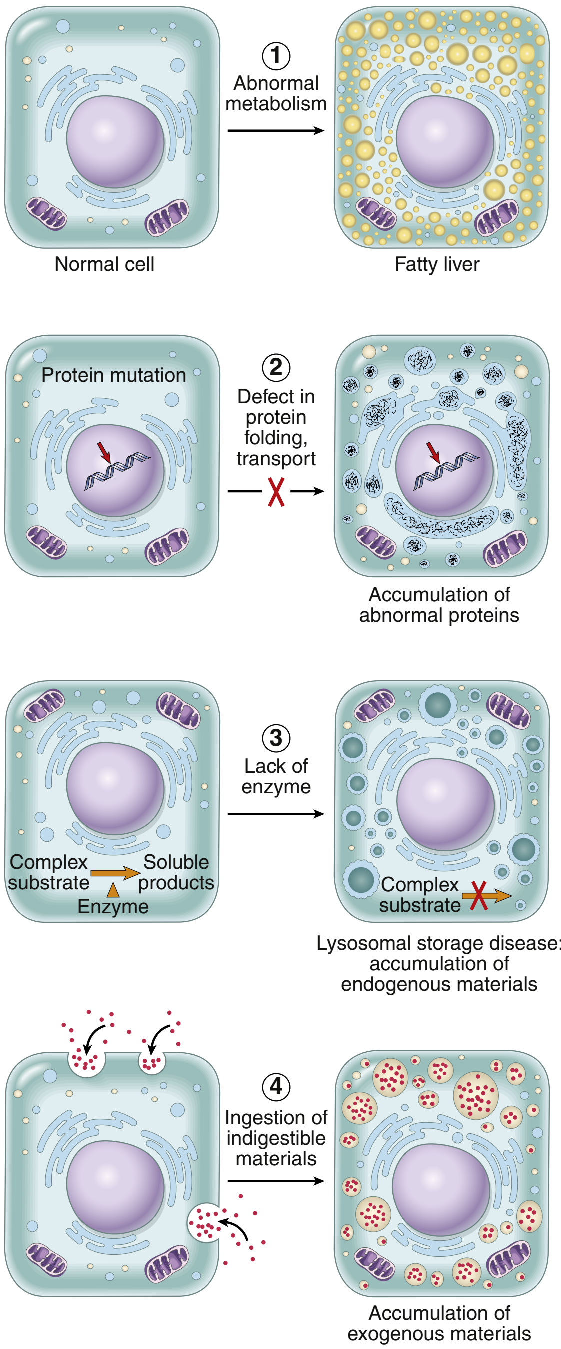

FIGURE 2-20 **Mechanisms of Intracellular Accumulations.** (From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V et al, editors: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Saunders.)

such as heavy metals, mineral dusts, or microorganisms, accumulate because of inhalation, ingestion, or infection.

In all storage diseases the cells attempt to digest, or catabolize, the "stored" substances. As a result, excessive amounts of metabolites (products of catabolism) accumulate in the cells and are expelled into the extracellular matrix, where they are taken up by phagocytic cells called *macrophages* (see Chapter 7). Some of these scavenger cells circulate throughout the body, whereas others remain fixed in certain tissues, such as the liver or spleen. As more and more macrophages and other phagocytes

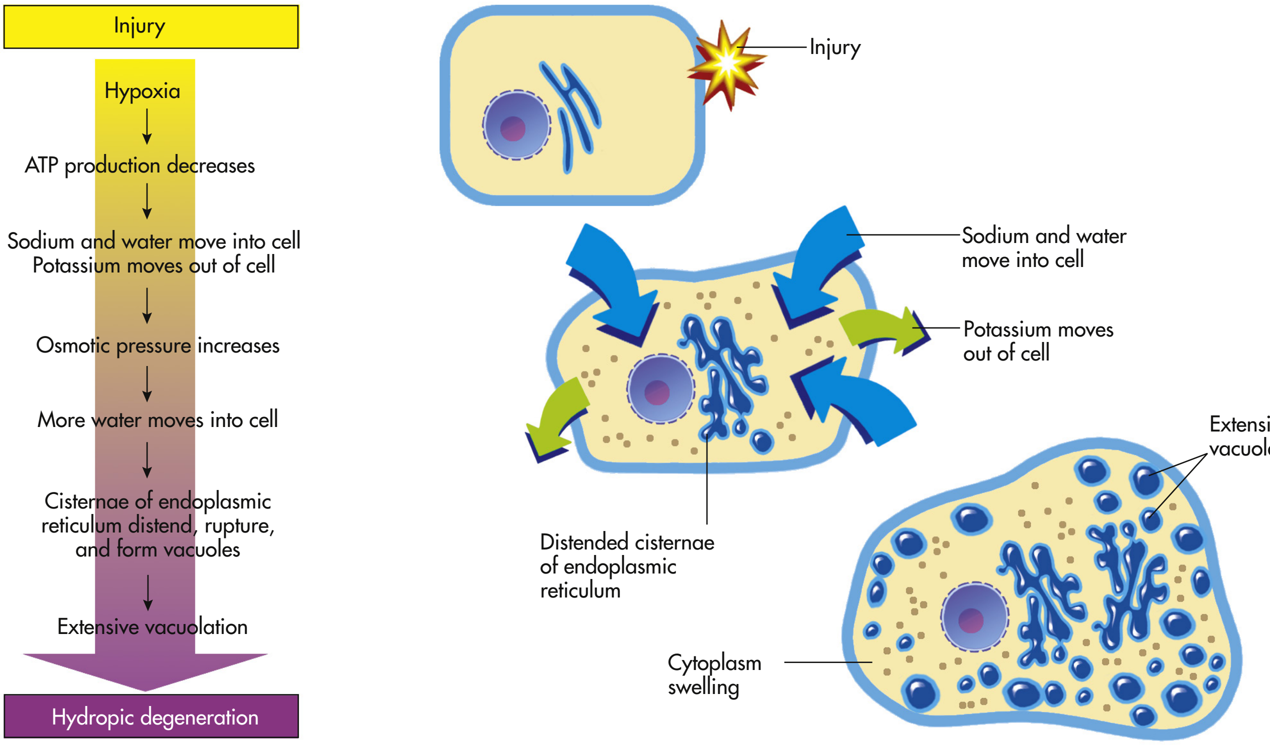

FIGURE 2-21 The Process of Oncosis (Formerly Known as Hydropic Degeneration). *ATP,* Adenosine triphosphate.

migrate to tissues that are producing excessive metabolites, the affected tissues begin to swell. This is the mechanism that causes enlargement of the liver (hepatomegaly) or the spleen (splenomegaly). Enlargement of one of these organs is a clinical manifestation of many of the storage diseases.

Water

Cellular swelling, the most common degenerative change, is caused by the shift of extracellular water into the cells. In hypoxic injury, movement of fluid and ions into the cell is associated with acute failure of metabolism and loss of ATP production. Normally, the pump that transports sodium ions out of the cell is maintained by the presence of ATP and ATPase, the active transport enzyme. In metabolic failure caused by hypoxia, reduced levels of ATP and ATPase permit sodium to accumulate in the cell, whereas potassium diffuses outward. The increase of intracellular sodium concentration increases osmotic pressure, which draws more water into the cell (transport mechanisms are described in Chapter 1). The cisternae of the endoplasmic reticulum become distended, rupture, and coalesce to form large vacuoles that isolate the water from the cytoplasm, a process called *vacuolation.* Progressive vacuolation results in cytoplasmic swelling called **oncosis** (which has replaced the old term *hydropic [water] degeneration*) or **vacuolar degeneration** (Figure 2-21). If cellular swelling affects all cells in an organ, the organ increases in weight and becomes distended and pale.

Cellular swelling is reversible and is considered to be sublethal. It is, in fact, an early manifestation of almost all types of cellular injury, including severe or lethal cell injury. It is also associated with high fever, hypokalemia (abnormally low concentrations of potassium in the blood; see Chapter 3), and certain infections.

Lipids and Carbohydrates

Certain metabolic disorders result in the abnormal intracellular accumulation of carbohydrates and lipids. The accumulations are caused by inherited disorders with insufficient enzymes or ineffective forms of enzymes. Carbohydrate excess disorders are called **mucopolysaccharidoses (MPSs)** and accumulations of both carbohydrates and lipids are called **mucolipidoses (MLs).** MPSs and MLs are classified as **lysosomal storage diseases** because they involve increased storage of carbohydrates or lipids, or both, in lysosomes. Substrate accumulation leads to lysosomal distortion with significant pathologic consequences. These substances may accumulate throughout the body but are found primarily in the cells of the spleen, liver, and central nervous system (CNS). Several of the most prevalent disorders include Tay-Sachs disease, Fabry disease, Gaucher disease, Niemann-Pick disease, the mucopolysaccharidoses, and Pompe disease. Accumulations in cells of the CNS can cause neurologic dysfunction and severe mental retardation. The mucopolysaccharidoses are progressive disorders that usually involve multiple organs, including the liver, spleen, heart, and blood vessels. The accumulated mucopolysaccharides are found in reticuloendothelial cells, endothelial cells, intimal smooth muscle cells, and fibroblasts throughout the body. These carbohydrate accumulations can cause corneal clouding, joint stiffness, and mental retardation.

Although lipids sometimes accumulate in heart and kidney cells, the most common site of intracellular lipid accumulation,

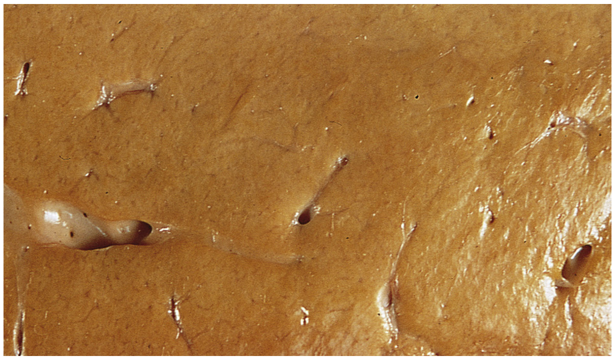

FIGURE 2-22 Fatty Liver. The liver appears yellow. (From Damjanov I, Linder J: *Pathology: a color atlas,* St Louis, 2000, Mosby.)

or **fatty change,** is liver cells. Because hepatic metabolism and secretion of lipids are crucial to proper body function, imbalances and deficiencies in these processes lead to major pathologic changes. Lipid accumulation in liver cells causes an organic condition known as *fatty liver,* or *fatty change* (Figure 2-22). As lipids fill the cells, vacuolation pushes the nucleus and other organelles aside. Grossly, the liver looks yellowish and greasy.

Lipid accumulation in liver cells occurs after cellular injury sets one or more of the following mechanisms in motion:

1. Increased movement of free fatty acids into the liver (starvation, for example, increases breakdown of triglycerides in adipose tissue, releasing fatty acids that subsequently enter liver cells)
2. Failure of the metabolic process that converts fatty acids to phospholipids, resulting in the preferential conversion of the fatty acids to triglycerides
3. Increased synthesis of triglycerides from fatty acids (increases in amounts of the enzyme α-glycerophosphatase, which can accelerate triglyceride synthesis)
4. Decreased synthesis of apoproteins (lipid-acceptor proteins)
5. Failure of lipids to bind with apoproteins and form lipoproteins
6. Failure of mechanisms that transport lipoproteins out of the cell
7. Direct damage to the endoplasmic reticulum by free radicals released by alcohol's toxic effects

Alcohol abuse is one of the most common causes of fatty liver (see Chapter 41). Fatty change caused by alcohol can lead to a form of liver fibrosis called *cirrhosis.* If alcohol intake ceases, the cirrhotic liver can return to a normal size and function. Fatty change from other causes, notably carbon tetrachloride poisoning, is often irreversible.

Cholesterol and cholesterol esters can accumulate and is noted in many pathologic states. These states include atherosclerosis, in which atherosclerotic plaques, smooth muscle cells, and macrophages within the intimal layer of the aorta and large arteries are filled with lipid-rich vacuoles of cholesterol and cholesterol esters. Other states include cholesterol-rich deposits in the gallbladder and Niemann-Pick disease (type C), which involve genetic mutations of an enzyme affecting cholesterol transport.

Glycogen

Intracellular accumulations of glycogen are seen in genetic disorders called *glycogen storage diseases* and in disorders of glucose and glycogen metabolism. Like water and lipid accumulation, glycogen accumulation results in excessive vacuolation of the cytoplasm. The most common cause of glycogen accumulation is diabetes mellitus, a disorder of glucose metabolism (see Chapter 22).

Proteins

Proteins provide cellular structure and constitute most of the cell's dry weight. They are synthesized on ribosomes in the cytoplasm from the essential amino acids lysine, threonine, leucine, isoleucine, methionine, tryptophan, valine, phenylalanine, and histidine. Protein accumulation probably damages cells in two ways. First, metabolites (enzymes) produced when the cell attempts to digest some proteins can damage cellular organelles when released from lysosomes. Second, excessive amounts of protein in the cytoplasm push against cellular organelles, disrupting organelle function and intracellular communication.

Protein excess accumulates primarily in the epithelial cells of the renal convoluted tubule and in the antibody-forming plasma cells (B lymphocytes) of the immune system. Several types of renal disorders cause excessive excretion of protein molecules in the urine (proteinuria). Normally, little or no protein is present in the urine, and its presence in significant amounts indicates cellular injury and altered cellular function in the glomerular membrane.

Accumulations of protein in B lymphocytes can occur during active synthesis of antibodies in the immune response. The excess aggregates of protein are called *Russell bodies.* Russell bodies have been identified in multiple myeloma (plasma cell tumor) (see Chapter 29).

Mutations in protein can slow protein folding, resulting in the accumulation of partially folded intermediates. An example is α_1-antitrypsin deficiency, which can cause emphysema. Certain types of cell injury are associated with the accumulation of cytoskeletal proteins. For example, the *neurofibrillary tangle* found in the brain in Alzheimer disease contains cytoskeletal protein fibrils.

Pigments

Pigment accumulations may be normal or abnormal, endogenous (produced within the body) or exogenous (produced outside the body). Endogenous pigments are derived, for example, from amino acids (e.g., tyrosine, tryptophan). They include melanin and the blood proteins—porphyrins, hemoglobin, and hemosiderin (ferritin). Lipid-rich pigments such as lipofuscin (the aging pigment or spots) give a yellow-brown color to cells undergoing slow, regressive, and often atrophic changes. Exogenous pigments include mineral dusts containing silica and iron particles, lead, silver salts, and dyes for tattoos.

Melanin. **Melanin** accumulates in epithelial cells (keratinocytes) of the skin and retina. It is an extremely important pigment because it protects the skin against long exposure to sunlight and is considered an essential factor in the prevention of skin

FIGURE 2-23 **Blue Nevus, Common Type.** Nevus is dark blue-black, small, and symmetric. (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

cancer (see Chapters 13 and 46). Ultraviolet light (e.g., sunlight) stimulates the synthesis of melanin, which probably absorbs ultraviolet rays during subsequent exposure. Melanin also may protect the skin by trapping the injurious free radicals produced by the action of ultraviolet light on skin.

Melanin is a brown-black pigment derived from the amino acid tyrosine. It is synthesized by epidermal cells called *melanocytes* and is stored in membrane-bound cytoplasmic vesicles called *melanosomes*. Melanosomes are particularly abundant in projections of melanocytic cytoplasm, called *dendrites,* from which they are transmitted to neighboring keratinocytes, where melanin accumulation occurs. (Keratinocytes, which constitute 95% of epidermal cells, are discussed with other skin components in Chapter 46.) The dendritic melanocytes form bridges between neighboring keratinocytes and inject melanosomes into the keratinocytes by an unknown mechanism.

Melanin also can accumulate in melanophores (melanin-containing pigment cells), macrophages, or other phagocytic cells in the dermis. Presumably these cells acquire the melanin from nearby melanocytes or from pigment that has been extruded from dying epidermal cells. This is the mechanism that causes freckles.

Although rare, melanin accumulation occurs in the skin of individuals with Addison disease (adrenocortical insufficiency resulting from disorders of the adrenal cortex; see Chapter 22). The increased melaninogenesis (melanin production) seen in Addison disease is caused by the loss of feedback control of adrenocorticotropic hormone (ACTH). Decreased hormonal secretion from the adrenal gland causes increased release of ACTH from the pituitary gland. In Addison disease the increase in melanin production occurs presumably because a segment of the ACTH molecule contains the melanin-stimulating hormone (MSH).

An increase in melanin concentration also occurs in the benign form of "pigmented moles" called *nevi* (Figure 2-23) (see Chapter 46). Malignant melanoma is a cancerous skin tumor that contains melanin and invades normal tissue early and widely and often leads to death.

A decrease in melanin production occurs in the inherited disorder of melanin metabolism called *albinism*. Albinism is often diffuse, involving all the skin, the eyes, and the hair. Albinism is also related to phenylalanine metabolism. In classic forms of this disease, the person with albinism is unable to convert tyrosine to dopa (3,4-dihydroxyphenylalanine), an intermediary in melanin biosynthesis. Melanin-producing cells are present in normal numbers, but they are unable to make melanin. Individuals with albinism are very sensitive to sunlight and quickly become sunburned. They are also at high risk for skin cancer.

Hemoproteins. **Hemoproteins** are among the most essential of the normal endogenous pigments. They include hemoglobin and the oxidative enzymes—the cytochromes. Knowledge of iron uptake, metabolism, excretion, and storage is central to an understanding of disorders involving these pigments (see Chapter 27). Hemoprotein accumulations in cells are caused by excessive storage of iron, which is transferred to the cells from the bloodstream. Iron enters the blood from three primary sources: (1) tissue stores, (2) the intestinal mucosa, and (3) macrophages that remove and destroy dead or defective red blood cells. The amount of iron in blood plasma also depends on the metabolism of the major iron-transport protein, *transferrin.*

Iron is stored in tissue cells in two forms: as ferritin and, when greater levels of iron are present, as hemosiderin. **Hemosiderin** is a yellow-brown pigment derived from hemoglobin. With pathologic states, excesses of iron cause hemosiderin to accumulate within cells. Accumulation of hemosiderin often occurs in areas of bruising and hemorrhage and in the lungs and spleen after congestion caused by heart failure. With a local hemorrhage, the skin first appears red-blue and then lysis of the escaped red blood cells occurs, causing the hemoglobin to be transformed to hemosiderin. The color changes noted in bruising reflect this transformation.

Hemosiderosis is a condition in which excess iron is stored as hemosiderin in the cells of many organs and tissues. This condition is common in individuals who have received repeated blood transfusions or prolonged parenteral administration of iron. Hemosiderosis is also associated with increased absorption of dietary iron, conditions in which iron storage and transport are impaired, and hemolytic anemia. Excessive alcohol ingestion also can lead to hemosiderosis. Normally, absorption of excessive dietary iron is prevented by an iron absorption process in the intestines. Failure of this process can lead to total-body iron accumulations in the range of 60 to 80 grams (g), compared with normal iron stores of 4.5 to 5 g. Excessive accumulations of iron, such as occur in hemochromatosis (a genetic disorder of iron metabolism and the most severe example of iron overload), are associated with liver and pancreatic cell damage.

Bilirubin is a normal yellow-to-green pigment of bile derived from the porphyrin structure of hemoglobin. Excesses of bilirubin within cells and tissues cause jaundice (icterus), or yellowing of the skin. Jaundice occurs when the bilirubin level exceeds 1.5 to 2 mg/dl of plasma, compared with the normal values of 0.4 to 1 mg/dl. Hyperbilirubinemia occurs with (1) destruction of red blood cells (erythrocytes), such as in hemolytic jaundice; (2) diseases affecting the metabolism and excretion of bilirubin in the liver; and (3) diseases that cause

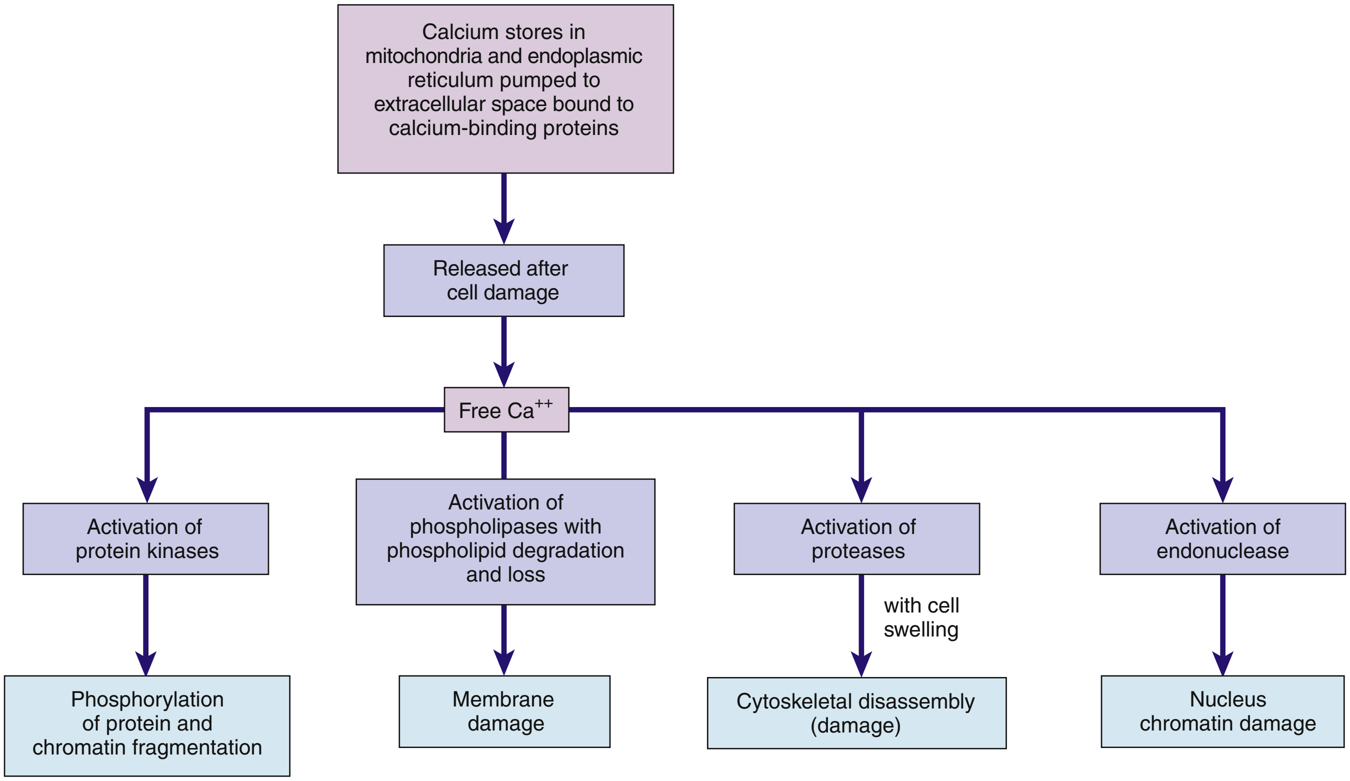

FIGURE 2-24 **Free Cytosolic Calcium: A Destructive Agent.** Calcium is normally removed from the cytosol by adenosine triphosphate (ATP)–dependent calcium pumps. In normal cells, calcium is bound to buffering proteins, such as calbindin or paralbumin, and is contained in the endoplasmic reticulum and the mitochondria. If there is abnormal permeability of calcium ion channels, direct damage to membranes, or depletion of ATP (i.e., hypoxic injury), calcium level increases in the cytosol. If the free calcium cannot be buffered or pumped out of cells, uncontrolled enzyme activation takes place, causing further damage. Uncontrolled entry of calcium into the cytosol is an important final pathway in many causes of cell death.

obstruction of the common bile duct, such as gallstones or pancreatic tumors. (For a detailed description of these diseases, see Chapter 41.) Certain drugs, specifically chlorpromazine and other phenothiazine derivatives, estrogenic hormones, and halothane (an anesthetic), can cause the obstruction of normal bile flow through the liver.

Because unconjugated bilirubin is lipid soluble, it can injure the lipid components of the plasma membrane. Albumin, a plasma protein, provides significant protection by binding unconjugated bilirubin in plasma. Unconjugated bilirubin causes two cellular effects: uncoupling of oxidative phosphorylation and loss of cellular proteins. These two effects could cause structural injury to the various membranes of the cell.

Calcium

Calcium salts accumulate in both injured and dead tissues (Figure 2-24). An important mechanism of cellular calcification is the influx of extracellular calcium in injured mitochondria (see p. 56). Another mechanism that causes calcium accumulation in alveoli (gas-exchange airways of the lungs), gastric epithelium, and renal tubules is the excretion of acid at these sites, leading to the local production of hydroxyl ions. Hydroxyl ions result in precipitation of calcium hydroxide ($Ca[OH]_2$) and hydroxyapatite ($3Ca_3[PO_4]_2Ca[OH]_2$), a mixed salt. Damage occurs when calcium salts clump and harden, interfering with normal cellular structure and function.

Pathologic calcification can be dystrophic or metastatic. **Dystrophic calcification** is the calcification of dying and dead tissues and occurs in chronic tuberculosis of the lungs and lymph nodes, in arteries with advanced atherosclerosis (narrowing as a result of plaque accumulation), and often in injured heart valves (Figure 2-25). Calcification of the heart valves interferes with opening and closing of the valves, causing heart murmurs (see Chapter 32). Calcification of the coronary arteries predisposes them to severe narrowing and thrombosis, which can lead to myocardial infarction. Another site of dystrophic calcification is the center of tumors. Over time, the center is deprived of oxygen supply, dies, and becomes calcified. The calcium salts appear as gritty, clumped granules that can become hard as stone. When several layers clump together, they resemble grains of sand and are called **psammoma bodies.**

The exact pathogenic mechanisms responsible for dystrophic calcification are unknown. A popular hypothesis is that with progressive deterioration of dead cells, the exposed denatured (changed) proteins preferentially bind with phosphate ions. The phosphate ions then react with calcium ions to form deposits of phosphate carbonate precipitates and, sometimes, crystalline formations of calcium phosphate. Dystrophic calcification develops slowly and is an explicit marker for the site of dead cells.

Metastatic calcification consists of mineral deposits that occur in undamaged normal tissues as the result of

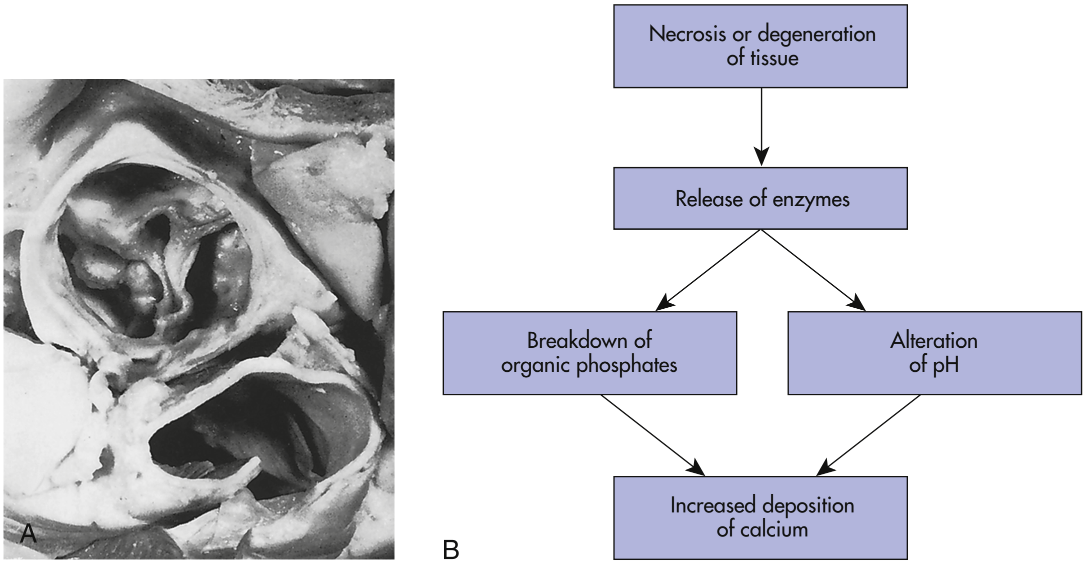

FIGURE 2-25 **Aortic Valve Calcification.** **A,** This aortic valve was unable to close because of calcification caused by rheumatic heart disease. **B,** Algorithm showing the dystrophic mechanism of calcification. (**A** from Damjanov I, Linder J, editors: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

hypercalcemia (excess of calcium in the blood; see Chapter 3). Conditions that cause hypercalcemia include hyperparathyroidism, toxic levels of vitamin D, hyperthyroidism, idiopathic hypercalcemia of infancy, Addison disease (adrenocortical insufficiency), systemic sarcoidosis, milk-alkali syndrome, and the increased bone demineralization that results from bone tumors, leukemia, and disseminated cancers. Hypercalcemia also can occur in some instances of advanced renal failure with phosphate retention, resulting in hyperparathyroidism.

Urate

In humans, uric acid (**urate**) is the major end product of purine catabolism because of the absence of the enzyme urate oxidase. Serum urate concentration is, in general, stable: approximately 5 mg/dl in postpubertal males and 4.1 mg/dl in postpubertal females. Disturbances in maintaining serum urate levels result in hyperuricemia and deposition of sodium urate crystals in the tissues, leading to painful disorders collectively called *gout.* These disorders include acute arthritis, chronic gouty arthritis, tophus (firm nodular subcutaneous deposits of urate crystals surrounded by fibrosis), and nephritis (inflammation of the nephron). Chronic hyperuricemia results in the deposition of urate in tissues, cell injury, and inflammation. Because urate crystals are not degraded by lysosomal enzymes, they persist in dead cells.

Systemic Manifestations

Systemic manifestations of cellular injury include a general sense of fatigue and malaise, a loss of well-being, and altered appetite. Fever is frequently present because of biochemicals produced during the inflammatory response (see Chapter 7). Table 2-9 summarizes the most significant systemic manifestations of cellular injury.

CELLULAR DEATH

Cell death has historically been classified as necrosis and apoptosis. **Necrosis** is characterized by rapid loss of the plasma membrane structure, organelle swelling, mitochondrial dysfunction, and the lack of typical features of apoptosis.[135] Apoptosis is known as a regulated or programmed cell process characterized by the "dropping off" of cellular fragments called apoptotic bodies. Until recently, only necrosis was considered passive or accidental, occurring after severe and sudden injury. It is the main outcome in several common injuries including ischemia, toxin exposure, certain infections, and trauma. It has now been proposed that under certain conditions, such as activation of death proteases, necrosis may be *regulated* or *programmed* in a well-orchestrated way as a back-up for apoptosis (apoptosis may progress to necrosis).[136,137] Hence, the new term used is **programmed necrosis,** or **necroptosis.** Historically, programmed cell death only referred to apoptosis. Now programmed cell death can be divided into several categories: type I apoptosis; type II autophagy (self-eating); and others include necrosis, senescence, and mitotic catastrophe.[138] Figure 2-26 illustrates the structural changes in cell injury resulting in necrosis or apoptosis. Table 2-10 compares the unique features of necrosis and apoptosis. Other forms of cell loss include autophagy (see p. 92).

Necrosis

Cellular death eventually leads to cellular dissolution, or necrosis. Necrosis is the sum of cellular changes after local cell death and the process of cellular self-digestion, known as autodigestion or **autolysis** (see Figure 2-26). Cells die long before any necrotic changes are noted by light microscopy.[139] The structural signs that indicate irreversible injury and progression

TABLE 2-9 SYSTEMIC MANIFESTATIONS OF CELLULAR INJURY

MANIFESTATION	CAUSE
Fever	Release of endogenous pyrogens (interleukin-1, tumor necrosis factor-alpha [TNF-α], prostaglandins) from bacteria or macrophages; acute inflammatory response
Increased heart rate	Increase in oxidative metabolic processes resulting from fever
Increase in number of leukocytes (leukocytosis)	Increase in total number of white blood cells because of infection; normal is 5000-9000/mm^3 (increase is directly related to the severity of the infection)
Pain	Various mechanisms, such as release of bradykinins, obstruction, pressure
Presence of cellular enzymes in extracellular fluid	Release of enzymes from cells of tissue*
Lactate dehydrogenase (LDH) (LDH isoenzymes)	Release from red blood cells, liver, kidney, skeletal muscle
Creatine kinase (CK) (CK isoenzymes)	Release from skeletal muscle, brain, heart
Aspartate aminotransferase (AST; SGOT)	Release from heart, liver, skeletal muscle, kidney, pancreas
Alanine aminotransferase (ALT; SGPT)	Release from liver, kidney, heart
Alkaline phosphatase (ALP)	Release from liver, bone
Amylase	Release from pancreas
Aldolase	Release from skeletal muscle, heart

*The rapidity of enzyme transfer is a function of the weight of the enzyme and the concentration gradient across the cellular membrane. The specific metabolic and excretory rates of the enzymes determine how long levels of enzymes remain elevated.

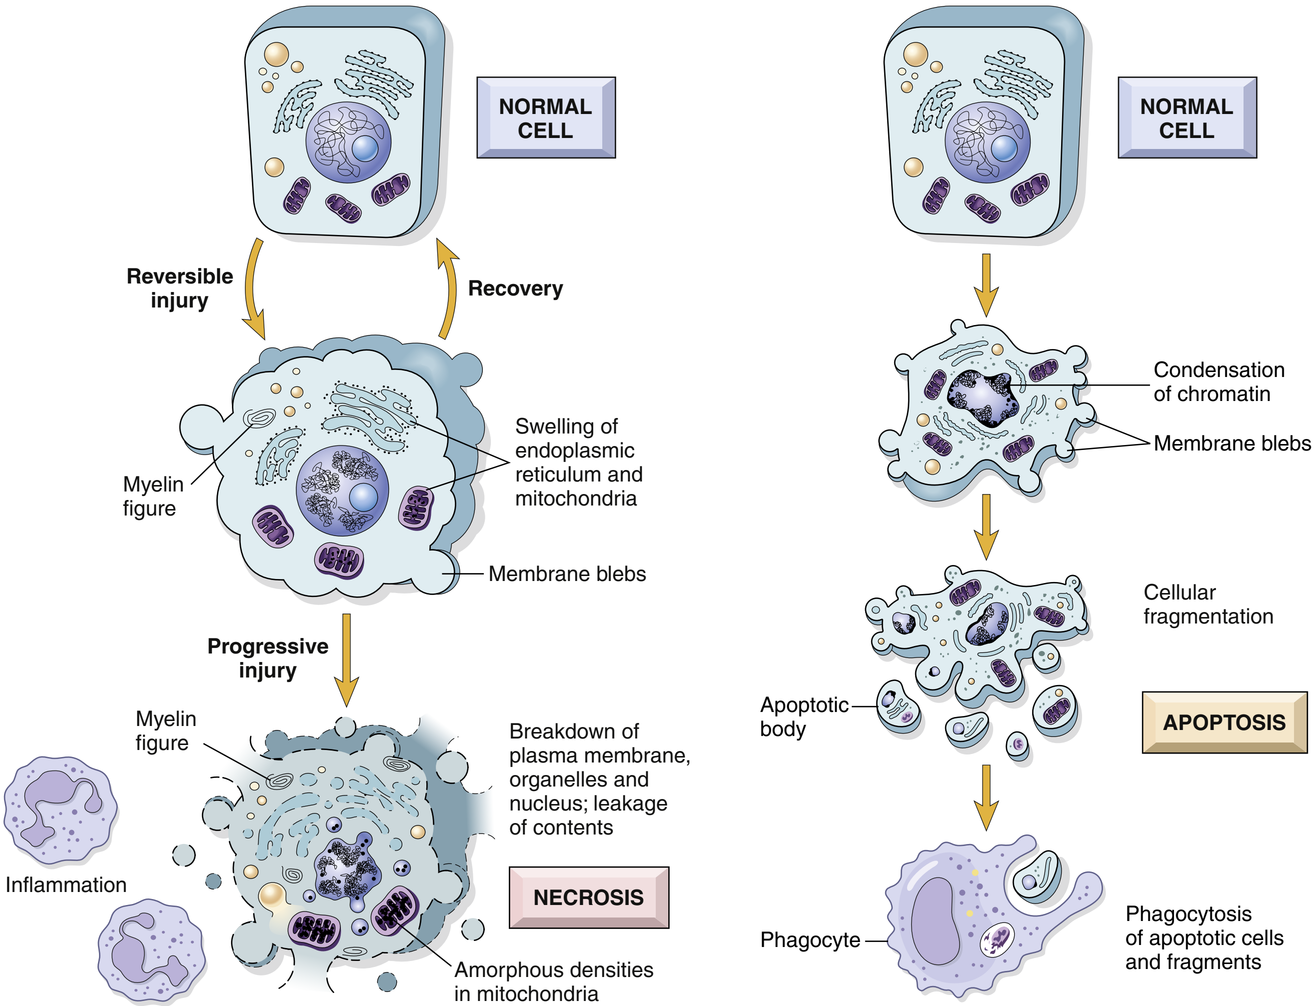

FIGURE 2-26 Schematic Illustration of The Morphologic Changes in Cell Injury Culminating in Necrosis or Apoptosis. Myelin figures come from degenerating cellular membranes and are noted within the cytoplasm or extracellularly. (From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V et al, editors: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Saunders.)

TABLE 2-10 FEATURES OF NECROSIS AND APOPTOSIS

FEATURE	NECROSIS	APOPTOSIS
Cell size	Enlarged (swelling)	Reduced (shrinkage)
Nucleus	Pyknosis → karyorrhexis → karyolysis	Fragmentation into nucleosome-size fragments
Plasma membrane	Disrupted	Intact; altered structure, especially orientation of lipids
Cellular contents	Enzymatic digestion; may leak out of cell	Intact; may be released in apoptotic bodies
Adjacent inflammation	Frequent	No
Physiologic or pathologic role	Invariably pathologic (culmination of irreversible cell injury)	Often physiologic, means of eliminating unwanted cells; may be pathologic after some forms of cell injury, especially DNA damage

From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V et al, editors: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Saunders.

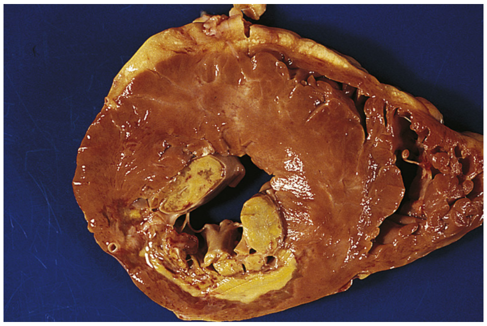

FIGURE 2-27 Coagulative Necrosis of Myocardium of Posterior Wall of Left Ventricle of Heart. A large anemic *(white)* infarct is readily apparent; note also the necrosis of papillary muscle. (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

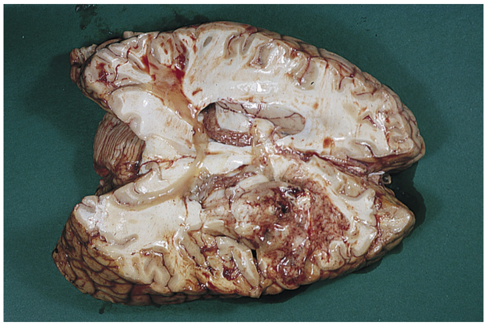

FIGURE 2-28 Liquefactive Necrosis of the Brain. The area of infarction is softened as a result of liquefactive necrosis. (From Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders.)

to necrosis are dense clumping and progressive disruption of genetic material and disruption of the plasma and organelle membranes. In later stages of necrosis, most organelles are disrupted, and **karyolysis** (nuclear dissolution and lysis of chromatin from the action of hydrolytic enzymes) is under way. In some cells, the nucleus shrinks and becomes a small, dense mass of genetic material **(pyknosis).** The pyknotic nucleus eventually dissolves (by karyolysis) as a result of the action of hydrolytic lysosomal enzymes on DNA.

Although necrosis still refers to death induced by nonspecific trauma or injury (cell stress or the heat shock response), the recent identification of molecular regulators governing programmed necrosis (necroptosis) has demonstrated an interconnected large network of signaling pathways.[137,140] Emerging evidence shows that programmed necrosis is associated with development, tissue damage during acute pancreatitis, and retinal detachment; and provides an innate immune response to viral infection, thus challenging the historic view of necrosis as passive cell death occurring in a disorganized or unregulated manner.[137,140]

Different types of necroses tend to occur in different organs or tissues and sometimes can indicate the mechanism or cause of cellular injury. The four major types of necroses are coagulative, liquefactive, caseous, and fatty. Another type, gangrenous necrosis, is *not* a distinctive type of cell death but refers to larger areas of tissue death.

Coagulative necrosis, which occurs primarily in the kidneys, heart, and adrenal glands, commonly results from hypoxia caused by severe ischemia or hypoxia caused by chemical injury, especially ingestion of mercuric chloride (Figure 2-27). Coagulation is caused by protein denaturation, which causes the protein albumin to change from a gelatinous, transparent state to a firm, opaque state, similar to that of a cooked egg white. The necrotic tissues appear firm and slightly swollen. Recent evidence indicates that an abnormality in intracellular levels of Ca^{++} (e.g., increased) may be a critical event in coagulation necrosis.[141]

Liquefactive necrosis commonly results from ischemic injury to neurons and glial cells in the brain (Figure 2-28). Dead brain tissue is readily affected by liquefactive necrosis because brain cells are rich in the digestive hydrolytic enzymes and lipids, and the brain contains little connective tissue. As the cells are digested by their own hydrolases, the tissue becomes soft, liquefies, and is walled off from healthy tissue, forming cysts. (Cyst formation is described in Chapter 7.)

Liquefactive necrosis can also result from bacterial infection, particularly by staphylococci, streptococci, and *Escherichia coli*. In this case the hydrolases are released from the lysosomes of neutrophils (phagocytes attracted to the infected area to kill the bacteria). Liquefaction of bacterial cells and neighboring tissue cells by neutrophilic hydrolases results in the accumulation of pus.

Caseous necrosis, which commonly results from tuberculous pulmonary infection, particularly *Mycobacterium tuberculosis,* is a combination of coagulative and liquefactive necrosis (Figure 2-29). The dead cells disintegrate, but the debris is not digested completely by hydrolases. Tissues appear soft and granular and resemble clumped cheese, hence its name. A granulomatous inflammatory wall encloses areas of caseous necrosis.

FIGURE 2-29 **Caseous Necrosis.** Tuberculosis of the lung, with a large area of caseous necrosis containing yellow-white and cheesy debris. (From Kumar V et al: Cellular responses to stress and toxic insults: adaptation, injury, and death. In Kumar V et al, editors: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2010, Saunders.)

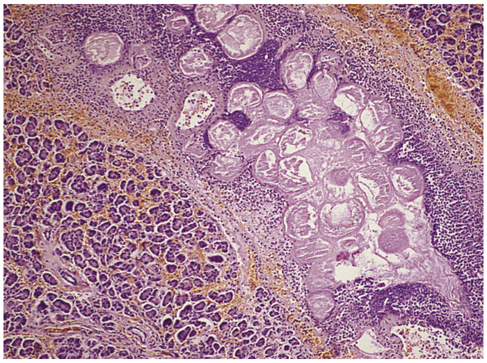

FIGURE 2-30 **Fat Necrosis of Pancreas.** Interlobular adipocytes are necrotic; these are surrounded by acute inflammatory cells. (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

Fat necrosis, which occurs in the breast, pancreas, and other abdominal structures, is cellular dissolution caused by powerful enzymes called *lipases* (Figure 2-30). Lipases break down triglycerides, releasing free fatty acids, which then combine with calcium, magnesium, and sodium ions, creating soaps (a process known as *saponification*). The necrotic tissue appears opaque and chalk white.

Gangrenous necrosis, a term commonly used in surgical clinical practice, refers to death of tissue and results from severe hypoxic injury, commonly occurring because of arteriosclerosis, or blockage, of major arteries, especially in the lower leg. With hypoxia and subsequent bacterial invasion, the tissues can undergo necrosis. **Dry gangrene** is usually the result of coagulative necrosis. The skin becomes very dry and shrinks, resulting in wrinkles, and its color changes to dark brown or black (Figure 2-31). **Wet gangrene** develops when neutrophils invade the site, causing liquefactive necrosis. This usually occurs in internal organs, causing the site to become cold, swollen, and black. A foul odor is present, produced by pus, and if systemic symptoms become severe, death can ensue.

Gas gangrene, a special type of gangrene, is caused by infection of injured tissue by one of many species of *Clostridium.*

FIGURE 2-31 **Gangrene of Toes.** Dry gangrene. (From Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders.)

These anaerobic bacteria produce hydrolytic enzymes and toxins that destroy connective tissue and cellular membranes and cause bubbles of gas to form in muscle cells. Gas gangrene can be fatal if enzymes lyse the membranes of red blood cells, destroying their oxygen-carrying capacity. Death is the result of shock. The condition is treated with antitoxins and supplemental oxygen delivered in a hyperbaric (pressurized) chamber.

Apoptosis

Apoptosis ("dropping off") is an important distinct type of cell death that differs from necrosis in several ways (see Figure 2-26 and Table 2-10). Apoptosis is an active process of cellular self-destruction—called *programmed cell death (type I)*—in both normal and pathologic tissue changes. It depends on a tightly regulated cellular program for its initiation and execution.[142] The average adult may create 10 billion new cells every day and destroy the same number.[143] Normal physiologic death by apoptosis occurs during embryogenesis; involution of hormone-dependent tissue after hormone withdrawal, such as involution of the lactating breast after weaning; cell loss in proliferating cell populations, such as immature lymphocytes in the bone marrow or thymus that do not express appropriate receptors; and elimination of possibly harmful lymphocytes that may be self-reactive and cause death of cells after they perform useful functions (for example, neutrophils after an acute inflammatory reaction). Death by apoptosis causes loss of cells in many pathologic states including the following:

- *Severe cell injury.* When cell injury exceeds repair mechanisms, the cell triggers apoptosis. DNA damage can result either directly or indirectly from production of free radicals.
- *Accumulation of misfolded proteins.* This may result from genetic mutations or free radicals. Excessive accumulation of misfolded proteins in the endoplasmic reticulum (ER) leads to a condition known as **endoplasmic reticulum stress (ER stress).** ER stress results in apoptotic cell death. This mechanism has been linked to several degenerative diseases of the CNS and other organs.
- *Infections (particularly viral).* Apoptosis may be the result of the virus directly or indirectly by the host immune response. Cytotoxic T lymphocytes respond to viral infections by inducing apoptosis and, therefore, eliminating the infectious cells. This process can cause tissue damage and it is the same for cell death in tumors and rejection of tissue transplants.

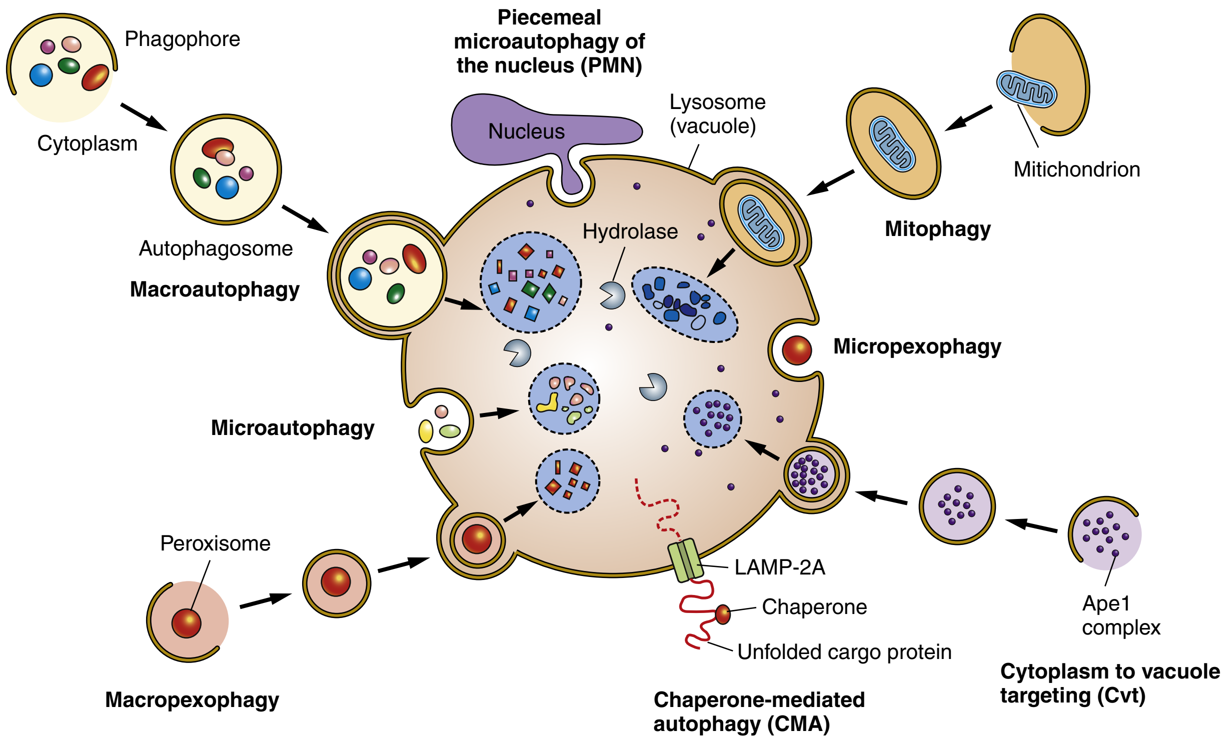

FIGURE 2-32 **Autophagy.** Three primary modes of autophagy include macrophagy, microphagy, and chaperone-mediated autophagy. Macrophagy is the formation of an autophagosome, a vacuole of nonlysosomal origin; microphagy involves direct uptake of cytosol, inclusions (e.g., glycogen), and organelles (e.g., ribosomes, peroxisomes at the lysosome vacuole); and chaperone-mediated autophagy (CMA) is a translocation process facilitated by certain proteins that are transported across the lysosomal membrane and degraded. Depending on the cargoes, autophagy can be selective or nonselective. During nonselective autophagy, a part of the cytoplasm is confiscated into a double-membrane autophagosome; it then fuses with the lysosome/vacuole. Specific degradation of peroxisomes can be achieved by either macroautophagy (macropexophagy) or microautophagy (micropexophagy). Piecemeal microautophagy of the nucleus causes degradation of a portion of the nucleus. Mitophagy, or degradation of the mitochondria, also occurs. (From Yen WL, Klionsky DJ: *Pathophysiology [Bethesda]* 23(5):248–262, 2008.)

- *Obstruction in tissue ducts.* In organs with duct obstruction, including the pancreas, kidney, and parotid gland, apoptosis causes pathologic atrophy.

Excessive or insufficient apoptosis is known as *dysregulated apoptosis*. A low rate of apoptosis can permit the survival of abnormal cells, for example, mutated cells that can increase cancer risk. Defective apoptosis may not eliminate lymphocytes that react against host tissue (self-antigens) leading to autoimmune disorders. Increased apoptosis is known to occur in several neurodegenerative diseases, ischemic injury (such as myocardial infarction and stroke), and death of virus-infected cells in many viral infections.

Autophagy: Death but Also Survival

The term **autophagy** is Greek, meaning "eating of self" (Figure 2-32). Autophagy, as a "recycling factory," is a self-destructive process and a survival mechanism. It is now considered important in diverse processes such as development, cell proliferation, remodeling, aging, tumor suppression, neurodegeneration, antigen presentation, innate immunity, regulation of organismal life span, and cell death.[144] When cells are starved or nutrient deprived, the autophagic process institutes cannibalization and recycles the digested contents.[145,146] Autophagy can maintain cellular metabolism under starvation conditions and remove damaged organelles and misfolded proteins under stress conditions, improving the survival of cells.

With metabolic stress, autophagy provides ATP and other macromolecules as energy sources to enable cell survival; if, however, the stress is excessive, cells may progress to autophagic programmed cell death, which is distinct from apoptosis.[138,147] Autophagic cell death **(type II programmed cell death)** is characterized by double- or multiple-membrane cytoplasmic vesicles engulfing bulk cytoplasm/cytoplasmic organelles, such as mitochondria and ER. However, in **type I programmed cell death** apoptosis is largely the result of caspase activation and destruction of the cellular components (see p. 91). It should be noted that several studies have failed to show a direct causal link between cell death and autophagy; thus autophagy may not be an executor of cell death but is required with other prodeath signals.[138] Research has shown cells undergoing autophagic cell death were engulfed by macrophages as well as targeted cells.[148]

Autophagy has been highlighted in cancer. It is controversial whether autophagy kills cancer cells or enables their survival under conditions of cell stress (for example, hypoxia). Some reports support that autophagy promotes cancer cell survival after chemotherapy or radiation therapy.[138,149] A causative link

between autophagy inhibition and increased tumor formation is the persistent DNA damage induced by ROS associated with dysfunctional mitochondria found in autophagic-deficient tissue.[150] These data and others have led investigators to hypothesize that autophagy probably functions to prevent cancer initially, but once a tumor develops the cancer cells can use autophagy for their own survival. Autophagy and apoptosis may be interconnected and possibly simultaneously regulated by the same trigger in tumor cells.[138]

Investigators are excited about the prospect of autophagy for the development of cancer and other therapeutic strategies. As a critical garbage-collecting and recycling process in healthy cells, the process of autophagy decelerates and may become less discriminating as the cell ages. Consequently, harmful agents accumulate in cells, damaging them and leading to aging. For example, failure to clear protein products in neurons of the CNS causing dementia and failure to clear ROS-producing mitochondria lead to nuclear DNA mutations and cancer. Thus, these processes may even partially define aging. Therefore, normal autophagy may potentially rejuvenate an organism and prevent cancer development as well as other degenerative diseases.[151] Autophagy also may be the last immune defense against infectious microorganisms that penetrate intracellularly.[152]

AGING AND ALTERED CELLULAR AND TISSUE BIOLOGY

The terms aging and life span tend to be used synonymously; however, they are not equivalent. *Aging* is usually defined as a normal physiologic process that is universal and inevitable, whereas *life span* is the time from birth to death and has been used to study the aging process.[153] Aging is associated with a gradual loss of homeostatic mechanisms whose underlying cause is perplexing,[154] and is a complex process because of a multiplicity of factors. Investigators are focused on genetic, epigenetic, inflammatory, oxidative stress, and metabolic origins of aging, including the study of genetic signatures in humans with exceptional longevity; the identification and recent discovery of epigenetic mechanisms that modulate gene expression; the role of intrauterine environment and lifelong patterns of health; personality, behavior, and social support; insulin/insulin-like growth factor 1 (IGF-1) signaling; and the contributions of cellular dysfunction and senescence to an inflammatory microenvironment that leads to chronic disease, frailty, and decreased life span. A major challenge of aging research has been to separate the causes of cell and tissue aging from the vast changes that accompany it.[154] Public health issues related to healthy aging require understanding of the nature of aging and the factors that predict healthy aging and delayed transition to increasing vulnerability and frailty.

Aging traditionally has not been considered a disease because it is "normal"; disease is usually considered "abnormal." Conceptually, this distinction seems clear until the concept of "injury" or "damage" is introduced; disease has been defined by some pathologists as the result of injury. *Chronologic aging* has been defined as the time-dependent loss of structure and function that proceeds very slowly and in such small increments that it appears to be the result of the accumulation of small, imperceptible injuries—a gradual result of wear and tear. One of the hallmarks of aging is the accumulation of damaged macromolecules. DNA damage can lead to cellular dysfunction both directly and indirectly as a consequence of cellular responses to damage that can lead to altered gene expression.[155,156] Age-related changes to macromolecules for long-lived cells, such as neurons and myofibers, lead to gradual loss of structure and function.

Replicative aging is the accumulation of cellular damage in continuously dividing cells, for example, epithelia of the skin or gastrointestinal tract. Replicative aging and chronologic aging are particularly important for adult stem cells because they divide throughout life.[157] As mutations increase with age, cell fates include apoptosis, malignant transformation, cell cycle arrest, or senescence.[158]

Despite the fact that aging and death are inevitable, life span, on the other hand, can be experimentally changed.[154] Genetic and environmental interventions have extended the life span of model organisms, such as the nematode worm *Caenorhabditis elegans (C. elegans)*, the fruit fly *Drosophilia melanogaster*, and mice.[159,160] Extending life span, however, is not equivalent to delaying aging![154] For example, treatment of an acute infection can prevent death but the fundamental *rate* of aging continues. Yet, investigators will study and try to isolate, manipulate, and reset so-called longevity genes to slow the rate of aging.

Recent advances in stem cell biology have begun to reveal the molecular mechanisms behind reprogramming events that occur during fertilization and when the nucleus of a mature somatic cell is transferred to an enucleated oocyte. Called somatic cell nuclear transfer (SCNT), this process gave rise to the first cloned mammal, Dolly the sheep, and led to the explosion of research in cloning.[154] SCNT is important in terms of demonstrating the ability of the oocyte cytoplasm to reprogram the donor nucleus. These reprogramming events have led to the process to create induced pluripotent stem cells (iPSCs).[161] The major emphasis of reprogramming research is the reversal of the differentiated program and attainment of a pluripotent state (differentiated cells in all three germ layers of the embryo) and not the reversal of aging.[154,162] Nevertheless, each of these processes is discussed in the context of resetting the aging clock.

Restoration of youthfulness to aged cells and tissues has created so-called rejuvenating interventions. Experiments to test whether cells and tissues from an old animal can be restored to a younger self include the approach called heterochronic (i.e., young-to-old or old-to-young) transplantations and heterochronic parabiosis, when the systemic circulations of two animals are joined. The systemic environment may become more youthful with restoration of protein components in the blood and tissues, especially chemokines and cytokines.[163]

Pharmacologic interventions may restore youthfulness at cellular and biochemical levels. The enzyme mammalian target of rapamycin (mTOR) senses cellular nutrient levels, thus regulating rates of protein synthesis and energy utilization.[154] Administration of the drug rapamycin, an mTOR inhibitor, can extend the life span of mice.[164] These and future studies may not just change differentiation programs of cells and tissue, but

possibly alter the aging clock. Although the accumulation of nuclear and mitochondrial DNA mutations has been correlated with aging and increasing the burden of mitochondrial DNA mutations can shorten life span, there is no direct evidence—yet—that a reduction in DNA mutations will increase life span. Observations in *C. elegans* suggest strongly that the causes of aging may be largely epigenetic.[154,165]

Normal Life Span and Life Expectancy

The **maximal life span** of humans is between 80 and 100 years and does not vary significantly among populations. In primitive societies, few individuals reach the maximal life span. However, in societies with improved sanitation, housing, nutrition, and health care, many individuals attain the maximal life span. **Life expectancy** is the average number of years of life remaining at a given age. Although a slow but steady rise in life expectancy has occurred generally in the United States, disparities exist among various counties. A surprising government-sponsored study by Harvard researchers found life expectancy actually *declined* in a number of counties (e.g., smallest unit of analysis) from 1983 to 1999 (see What's New? Decline in Life Expectancy in Some U.S. Counties).

Life Expectancy Differences Across America

Although maximal life span has not changed significantly over time, improved public health strategies and health advances in the United States during the last century added about 30 years to life expectancy between 1900 and 2000. This increase in life expectancy has not affected all Americans. In each successive age group from 65 years and older, women outnumber men; thus women have a greater life expectancy than men. Increases in life expectancy have resulted in a larger older adult population and, for some, inherent problems of disability, disease, and socioeconomic hardship.

Longevity in the United States has recently been the subject of several reports.[166-168] Although U.S. spending on health care far exceeds that of other developed countries, life expectancy and key measures of health lag behind other high-income countries[169] (Table 2-11).

In the United States, chronic health conditions associated with modifiable risk factors, such as smoking, nutrition, weight, and physical activity, represent 6 of the 10 costliest medical conditions.[170] These preventable conditions lead to diseases and injuries and cause soaring medical and labor costs that saddle U.S. employers and bankrupt families. All of these conditions are highly amendable to population-based preventive strategies, which have been slow to develop; 20% of adults still smoke and 50% of adults and 20% of children are overweight or obese.[171] It is estimated that one third of American adults will develop diabetes by 2050 (up from one tenth today).[172] The current generation of children and young adults in the United States could

WHAT'S NEW?

Decline in Life Expectancy in Some U.S. Counties

Continuing rise in life expectancy for *all* Americans is not happening. Long-term analysis of county trends has revealed startling data.

Between 1961 and 1999, the *average* life expectancy in the United States increased from 73.5 to 79.6 years for women and from 66.9 to 74.1 years for men. However, the differences in mortality by county between the most disadvantaged populations and those with the most advantages began to *widen* in the early 1980s. Life expectancy between 1961 and 1999 in the male advantaged population (best-off group) rose from 70.5 to 78.7 years and from 76.9 to 83 years for females. In the female disadvantaged populations (worst-off group) starting in the early 1980s, life expectancy remained relatively stable (68.7 years in 1961, 74.5 years in 1983, and only 75.5 years in 1999). The worst-off men had a decline, rising again in the 1990s.

The gains made, particularly for cardiovascular disease, began to plateau in the 1980s because of rising mortality from lung cancer, chronic obstructive pulmonary disease, and diabetes. A major contributor, which peaked later for women than for men, is smoking. Smoking is thought to be a significant contributor for women, as well as overweight, obesity, and hypertension. The worst-off counties also showed a rise in the prevalence of HIV/AIDS and homicide in men.

Statistically significant declines for women occurred in 180 of 3141 counties and in 11 counties for men. In addition, 783 counties showed life expectancy declines for women whereas 48 counties showed declines for men, but this was not statistically significant. Life expectancy was worse in all southwestern Virginia counties, with a drop over the 16-year period of about 6 years in women and 2.5 years in men. The greatest improvements occurred in western desert counties, where life expectancy rose almost 5 years for women and about 7 years for men.

The life expectancy "gap" is *increasing* between rich and poor and between high and low educational attainment. This increase is occurring despite the gap between men and women and between blacks and whites. In addition, other indices include geography and community assets.

The analysis of county data demonstrates that the 1980s and 1990s were the beginning of the era of increased inequalities in mortality in the United States. Dividing the United States into "eight Americas," it is now evident that disparities in mortality affect millions of Americans. The gap is enormous. The "eight Americas" analysis revealed the highest levels of life expectancy on record, which were for U.S.-born Asian females (America 1), 3 years higher than that of females in Japan. The next highest group was low-income, white rural populations in Minnesota, the Dakotas, Iowa, Montana, and Nebraska (America 2), with a life expectancy of 76.2 years for males and 81.8 years for females. Blacks living in high-risk urban areas (America 8) had the lowest life expectancy, with almost 4 times as many of these individuals likely to die before age 60 and 3.8 and 4.7 times (females and males, respectively) more likely to die before age 45 (compared to the America 1 [Asian] group)! The excess young and middle-aged deaths in America 8 were observed to be caused by injuries, cardiovascular disease, liver cirrhosis, diabetes, HIV, and homicide.

In summary, large disparities in life expectancy exist across America because of differences in the prevalence of chronic diseases and injuries with known risk factors, including alcohol use, tobacco smoking, overweight and obesity, elevated blood pressure, elevated cholesterol level, and poor glucose control.

become the first generation to have shorter life spans, multiple medical conditions, and fewer healthy years of life than those of their parents.[173]

Aging: Degenerative Extracellular Changes

Extracellular factors that affect the aging process include the binding of collagen; the increase in free radicals' effects on cells; the structural alterations of fascia, tendons, ligaments, bones, and joints; and the development of peripheral vascular disease, particularly arteriosclerosis (see Chapter 32).

Aging affects the extracellular matrix with increased cross-linking, decreased synthesis and increased degradation of collagen. These changes, together with the disappearance of elastin and changes in proteoglycans and plasma proteins, cause disorders that result in dehydration and wrinkling of the skin (see Chapter 46). Other age-related defects in the extracellular matrix include skeletal muscle alterations (e.g., atrophy, decreased tone, loss of contractility), cataracts, diverticula, hernias, and rupture of intervertebral disks.

Free radicals of oxygen (see p. 59) that result from oxidative stress (e.g., respiratory chain, phagocytosis, prostaglandin synthesis) are known to damage tissues during the aging process. These oxygen products are extremely reactive and can damage nucleic acids, destroy polysaccharides, oxidize proteins, peroxidize unsaturated fatty acids, and kill and lyse cells. Oxidant effects on target cells can lead to malignant transformation, presumably through DNA damage. That progressive and cumulative damage from oxygen radicals may lead to harmful alterations in cellular function is consistent with those alterations of aging. This hypothesis is founded on the wear-and-tear theory of aging, which states that damages accumulate with time, decreasing the organism's ability to maintain a steady state. Because these oxygen-reactive species not only can permanently damage cells but also may lead to cell death, there is new support for their role in the aging process.

Of much interest is the relationship between aging and the disappearance or alteration of extracellular substances important for blood vessel integrity. Advancing age is an important risk factor for the development of cardiovascular diseases. Vascular oxidative stress increases with age without a compensatory increase in antioxidant defenses.[174] Vascular endothelial dysfunction is characterized by a shift from a vasodilatory, anti-coagulative, anti-proliferative, and anti-inflammatory state to a pro-inflammatory, pro-proliferative, and pro-coagulative state with consequent increased risk for cardiovascular events and diseases (Figure 2-33).

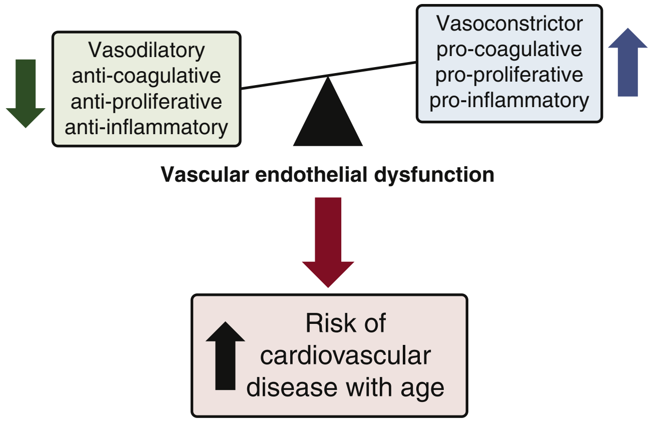

FIGURE 2-33 Vascular Endothelial Function and Increased Risk of Cardiovascular Diseases. Endothelial dysfunction is characterized by a shift from a vasodilatory, anti-coagulative, anti-proliferative, and anti-inflammatory state to a pro-proliferative and pro-inflammatory state, leading to an increased risk of cardiovascular disease with aging. (Adapted from Seals DR, Jablonski KL, Donato AJ: *Clin Sci* 120:357–375, 2011.)

Oxidative stress plays an important role in initial atherosclerotic lesion formation: its progression and destabilization.[175] With aging, lipid, calcium, and plasma proteins are deposited in vessel walls. These depositions cause basement membrane thickening and alterations in smooth muscle functioning, resulting in arteriosclerosis (a progressive disease that causes serious problems in the aged, including stroke, myocardial infarction, renal disease, and peripheral vascular disease).

Cellular Aging

Cellular changes characteristic of aging include atrophy, decreased function, and loss of cells, possibly by apoptosis.

Loss of cellular function from any of these causes initiates the compensatory mechanisms of hypertrophy and hyperplasia of remaining cells, which can lead to metaplasia, dysplasia, and neoplasia. All these changes can alter receptor placement and function, nutrient pathways, secretion of cellular products, and neuroendocrine control mechanisms. In the aged cell, DNA, RNA, cellular proteins, and membranes are most susceptible to injurious stimuli. DNA is particularly vulnerable to such injuries as breaks, deletions, and additions. Although it can repair itself with time, the aged cell's capacity for DNA repair is decreased. Lack of DNA repair increases the cell's susceptibility to mutations that may be lethal or may promote the development of neoplasia.

Mitochondria are the organelles responsible for the generation of most of the energy used by eukaryotic cells. Mitochondrial DNA (mtDNA) encodes some of the proteins of the electron transfer chain, the system necessary for the conversion of adenosine diphosphate (ADP) to ATP. Mutations in mtDNA can deprive the cell of ATP, and mutations are correlated with the aging process. The most common age-related mtDNA mutation in humans is a large rearrangement called the *4977 deletion,* or *common deletion,* and is found in humans more than 40 years old.

The production of ROS under physiologic conditions is associated with activity of the respiratory chain in aerobic ATP production. Therefore, increased mitochondrial activity per se can be an "oxidative stress" to cells. The production of ROS is markedly increased in many pathologic conditions in which the respiratory chain is impaired. Because mtDNA, which is essential for normal oxidative phosphorylation, is located in proximity to the ROS-generating respiratory chain, it is more oxidatively damaged than is nuclear DNA. Cumulative damage of mtDNA is implicated in the aging process as well as in the progression of such common diseases as diabetes, cancer, and heart failure.

Tissue and Systemic Aging

It is probably safe to say that every physiologic process can be shown to function less efficiently with increasing age. The most characteristic tissue change with age is a progressive stiffness or rigidity that affects many systems, including the arterial, pulmonary, and musculoskeletal systems. A consequence of blood vessel and organ stiffness is a progressive increase in peripheral resistance to blood flow. The movement of intracellular and extracellular substances also usually decreases with age as does the diffusion capacity of the lung. Blood flow through organs decreases; for example, renal plasma flow decreases.

Changes in the endocrine and immune systems include thymus atrophy. Although this occurs at puberty, it causes a decreased immune response to T-dependent antigens (foreign proteins), increased formation of autoantibodies and immune complexes (antibodies bound to antigen), and an overall decrease in the immunologic tolerance for the host's own cells, which further diminishes the effectiveness of the immune system later in life. The reproductive system loses ova in women, and spermatogenesis in men is decreased. Responsiveness to hormones decreases in the breast and endometrium.

The stomach experiences decreases in the rate of emptying and secretion of hormones and hydrochloric acid. Muscular atrophy diminishes mobility by decreasing motor tone and contractility. **Sarcopenia,** the loss of muscle mass and strength, can occur into old age. The skin of the aged individual is affected by atrophy and wrinkling of the epidermis and by alterations in underlying dermis, fat, and muscle.

Total body changes include a decrease in height; a reduction in circumference of the neck, thighs, and arms; widening of the pelvis; and lengthening of the nose and ears. Several of these changes are the result of tissue atrophy and decreased bone mass caused by osteoporosis and osteoarthritis. Some body composition changes include an increase in body weight, which begins in middle age (men gain until 50 years of age and women until 70 years), and an increase in fat mass followed by a decrease in stature, weight, **fat-free mass (FFM),** and body cell mass at older ages. FFM includes all minerals, proteins, and water plus all other constituents except lipids. As the amount of fat increases, the percentage of total body water decreases. Increased body fat and centralized fat distribution (abdominal) are associated with non–insulin-dependent diabetes and heart disease. Total body potassium concentration also decreases because of decreased cellular mass. An increased sodium/potassium ratio suggests that the decreased cellular mass is accompanied by an increased extracellular compartment.

Although some of these alterations are probably inherent in aging, others represent consequences of aging. Advanced age increases susceptibility to disease, and death occurs after an injury or insult because of diminished cellular, tissue, and organic function. To determine that an individual "died of old age" would be a monumental if not impossible task.

Frailty

Frailty is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. Recently, investigators hypothesized that the clinical manifestations of frailty include a cycle of negative energy balance, sarcopenia, and diminished strength and tolerance for exertion.[176,177] For research and clinical purposes, the criteria indicating compromised energetics include low grip strength, slowed walking speed, low physical activity, and unintentional weight loss.[177] The syndrome is complex, involving oxidative stress, dysregulation of inflammatory cytokines and hormones, malnutrition, physical inactivity, and muscle apoptosis (see review).[177] Additionally, the clinical condition of frailty includes decreased lean body mass (sarcopenia), osteopenia, cognitive impairment, and anemia.[178] Several physiologic gender differences may explain differing levels of frailty: (1) higher baseline levels of muscle mass for men may be protective against frailty, (2) testosterone and growth hormone can provide advantages in muscle mass maintenance, (3) cortisol is more dysregulated in older women than older men, (4) alterations in immune function and immune responsiveness to sex steroids make men more vulnerable to sepsis and infection and women vulnerable to chronic inflammatory conditions and muscle mass loss, and (5) lower levels of activity and caloric intake may influence greater susceptibility to frailty in women.

SOMATIC DEATH

Somatic death is death of the entire person. Unlike the changes that follow cellular death in a live body, **postmortem change** is diffuse and does not involve components of the inflammatory response. Within minutes of death, manifestations of postmortem change appear, eliminating any difficulty in determining that death has occurred. The most notable manifestations are complete cessation of respiration and circulation. The surface of the skin usually becomes pale and yellowish; however, the lifelike color of the cheeks and lips may persist after death from causes such as carbon monoxide poisoning, drowning, and chloroform poisoning.

Body temperature falls gradually immediately after death and then more rapidly (approximately 1.0° to 1.5° F/hr) until, after 24 hours, body temperature equals that of the environment. After death caused by certain infective diseases, body temperature may continue to rise for a short time. Postmortem reduction of body temperature is called **algor mortis.**

Blood pressure within the retinal vessels decreases, causing muscle tension to decrease and the pupils to become dilated. The face, nose, and chin begin to look "sharp" or "peaked" as blood and fluids drain from these areas. Gravity causes blood to settle in the most dependent, or lowest, tissues, which develop a purple discoloration called **livor mortis.** Incisions at this time usually fail to cause bleeding. The skin loses its elasticity and transparency.

Within 6 hours after death, acidic compounds accumulate within the muscles because of the breakdown of carbohydrate and the depletion of ATP. This interferes with ATP-dependent detachment of myosin from actin (contractile proteins), and muscle stiffening, or **rigor mortis,** develops. The smaller muscles are usually affected first, particularly the muscles of the jaw. Within 12 to 14 hours, rigor mortis usually affects the entire body. Rigor mortis gradually diminishes and the body becomes flaccid in 12 to 14 hours.

Signs of putrefaction—state of decay with foul-smelling odor—are generally obvious about 24 to 48 hours after death. Putrefactive changes vary depending on the temperature of the environment. The most visible is greenish discoloration of the skin, particularly on the abdomen. The discoloration is thought to be related to the diffusion of hemolyzed blood into the tissues and the production of sulfhemoglobin. Slippage or loosening of the skin from underlying tissues occurs at the same time. After this, swelling or bloating of the body and liquefactive changes occur, sometimes causing opening of the body cavities. At a microscopic level, putrefactive changes are associated with the release of enzymes and lytic dissolution called **postmortem autolysis.**

SUMMARY REVIEW

Cellular Adaptation

1. Injury to cells and their surrounding environment, called the extracellular matrix, leads to tissue and organ injury. Cellular adaptation is an alteration that enables the cell to maintain a steady state despite adverse conditions.
2. Atrophy is a decrease in cellular size. The mechanisms probably include decreased protein synthesis, increased protein catabolism, or both.
3. Physiologic atrophy occurs with early development; for example, the thymus gland involutes and atrophies. Pathologic atrophy occurs as a result of decreases in workload, use, pressure, blood supply, nutrition, hormonal stimulation, and nervous stimulation.
4. Aging causes brain cells and endocrine-dependent organs, such as the gonads, to become atrophic.
5. Hypertrophy is an increase in the size of cells caused by increased work demands or hormonal stimulation. Hypertrophy can be physiologic or pathologic. Amounts of protein in the plasma membrane, endoplasmic reticulum, microfilaments, and mitochondria are increased.
6. Hyperplasia is an increase in the number of cells caused by an increased rate of cellular division. Compensatory hyperplasia enables certain organs to regenerate. Hormonal hyperplasia is stimulated by hormones to replace lost tissue or support new growth, such as during pregnancy.
7. Pathologic hyperplasia is the abnormal proliferation of normal cells in response to excessive hormonal stimulation of growth factors on target cells.
8. Dysplasia, or atypical hyperplasia, is an abnormal change in the size, shape, and organization of mature tissue cells.
9. Metaplasia is the reversible replacement of one mature cell type by another less mature cell type. Metaplasia is thought to develop from a reprogramming of stem cells existing in most epithelia or of undifferentiated mesenchymal cells in connective tissue.

Cellular Injury

1. Injury to cells and to the extracellular matrix (ECM) leads to injury of tissues and organs, ultimately determining the structural patterns of disease. Injured cells may recover (reversible injury) or die (irreversible injury).
2. Cellular injury is caused by a lack of oxygen (hypoxia), free radicals, caustic or toxic chemicals, infectious agents, unintentional and intentional injury, inflammatory and immune responses, genetic factors, insufficient nutrients, or physical trauma from many causes. Injurious stimuli cause cell stress.
3. Cell injury can be acute or chronic, and it can be reversible or irreversible. It can involve necrosis, apoptosis, autophagy, accumulation, or pathologic calcification.
4. Four biochemical themes are important to cell injury: (a) depletion of ATP, (b) decreased levels of oxygen and increased levels of oxygen-derived free radicals, (c) increased concentration of intracellular calcium and loss of calcium steady state, and (d) defects in membrane permeability.

SUMMARY REVIEW—cont'd

5. The sequence of events leading to cell death is commonly decreased ATP production, failure of active transport mechanisms (the Na^+-K^+ pump), cellular swelling, detachment of ribosomes from the endoplasmic reticulum, cessation of protein synthesis, mitochondrial swelling as a result of calcium accumulation, vacuolation, leakage of digestive enzymes from lysosomes, autodigestion of intracellular structures, lysis of the plasma membrane, and death.
6. The initial insult in hypoxic injury is usually ischemia—the cessation of blood flow into vessels that supply the cell with oxygen and nutrients.
7. An important mechanism of membrane damage is injury caused by free radicals, including oxidative stress. Free radicals are difficult to control and initiate chain reactions.
8. Free radicals can cause (a) lipid peroxidation or the destruction of unsaturated fatty acids, (b) alterations of proteins, and (c) alterations in DNA.
9. The initial insult in chemical injury is damage or destruction of the plasma membrane. Examples of chemical agents that cause cellular injury include lead, carbon monoxide, ethanol, mercury, and social or street drugs. The leading cause of child poisoning is medications.
10. Unintentional and intentional injuries are an important health problem in the United States. Death caused by injuries is more common in men than women and more prevalent among blacks vs. whites and other racial groups.
11. Injuries by blunt force are the result of the application of mechanical energy to the body resulting in tearing, shearing, or crushing of tissues. The most common types of blunt-force injuries include motor vehicle accidents and falls.
12. Asphyxial injuries are caused by a failure of cells to receive or use oxygen. These injuries can be grouped into four general categories: suffocation, strangulation, chemical asphyxiants, and drowning.
13. Injury from microorganisms lies in their ability to survive and proliferate in the human body. Injury depends on the microorganisms' ability to invade and destroy cells, produce toxins, and produce damaging hypersensitivity reactions.
14. A leading cause of errors in health care is medication errors.
15. Activation of inflammation and immunity, which occurs after cellular injury or infection, involves powerful biochemicals and proteins capable of damaging normal (uninjured and uninfected) cells.
16. Genetic disorders injure cells by altering the nucleus and the plasma membrane's structure, shape, receptors, or transport mechanisms.
17. Deprivation of essential nutrients (proteins, carbohydrates, lipids, vitamins) can cause cellular injury by altering cellular structure and function, particularly of transport mechanisms, chromosomes, the nucleus, and DNA.
18. Injurious physical agents include temperature extremes and climate change, changes in atmospheric pressure, ionizing radiation, illumination, mechanical stresses (e.g., repetitive body movements), and noise.

Manifestations of Cellular Injury

1. Manifestations of cellular injury include accumulations of water, lipids, carbohydrates, glycogen, proteins, pigments, hemosiderin, bilirubin, calcium, and urate.
2. Accumulations harm cells by "crowding" the organelles and by causing excessive (and sometimes harmful) metabolites to be produced during their catabolism. The metabolites are released into the cytoplasm or expelled into the extracellular matrix.
3. Cellular swelling, the accumulation of excessive water in the cell, is caused by the failure of transport mechanisms and is a sign of many types of cellular injury.
4. Accumulations of organic substances—lipids, carbohydrates, glycogen, proteins, and pigments—are caused by disorders in which (a) cellular uptake of the substance exceeds the cell's capacity to catabolize (digest) or use it or (b) cellular anabolism (synthesis) of the substance exceeds the cell's capacity to use or secrete it.
5. Dystrophic calcification (accumulation of calcium salts) is always a sign of pathologic change because it occurs only in injured or dead cells. Free calcium in the cytosol can cause activation of protein kinases, activation of phospholipases and membrane damage, and damage or disassembly of the cytoskeleton. Metastatic calcification, however, can occur in uninjured cells in individuals with hypercalcemia.
6. Disturbances in urate metabolism can result in hyperuricemia and deposition of sodium urate crystals in tissue, leading to a painful disorder called *gout*.
7. Systemic manifestations of cellular injury include fever, leukocytosis, increased heart rate, pain, and serum elevations of enzymes in the plasma.

Cellular Death

1. Two main types of cell death are necrosis and apoptosis. Type I cell death (e.g., caspases) is often referred to as apoptosis, whereas type II is called autophagic cell death.
2. Necrosis is the sum of the changes after local cell death and includes the processes of inflammation and cellular lysis.
3. The four major types of necrosis are coagulative, liquefactive, caseous, and fat. Different types of necrosis occur in different tissues.
4. Structural signs that indicate irreversible injury and progression to necrosis are the dense clumping and disruption of genetic material and the disruption of the plasma and organelle membranes.
5. Gangrenous necrosis, or gangrene, is tissue necrosis caused by hypoxia and subsequent bacterial invasion.
6. Apoptosis, a different type of cellular death, is a process of selective cellular self-destruction called programmed cell death. Other forms of programmed cell death (type II) include autophagic ("eat oneself") cell death.

Aging

1. It is difficult to determine the physiologic (normal) from the pathologic changes of aging. One of the hallmarks of aging is

SUMMARY REVIEW—cont'd

the accumulation of damaged macromolecules. Life span can be experimentally changed.

2. Humans have an inherent maximal life span (80 to 100 years) that is dictated by currently unknown intrinsic mechanisms.
3. Although the maximal life span has not changed significantly over time, the average life span, or life expectancy, has increased. However, this increase in life expectancy in the United States is not experienced by all Americans.
4. The emerging focus in the biology of aging includes epigenetic and genetic changes, inflammatory response, oxidative stress, metabolic and endocrine regulation, intrauterine and lifelong patterns of health, decline in cell renewal by adult stem cells, and accumulated cell damage related to cancer and aging.
5. Frailty is a common clinical syndrome in older adults, leaving a person vulnerable to falls, functional decline, disability, disease, and death. The syndrome is complex, involving oxidative stress, dysregulation of inflammatory cytokines and hormones, malnutrition, physical inactivity, and muscle apoptosis. Women have a higher risk of frailty than men.

Somatic Death

1. Somatic death is death of the entire organism. Postmortem change is diffuse and does not involve the inflammatory response.
2. Manifestations of somatic death include cessation of respiration and circulation, gradual lowering of body temperature, dilation of pupils, loss of elasticity and transparency in the skin, stiffening of muscles (rigor mortis), and discoloration of the skin (livor mortis). Signs of putrefaction are obvious about 24 to 48 hours after death.

CHAPTER OUTLINE

The cells of the body live in a fluid environment that requires electrolyte and acid-base concentrations maintained within a very narrow range. A balance is maintained by an integration of renal, hormonal, and neural functions. Changes in the composition of electrolytes affect electrical potentials of excitatory cells and cause shifts of fluid from one compartment to another that can affect cell function. Fluid fluctuations also affect blood volume and therefore blood pressure. Alterations in pH (measure of the acidity or alkalinity of a solution) disrupt the cellular function of enzyme systems and can cause cell injury. Disturbances in fluid and electrolyte or acid-base balance are common and can be life threatening. Understanding how alterations occur and the body's ability to compensate or correct the disturbance is important for comprehending many pathophysiologic conditions.

DISTRIBUTION OF BODY FLUIDS

The fluids of the body are distributed among functional compartments, or spaces, and provide a transport medium for cellular and tissue function. Water moves freely among body compartments and is distributed by osmotic and hydrostatic forces. Two thirds of the body's water is **intracellular fluid** (**ICF**) and one third is in the **extracellular fluid** (**ECF**) compartments.

The two main ECF compartments are the **interstitial fluid** and the **intravascular fluid,** the latter being the blood plasma. Other ECF compartments include the lymph and the transcellular fluids, such as the saliva, intestinal, biliary, hepatic, pancreatic, and cerebrospinal fluids; sweat; urine; and pleural, synovial, peritoneal, pericardial, and intraocular fluids (Table 3-1).

The sum of fluids within all compartments constitutes the **total body water (TBW)** (Table 3-2). The volume of TBW is usually expressed as a percentage of body weight in kilograms. The standard value for TBW is 60% of the weight of a 70-kg adult male, which is equivalent to 42 L of fluid (Table 3-3). The rest of the body weight is composed of fat and fat-free solids, particularly bone.

Although daily fluid intake may fluctuate widely, the body regulates water volume within a relatively narrow range. The primary sources of body water are drinking of fluids, ingestion of water in food, and derivation of water from oxidative metabolism. Normally, the largest amounts of water are lost through renal excretion. Lesser amounts are eliminated through the stool and through vaporization from the skin and lungs (insensible water loss) (Table 3-4).

Although the amount of fluid within the various compartments is relatively constant, exchange of solutes (e.g., salts) and water occurs between compartments to maintain their unique compositions. The percentage of TBW varies with the amount of body fat and age. Because fat is water repelling (hydrophobic), very little water is contained in adipose cells. Individuals with more body fat have proportionately less TBW and tend to be more susceptible to fluid imbalances that cause dehydration.

AGING AND DISTRIBUTION OF BODY FLUIDS

The distribution and amount of TBW change with age (see Table 3-3). In newborn infants, TBW is about 75% to 80% of body weight because infants store less fat. In the immediate postnatal period, a physiologic loss of body water occurs, equivalent to about 5% of body weight as the infant adjusts to a new environment. Infants are particularly susceptible to significant changes in TBW because of their high metabolic rate and potential for evaporative fluid loss attributable to their greater body surface area in proportion to total body size. Loss of fluids from diarrhea can represent a significant proportion of body weight in infants. Renal mechanisms that regulate fluid and electrolyte conservation may not be mature enough to counter the losses, so dehydration can develop rapidly.

During childhood, TBW slowly decreases to 60% to 65% of body weight. At adolescence the percentage of TBW approaches adult proportions, and gender differences begin to appear. Males eventually have a greater percentage of body water as a function of increasing muscle mass. Females have more body fat and less muscle as a function of estrogens and therefore have less body water.

With increasing age the percentage of TBW declines further still. The decrease is caused in part by an increased amount of fat

TABLE 3-1 APPROXIMATE CONCENTRATIONS OF ELECTROLYTES IN TRANSCELLULAR FLUIDS

FLUID	NA^+ (mEq/L)	K^+ (mEq/L)	CL^- (mEq/L)	HCO_3^- (mEq/L)
Saliva	33	20	34	40
Gastric juice*	60	9	84	0
Bile	149	5	101	45
Pancreatic juice	141	5	77	92
Ileal fluid	129	11	116	29
Cecal fluid	80	21	48	22
Cerebrospinal fluid	141	3	127	23
Sweat	45	5	58	0

*The Cl^- concentration exceeds the Na^+, K^+ concentration by 15 mEq/L in gastric juice. This largely represents the secretions of hydrochloric acid by parietal cells.

TABLE 3-2 DISTRIBUTION OF BODY WATER

	PERCENTAGE OF BODY WEIGHT	VOLUME (L)
Intracellular fluid (ICF)	40	28
Extracellular fluid (ECF)	20	14
Interstitial	(15)	(11)
Intravascular	(5)	(3)
Total body water (TBW)	60	42

TABLE 3-3 TOTAL BODY WATER* IN RELATION TO BODY WEIGHT

BODY BUILD	TBW (%) ADULT MALE	TBW (%) ADULT FEMALE	TBW (%) INFANT
Normal	60	50	70
Lean	70	60	80
Obese	50	42	60

*NOTE: TBW (total body water) is a percentage of body weight.

TABLE 3-4 NORMAL WATER GAINS AND LOSSES (70-KG MAN)

	DAILY INTAKE (ML)		DAILY OUTPUT (ML)
Drinking ≈60%	1400-1800	Urine ≈60%	1400-1800
Water in food ≈30%	700-1000	Stool ≈2%	100
Water of oxidation ≈10%	300-400	Skin ≈10%	300-500
		Lungs ≈28%	600-800
TOTAL	2400-3200		2400-3200

and a decreased amount of muscle and by a reduced ability to regulate sodium and water balance. With older age the kidneys becomes less efficient at conserving sodium and therefore have difficulty concentrating the urine. Insensible water loss through the skin may increase and thirst perception may be impaired. The normal reduction of TBW in older adults becomes clinically important when the body is under stress, such as development of fever or dehydration; loss of body fluids at such times can be severe and life threatening.[1]

Water Movement Between ICF and ECF

The movement of water between ICF and ECF compartments is primarily a function of osmotic forces. (Osmosis and other mechanisms of passive transport are discussed in Chapter 1.) Water moves freely by diffusion through the lipid bilayer cell membrane and through **aquaporins,** a family of water channel proteins that provide permeability to water.[2] The osmolality (number of osmoles of solute per kilogram of fluid [Osm/kg]) of TBW is normally at equilibrium. Sodium is responsible for the osmotic balance of the ECF space. Potassium maintains the osmotic balance of the ICF space. The osmotic force of ICF proteins and other nondiffusible substances is balanced by the active transport of ions out of the cell. Water crosses cell membranes freely so the osmolality of TBW is normally at equilibrium. Normally the ICF is not subject to rapid changes in osmolality but when ECF osmolality changes, water moves from one compartment to another until osmotic equilibrium is reestablished (see Figure 3-6, p. 110).

Water Movement Between Plasma and Interstitial Fluid

The distribution of water and the movement of nutrients and waste products between the plasma in the tissue capillaries and interstitial spaces occur as a result of changes in hydrostatic pressure and osmotic forces at the arterial and venous ends of the capillary. Water, sodium, and glucose move readily across the capillary membrane. The plasma proteins maintain the effective osmolality (concentration of solutes per kilogram of solution), do not cross the capillary membrane, and generate plasma oncotic pressure. Albumin is the plasma protein that is primarily responsible for the plasma oncotic pressure because it has the highest concentration. Osmotic forces within the capillary are balanced by the hydrostatic pressure, which is primarily determined by blood pressure and blood volume.

As plasma flows from the arterial to the venous end of the capillary, four forces determine if fluid moves out of the capillary and into the interstitial space (filtration) or if fluid moves back into the capillary from the interstitial space (reabsorption):

1. **Capillary hydrostatic pressure (blood pressure)** facilitates the outward movement of water from the capillary to the interstitial space.
2. **Capillary (plasma) oncotic pressure** osmotically attracts water from the interstitial space back into the capillary.
3. **Interstitial hydrostatic pressure** facilitates the inward movement of water from the interstitial space into the capillary.
4. **Interstitial oncotic pressure** osmotically attracts water from the capillary into the interstitial space.

The movement of fluid back and forth across the capillary wall is called **net filtration** and is best described by the **Starling hypothesis:**

Net filtration = (Forces favoring filtration) − (Forces opposing filtration)

Forces favoring filtration = Capillary hydrostatic pressure and interstitial oncotic pressure

Forces opposing filtration = Capillary oncotic pressure and interstitial hydrostatic pressure

Normally the interstitial forces are negligible because only a very small percentage of plasma proteins crosses the capillary membrane and interstitial fluid moves into cells or is drawn back into the plasma. Thus the major forces for filtration are within the capillary.

As the plasma flows from the arterial to the venous end of the capillary, the force of hydrostatic pressure facilitates the movement of water across the capillary membrane. Oncotic pressure remains fairly constant because plasma proteins normally do not cross the capillary membrane. At the arterial end of the capillary, hydrostatic pressure is greater than capillary oncotic pressure and water filters into the interstitial space. Because of oncotic forces, some water moves back into the capillary, but the net effect is loss of water from the capillary. This loss of water from the plasma decreases the hydrostatic pressure within the capillary; thus at the venous end of the capillary, oncotic pressure exceeds hydrostatic pressure. Fluids then are attracted back into the circulation, balancing the movement of fluids between the plasma and the interstitial space. The overall effect is filtration at the arterial end and reabsorption at the venous end (Figure 3-1). Interstitial hydrostatic pressure promotes the movement of about 10% of the interstitial fluid along with small amounts of protein into the lymphatics, which eventually returns to the circulation.

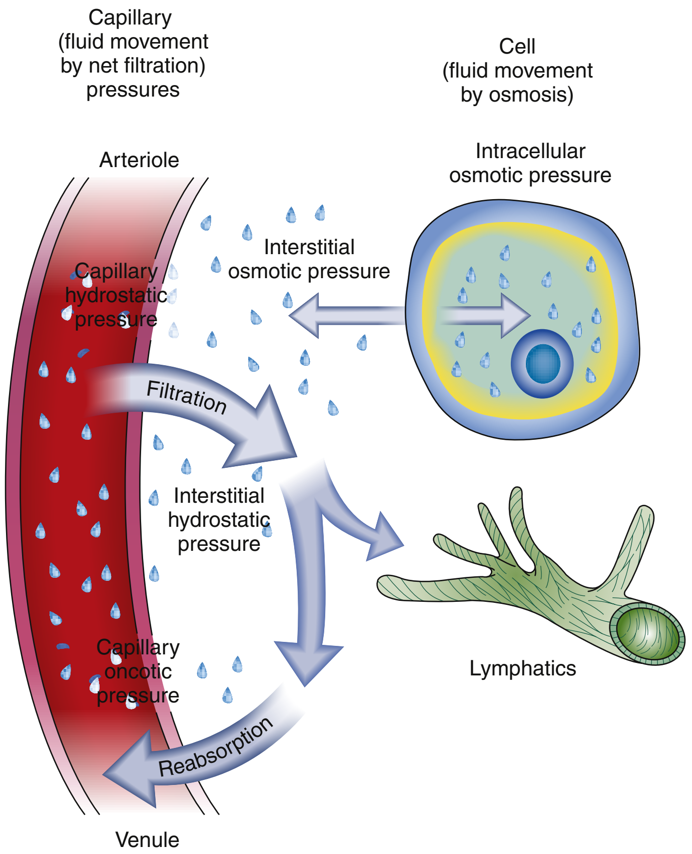
An important factor in capillary filtration of fluid is the integrity of the capillary membrane. Changes in membrane permeability may permit the escape of plasma proteins into the interstitial space. The normal relationship defined by the Starling hypothesis is altered with the osmotic movement of water into the interstitial space, causing tissue edema.

ALTERATIONS IN WATER MOVEMENT

Edema

Edema is the excessive accumulation of fluid within the interstitial spaces. It is often a problem of fluid distribution and does not necessarily indicate a fluid excess. In some conditions, sequestered fluids can cause both edema and intravascular dehydration. The pathophysiologic process of edema is related to an increase in the forces favoring fluid filtration from the capillaries or lymphatic channels into the tissues. The four most common mechanisms are:

1. Increased capillary hydrostatic pressure
2. Decreased plasma oncotic pressure
3. Increased capillary membrane permeability
4. Lymphatic obstruction (Figure 3-2)



Arterial Capillary Pressures		Venous Capillary Pressures	
Capillary hydrostatic pressure	35 mmHg	Capillary hydrostatic pressure	18 mmHg
Interstitial fluid hydrostatic pressure	2 mmHg	Interstitial fluid hydrostatic pressure	1 mmHg
Net hydrostatic pressure	**33 mmHg**	**Net hydrostatic pressure**	**17 mmHg**
Capillary oncotic pressure	24 mmHg	Capillary oncotic pressure	25 mmHg
Interstitial fluid oncotic pressure	0 mmHg	Interstitial fluid oncotic pressure	0 mmHg
Net oncotic pressure	**24 mmHg**	**Net oncotic pressure**	**25 mmHg**
Net filtration pressure	**19 mmHg**	**Net filtration pressure**	**28 mmHg**

FIGURE 3-1 Capillary Filtration Forces. Water, electrolytes, and small molecules exchange freely between the vascular compartment and the interstitial space at the site of capillaries and small venules. The rate and amount of exchange are driven by the physical forces of hydrostatic and oncotic pressures and the permeability and surface area of the capillary membranes. The two opposing hydrostatic pressures are capillary hydrostatic pressure and interstitial hydrostatic pressure. The two opposing oncotic pressures are capillary oncotic pressure and interstitial oncotic pressure. The *forces that favor filtration* from the capillary are capillary hydrostatic pressure and interstitial oncotic pressure, and the *forces that oppose filtration* are capillary oncotic pressure and interstitial hydrostatic pressure. The sum of their effects is known as *net filtration pressure* (NFP). In the example of normal exchange illustrated here, a small amount of fluid moves to the lymph vessels, which accounts for the net filtration difference between the arterial and venous ends of the capillary.

PATHOPHYSIOLOGY. **Increased capillary hydrostatic pressure** can result from venous obstruction or sodium and water retention. Venous obstruction causes hydrostatic pressure to increase behind the obstruction, pushing fluid from the capillaries into the interstitial spaces. Venous blood clots, hepatic obstruction, right heart failure, tight clothing around the extremities, and prolonged standing are common causes of venous obstruction. Right congestive heart failure, renal failure, and cirrhosis of the liver are conditions associated with excessive sodium and water retention, which in turn cause volume overload, increased venous pressure, and edema.

Decreased plasma oncotic pressure results from *losses or diminished production of plasma albumin*. Decreased oncotic

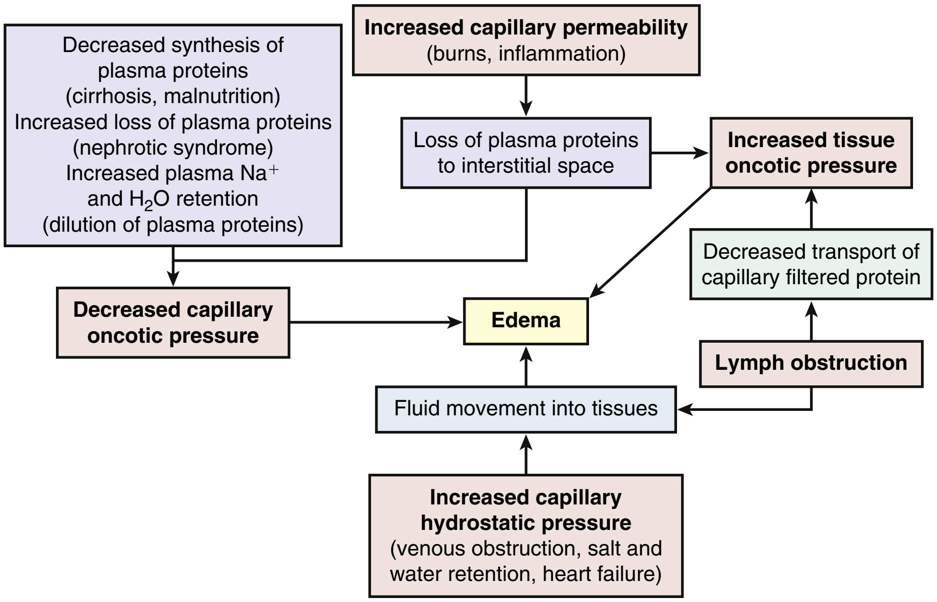


FIGURE 3-2 Mechanisms of Edema Formation.

attraction of fluid within the capillary causes fluid to move into the interstitial space, resulting in edema. Decreased synthesis of plasma protein and decreased oncotic pressure may occur with liver disease or protein malnutrition. Losses of plasma proteins occur with glomerular diseases of the kidney (nephrotic syndrome), hemorrhage, and serous drainage from open wounds or burns.

Increased capillary permeability is usually associated with *inflammation and the immune response*. (Immunity is discussed in Chapters 7, 8, and 9; inflammation is discussed in Chapters 7 and 9.) These responses are often the result of trauma such as burns or crushing injuries, neoplastic disease, allergic reactions, and infection. Excess amounts of fluid escape from the plasma to the interstitial space and produce edema. This type of edema is often very severe because of loss of proteins from the vascular space, which decreases capillary oncotic pressure and increases interstitial oncotic pressure.

Lymphatic obstruction occurs when the *lymphatic channels are blocked* because of infection or tumor. Proteins and fluids are not reabsorbed and accumulate in the interstitial space, causing **lymphedema.** Lymphedema of the arm or leg also can occur after surgical removal of axillary or femoral lymph nodes, respectively, for treatment of cancer.[3]

CLINICAL MANIFESTATIONS. Edema may be localized or generalized. Some *localized edema* is usually limited to the site of tissue injury, as in a sprained joint. Local edema can also occur within particular organs, causing, for example, cerebral edema in the brain and pulmonary edema in the lungs. Edema of specific organs, such as the brain, lung, or larynx, can be life threatening.

Generalized edema is manifested by a more uniform distribution of fluid in interstitial spaces throughout the body. *Dependent edema,* in which fluid accumulates in gravity-dependent areas of the body, might appear in the feet and legs when standing and in the sacral area and buttocks when supine. Dependent edema can be identified by using the fingers to press away edematous fluid in tissues overlying bony prominences. A pit will be left in the skin; hence the term *pitting edema* (Figure 3-3).

FIGURE 3-3 Pitting Edema. (From Bloom A, Ireland J: *Color atlas of diabetes,* ed 2, St Louis, 1992, Mosby.)

Edema is usually associated with swelling and puffiness, tight-fitting clothes and shoes, and limited movement of the affected area. Weight gain can be significant. The accumulation of fluid increases the distance required for nutrients, oxygen, and wastes to move between capillaries and cells in the tissues. Increased tissue pressure also may diminish capillary blood flow, leading to ischemia. Therefore, wounds heal more slowly and formation of pressure sores increases (see Chapter 46).

As edematous fluid accumulates, it is trapped in a "third space" (i.e., the interstitial space) and dehydration can develop as a result of this sequestering of fluid. Such sequestration

occurs with severe burns, in which large amounts of vascular fluid are lost to the interstitial spaces, reducing plasma volume and causing shock (see Chapter 48).

EVALUATION AND TREATMENT. Specific conditions causing edema require diagnosis. Edema may be treated symptomatically until the underlying disorder is corrected. Supportive measures include elevating edematous limbs, using compression stockings or devices, avoiding prolonged standing, restricting salt intake, and taking diuretics.

SODIUM, CHLORIDE, AND WATER BALANCE

The kidneys and hormones have a central role in maintaining sodium and water balance. Because water follows the osmotic gradients established by changes in salt concentration, sodium balance and water balance are intimately related. Sodium is regulated by the renal effects of aldosterone from the adrenal cortex and natriuretic peptides from the heart. Water balance is primarily regulated by antidiuretic hormone (ADH; also known as *arginine-vasopressin*) from the posterior pituitary.

TABLE 3-5 DISTRIBUTION OF ELECTROLYTES IN BODY COMPARTMENTS

	EXTRACELLULAR FLUID (mEq/L)	INTRACELLULAR FLUID (mEq/L)
Cations		
Sodium	142	10
Potassium	5	156
Calcium	5	4
Magnesium	2	26
TOTAL	154	196
Anions		
Bicarbonate	24	12
Chloride	104	4
Phosphate	2	40-95
Proteins	16	54
Other anions	8	31-86
TOTAL	154	196 (average)

Sodium and Chloride Balance

Sodium accounts for 90% of the ECF cations (positively charged ions). The distribution of electrolytes in body compartments is summarized in Table 3-5 and the concentration of electrolytes is summarized in Table 3-1. As the most abundant ECF cation, along with its constituent anions (negatively charged ions) chloride and bicarbonate, sodium regulates extracellular osmotic forces and therefore regulates water balance. Sodium is important in other body functions, including maintenance of neuromuscular irritability for conduction of nerve impulses (in conjunction with potassium and calcium), regulation of acid-base balance (through sodium bicarbonate and sodium phosphate), participation in cellular chemical reactions, and transport of substances across the cellular membrane (see Chapter 1).

The kidney, in conjunction with neural and hormonal mediators, maintains normal serum sodium concentration within a narrow range (135 to 145 mEq/L) primarily through renal tubular reabsorption. The average dietary intake of sodium ranges from 5 to 6 g/day; the minimal daily requirement of sodium is 500 mg. Sweating depletes sodium and water volume and increases the body's sodium requirement.

Hormonal regulation of sodium balance is mediated by **aldosterone,** a mineralocorticoid (steroid) synthesized and secreted from the adrenal cortex as the end product of the renin-angiotensin-aldosterone system (Figure 3-4) (also see Chapters 21 and 37). When circulating blood pressure and renal blood flow, or serum sodium concentrations, are reduced, **renin,** an enzyme secreted by the juxtaglomerular cells of the kidney, is released. Renin stimulates the formation of **angiotensin I,** an

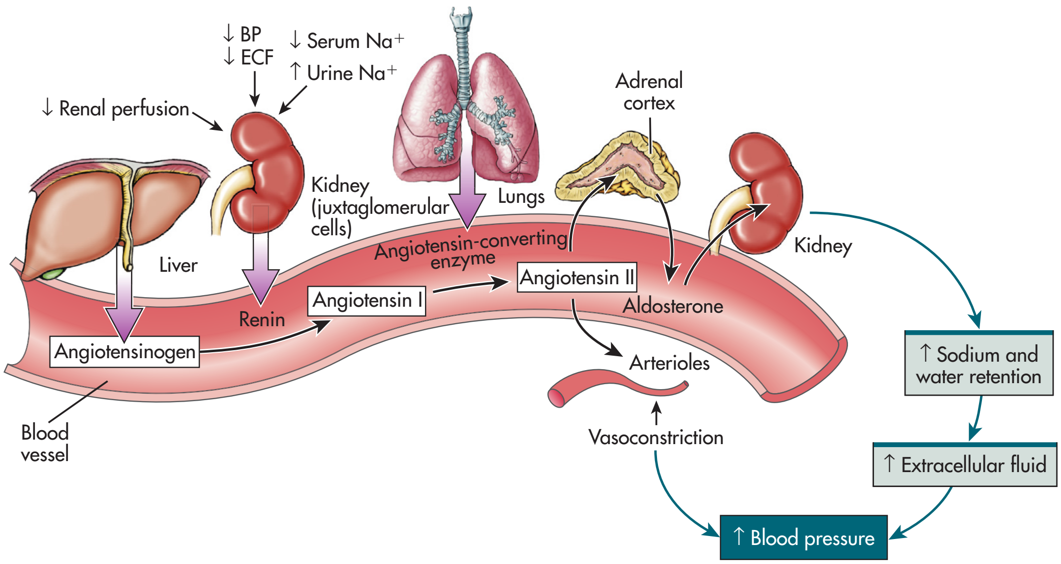

FIGURE 3-4 The Renin-Angiotensin-Aldosterone System. *BP,* Blood pressure; *ECF,* extracellular fluid; *Na,* sodium. (From Lewis et al: *Medical-surgical nursing: assessment and management of clinical problems,* ed 8, St. Louis, 2011, Mosby.)

inactive polypeptide. Angiotensin-converting enzyme (ACE) in pulmonary vessels converts angiotensin I to angiotensin II. **Angiotensin II** has two major functions: it causes vasoconstriction, which elevates systemic blood pressure, and it stimulates the secretion of aldosterone. Aldosterone promotes sodium and water reabsorption by the proximal tubules of the kidneys, thus conserving sodium, blood volume, and blood pressure. Aldosterone also stimulates secretion (and therefore excretion) of potassium by the distal tubule of the kidney, reducing potassium concentrations in the ECF. The restoration of sodium levels, blood volume, and renal perfusion then inhibits further release of renin.

Natriuretic peptides are hormones that include atrial natriuretic peptide (ANP) produced by myoendocrine atrial cells, brain natriuretic peptide (BNP—named brain since it was first discovered in porcine brain) produced by myoendocrine ventricular cells, and urodilatin (an ANP analog) synthesized within the kidney. ANP and BNP are released when there is an increase in transmural atrial pressure caused by increased intra-atrial volume as may occur with heart failure.[4] ANP and BNP increase sodium and water excretion by the kidneys, which lowers blood volume and pressure. Urodilatin is released from distal tubular kidney cells when there is increased arterial pressure and increased renal blood flow. These hormones are natural antagonists to the renin-angiotensin-aldosterone system. The restoration of lower atrial pressure then inhibits further release of ANP and BNP.

Chloride is the major anion in the ECF and provides electroneutrality, particularly in relation to sodium. Chloride transport is generally passive and follows the active transport of sodium so that increases or decreases in chloride are proportional to changes in sodium. Chloride concentration tends to vary inversely with changes in the concentration of bicarbonate (HCO_3^-), the other major ECF anion.

Water Balance

One manner by which water balance is regulated is through the perception of thirst. Thirst is a sensation that stimulates water-drinking behavior. Thirst is experienced when water loss equals 2% of an individual's body weight or when there is an increase in osmolality. Dry mouth, hyperosmolality, and plasma volume depletion activate hypothalamic **osmoreceptors.** The action of the osmoreceptors then causes thirst. Drinking water restores plasma volume and dilutes the ECF osmolality.

Water balance also is directly regulated by **antidiuretic hormone (arginine-vasopressin),** which is secreted when plasma osmolality increases or circulating blood volume decreases and blood pressure drops (Figure 3-5). Increased plasma osmolality occurs with a water deficit or sodium excess in relation to water. The increased osmolality stimulates hypothalamic osmoreceptors. In addition to causing thirst, the stimulated osmoreceptors signal the posterior pituitary to release ADH. The action of ADH is to increase the permeability of renal tubular cells to water, increasing water reabsorption and promoting the restoration of plasma volume and blood pressure. Urine concentration increases, and the reabsorbed water decreases plasma osmolality, returning it toward normal. Like most hormones, ADH is regulated by a feedback mechanism. The restoration of plasma osmolality, blood volume, and blood pressure then inhibits ADH secretion.

With fluid loss (dehydration) (e.g., from vomiting, diarrhea, or excessive sweating), a decrease in blood volume and blood pressure often occurs. **Baroreceptors (volume/pressure sensitive receptors)** (stretch receptors that are sensitive to changes in arterial volume and pressure) also stimulate the release of ADH. Baroreceptors are located in the right and left atria and large veins, and in the aorta, pulmonary arteries, and carotid sinus. When arterial and atrial pressure drops baroreceptors signal the hypothalamus to release ADH. The reabsorption of water mediated by ADH then promotes the restoration of plasma volume and blood pressure (see Figure 3-5). ADH also stimulates arterial vasoconstriction.

ALTERATIONS IN SODIUM, CHLORIDE, AND WATER BALANCE

Alterations in sodium and water balance are closely related. Water imbalances may develop because of changes in osmotic gradients caused by gain or loss of salt. Likewise, sodium imbalances occur with alterations in body water volume. Generally the alterations can be classified as changes in tonicity, or the change in concentration of electrolytes in relation to water (see Chapter 1). Alterations can therefore be classified as isotonic, hypertonic, or hypotonic (Table 3-6 and Figure 3-6).

Isotonic Alterations

The term **isotonic** refers to a solution that has the same concentration of solutes as the plasma. Isotonic alterations occur when changes in TBW are accompanied by proportional changes

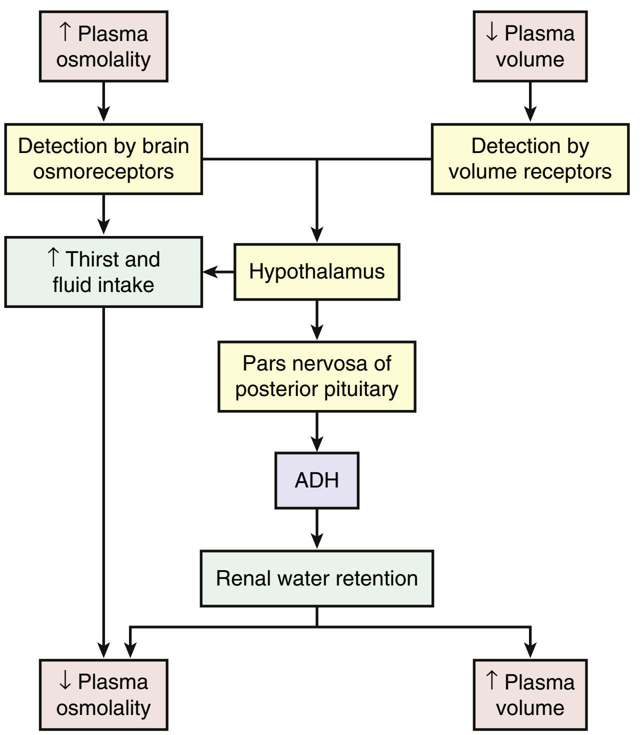

FIGURE 3-5 The Antidiuretic Hormone (ADH) System.

in the amounts of electrolytes and water. For example, if an individual loses pure plasma or ECF, fluid volume is depleted but the number and type of electrolytes (e.g., sodium) and the osmolality remain within a normal range. Excessive amounts of isotonic body fluids can result from excessive administration of intravenous normal saline (0.9% NaCl) or oversecretion of aldosterone with renal retention of both sodium and water. *Isotonic fluid loss* results in hypovolemia. Causes include hemorrhage, severe wound drainage, and excessive diaphoresis (sweating). Loss of extracellular volume results in weight loss, dryness of skin and mucous membranes, decreased urine output, increased hematocrit value, and symptoms of hypovolemia. Indicators of hypovolemia include a rapid heart rate and flattened neck veins, and can present with a normal or decreased blood pressure. In severe states, hypovolemic shock (severe hypotension) can occur (see Chapter 48).

Isotonic fluid excesses result in hypervolemia. Causes include excessive administration of intravenous fluids, hypersecretion of aldosterone, the effects of drugs such as cortisone, or renal failure. Weight gain and a decrease in hematocrit level and plasma protein concentration caused by the diluting effect of excess plasma volume will occur. The neck veins may distend, and the blood pressure increases. Increased capillary hydrostatic pressure leads to edema formation. If the plasma volume is great enough, pulmonary edema and heart failure develop.

TABLE 3-6 WATER AND SOLUTE IMBALANCES

TONICITY	MECHANISM
Isotonic (isoosmolar) imbalance	Gain or loss of extracellular fluid (ECF) resulting in a concentration equivalent to a 0.9% sodium chloride (salt) solution (normal saline); no shrinking or swelling of cells
Hypertonic (hyperosmolar) imbalance	Imbalance that results in an ECF concentration >0.9% salt solution; that is, water loss or solute gain; cells shrink in a hypertonic fluid
Hypotonic (hypoosmolar) imbalance	Imbalance that results in an ECF <0.9% salt solution; that is, water gain or solute loss; cells swell in a hypotonic fluid

Hypertonic Alterations

Hypertonic fluid alterations develop when the osmolality of the ECF is elevated above normal (greater than 294 mOsm). The most common causes are an increased concentration of ECF sodium (hypernatremia) or a deficit of ECF free water. In both instances the hypertonicity of the ECF attracts water from the intracellular space, causing ICF dehydration. A primary increase

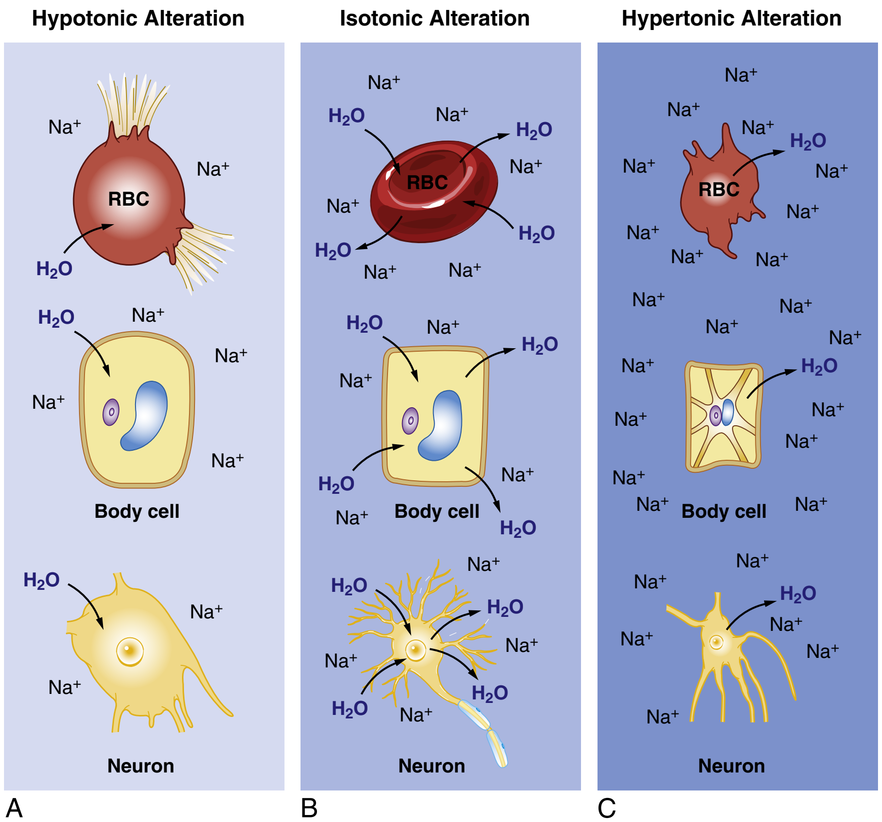

FIGURE 3-6 Effects of Alterations in Extracellular Sodium Concentration in RBC, Body Cell, and Neuron. **A,** *Hypotonic Alteration:* Decrease in ECF sodium (Na) concentration (hyponatremia) results in ICF osmotic attraction of water with swelling and potential busting of cells. **B,** *Isotonic Alteration:* Normal concentration of sodium in the ECF and no change in shifts of fluid in or out of cells. **C,** *Hypertonic Alteration:* An increase in ECF sodium concentration (hypernatremia) results in osmotic attraction of water out of cells with cell shrinkage. *RBC,* Red blood cell.

in the amount of ECF sodium causes an osmotic attraction of water and symptoms of *hypervolemia*. In contrast, a hypertonic state caused primarily by free water loss leads to *hypovolemia* (Table 3-7).

Hypernatremia

PATHOPHYSIOLOGY. **Hypernatremia** occurs when serum sodium levels exceed 147 mEq/L. Increased serum sodium concentration may be caused by loss of water (most common) or an acute gain in sodium. With water loss, both ICF dehydration and ECF dehydration occur. Hyperosmolality is a common result of hypernatremia. Because sodium is largely in the ECF, increases in the concentration of sodium cause intracellular dehydration and hypervolemia (see Table 3-7 and Figure 3-6, *C*).

Increased sodium concentration caused by water deprivation or water loss is associated with fever or respiratory tract infections, which increase the respiratory rate and enhance water loss from the lungs. Diabetes insipidus (deficiency of ADH), polyuria (frequent urination), profuse sweating, and diarrhea cause water loss in relation to sodium concentration. Infants with severe diarrhea are particularly vulnerable. Insufficient water intake also can cause hypernatremia (e.g., individuals who are immobilized or receiving gastric feedings, those who are comatose or confused, or infants because they cannot communicate thirst).

Increased sodium retention occurs because of (1) inappropriate administration of hypertonic saline solution (e.g., as sodium bicarbonate for treatment of acidosis during cardiac arrest); (2) oversecretion of aldosterone (as in primary hyperaldosteronism), where sodium reabsorption exceeds water reabsorption; or (3) Cushing syndrome (caused by excess secretion of adrenocorticotropic hormone [ACTH], which also causes increased secretion of aldosterone). High amounts of dietary sodium rarely cause hypernatremia in a healthy individual because the sodium is eliminated by the kidneys. However, increased amounts of dietary sodium (greater than 5 grams per day) is associated with cardiovascular disease (see Chapter 32).

CLINICAL MANIFESTATIONS. Water is redistributed to the extracellular space, and intracellular dehydration ensues. Thirst, fever, dry mucous membranes, hypotension, tachycardia, low jugular venous pressure, and restlessness are associated with hypernatremia as a result of water loss. Pulmonary edema occurs when water shifts from the ICF to the interstitial space. Central nervous system symptoms are the most serious and are related to alterations in membrane potentials and shrinking of brain cells. Symptoms include muscle twitching and hyperreflexia (hyperactive reflexes), confusion, coma, convulsions, and cerebral hemorrhage from stretching of veins.

EVALUATION AND TREATMENT. The serum sodium level is usually more than 147 mEq/L. If there is water loss, urine specific gravity will be greater than 1.030 and the levels of hematocrit and plasma proteins will be elevated. The treatment of hypernatremia is to give an isotonic salt-free fluid (5% dextrose in water) until the serum sodium level returns to normal.[5] Fluid replacement must be given slowly to prevent cerebral edema and serum sodium levels need to be closely monitored. Hypervolemia and hypovolemia require treatment of the underlying clinical condition.

TABLE 3-7 CAUSES AND CONSEQUENCES OF HYPERTONIC IMBALANCES

CAUSATIVE FACTOR	MECHANISM	ECF EFFECTS	ICF EFFECTS
Increased sodium (hypernatremia)	Excessive hypertonic salt solutions Intravenous hypertonic sodium Saline-induced abortions Selected infant formulas Hyperaldosteronism Cushing syndrome	Hypervolemia Weight gain Bounding pulse Increased blood pressure Edema Venous distention Neuromuscular symptoms Muscle weakness Seizures	Intracellular dehydration Thirst Fever Decreased urine output Shrinkage of brain cells Confusion Coma Cerebral hemorrhage
Water deficit	Water deprivation Confusion or coma Inability to communicate Loss of thirst Water loss Watery diarrhea Diabetes insipidus Excessive diuresis Excessive diaphoresis	Hypovolemia Weight loss Weak pulses Postural hypotension Tachycardia	Intracellular dehydration See above

TABLE 3-8 CAUSES AND CONSEQUENCES OF HYPOTONIC IMBALANCES

CAUSATIVE FACTOR	MECHANISM	ECF EFFECTS	ICF EFFECTS
Decreased sodium (hyponatremia)	Inadequate intake Hypoaldosteronism Excessive diuretic therapy Furosemide Ethacrynic acid Thiazides	Extracellular volume contraction and hypovolemia (but may not if there is water excess)	Increased intracellular water; edema Brain cell swelling, irritability, depression, confusion Systemic cellular edema, including weakness, anorexia, nausea, and diarrhea
Water excess	Excessive pure water intake Excessive administration of hypotonic intravenous solutions Drinking water to replace isotonic fluid losses Tap water enemas Psychogenic polydipsia Renal water retention Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)	Extracellular volume expands with hypervolemia (but may not if fluid is trapped in intracellular space)	Edema (see above)
Other factors	Isotonic dehydration treated with intravenous D_5W; glucose in D_5W solution is metabolized to water, contributing to hyponatremia Nephrotic syndrome Cirrhosis Cardiac failure	Hypervolemia or hypovolemia	Edema (see above)

D_5W, Dextrose 5% in water; *ECF,* extracellular fluid; *ICF,* intracellular fluid.

Hyperchloremia

Because chloride follows sodium, **hyperchloremia** (elevation of serum chloride concentration greater than 105 mEq/L) often accompanies hypernatremia, as well as plasma bicarbonate deficits, as in hyperchloremic metabolic acidosis (see p. 126). There are no specific symptoms or treatment for chloride excess and treatment is related to management of the underlying disorder.

Water Deficit

PATHOPHYSIOLOGY. **Dehydration** refers to water deficit, but also is commonly used to indicate both sodium and water loss (isotonic or isoosmolar dehydration). **Pure water deficits** (hyperosmolar or hypertonic dehydration) are rare because most people have access to water. Individuals who are comatose or paralyzed continue insensible water losses through the skin and lungs with a minimal obligatory formation of urine. Hyperventilation caused by fever also may precipitate water deficit. The most common cause of water loss is increased renal clearance of free water as a result of impaired tubular function or inability to concentrate the urine, as with diabetes insipidus (decreased or absent ADH) (see Table 3-7 and Chapter 22).

CLINICAL MANIFESTATIONS. Marked water deficit is manifested by symptoms of dehydration: headache, thirst, dry skin and mucous membranes, weight loss, decreased urine output, and concentrated urine (with the exception of diabetes insipidus). Skin turgor may be normal or decreased. Symptoms of hypovolemia, including tachycardia, weak pulses, and postural hypotension, may be present.

EVALUATION AND TREATMENT. Elevated levels of hematocrit, serum sodium concentration, urine and serum osmolality, and urine specific gravity are associated with moderate water loss.

Treatment is to give water and stop fluid loss. Fluid replacement must be given slowly enough to prevent rapid movement of water into brain cells, which causes cerebral edema, seizures, brain injury, and death. When intravenous replacement is required, hypotonic saline solutions or 5% dextrose in water is used because pure water lyses red blood cells.

Hypotonic Alterations

Hypotonic fluid imbalances occur when the osmolality of the ECF is less than normal (less than 280 mOsm). The most common causes are sodium deficit (hyponatremia) or free water excess (water intoxication). Both causes lead to an intracellular overhydration (cellular edema) and cell swelling when water moves into the cell, where the osmotic pressure is greater (see Figure 3-6, *A*). Cerebral and pulmonary edema occur in conjunction with these fluid shifts.[6] With hyponatremia, the plasma volume then decreases, leading to symptoms of hypovolemia. With free water excess, the ECF volume is elevated, causing symptoms of hypervolemia (Table 3-8).

Hyponatremia

PATHOPHYSIOLOGY. **Hyponatremia** develops when the serum sodium concentration decreases to less than 135 mEq/L. It is the most common electrolyte disorder in hospitalized individuals.[7] Hyponatremia may be caused by sodium loss, inadequate sodium intake, or dilution of the body's sodium level. Clinical syndromes

WHAT'S NEW?

Hyponatremia and Hospitalization

Hyponatremia (serum sodium concentration <135 mmol/L) and severe hyponatremia (serum sodium concentration <120 mmol/L) are the most common electrolyte abnormalities among hospitalized individuals with risk for severe morbidity and mortality. Hyponatremia can be difficult to diagnose because it can develop with euvolemia, hypervolemia, or hypovolemia. In addition to older adults, children and premenopausal women are at particular risk as well as those receiving treatment in intensive care units and persons with cirrhosis with ascites, heart failure syndromes, brain injury, sepsis, or multiple organ failure. Death or brain damage may range from 50% to 83% and is related to cerebral edema, increased intracranial pressure, and cerebral hypoxemia, with symptoms of seizure, respiratory arrest, coma, and death. Use of thiazide diuretics is a common cause of hyponatremia and can occur within 2 weeks of initiation of treatment. Postoperative hyponatremia is caused by administration of hypotonic fluids and dysregulation of the secretion of antidiuretic hormone (arginine-vasopressin). Treatment with fluid restriction, diuretic treatment, sodium replacement, and urea administration is effective in less severe cases. Hypertonic sodium chloride is usually safe with acute hyponatremia. Brain myelinolysis is a risk if treatment is given too rapidly. Arginine-vasopressin receptor antagonists (vaptans) can provide effective treatment and they work by increasing blood flow to the kidney with increased urine formation without loss of electrolytes. Vaptans are contraindicated in hypovolemic hyponatremia. Frequent monitoring with attention to subtle symptoms and early treatment lead to improved outcomes.

Data from Aperis G, Alivanis P: *Rev Recent Clin Trials* 6(2):177–188, 2011; Chawla A et al: *Clin J Am Soc Nephrol* 6(5):960–965, 2011; Elhassan EA, Schrier RW: *Exp Opin Investig Drugs* 20(3):373–380, 2011; Human T: *Pharmacother* 31(5 Suppl):18S–24S, 2011; Robertson GL: *Nat Rev Endocrinol* 7(3):151–161, 2011; Pfennig CL, Slovis CM: *Emerg Med Pract* 14(10):1–26, 2012; Vaishya R et al: *J Indian Med Assoc* 110(2):94–97, 2012; Konishi M et al: *J Card Fail* 18(8):620–625, 2012; Lindner G, Schwarz C: *Minerva Med* 103(4):279–291, 2012.

that may cause hyponatremia include syndrome of inappropriate secretion of antidiuretic hormone (SIADH, excess ADH) or failure of the distal tubules to reabsorb sodium. Sodium deficits usually cause hypoosmolality and water moves into cells, resulting in cell swelling (see Figure 3-6, *A*, and What's New? Hyponatremia and Hospitalization).

Pure sodium deficits are usually caused by diuretics[8] and extrarenal losses such as vomiting, diarrhea, gastrointestinal suctioning, or burns. **Inadequate intake of dietary sodium** is rare but can occur in individuals consuming low-sodium diets, particularly among those taking diuretics. **Dilutional hyponatremias** occur when there is an excess of TBW in relation to total body sodium or a shift of water from the ICF to the ECF space (e.g., administration of mannitol). Replacement of fluid loss with intravenous 5% dextrose in water also can cause a dilutional hyponatremia because once the glucose is metabolized, a hypotonic solution remains with a diluting effect. Use of excess hypotonic saline (e.g., 0.45% NaCl) may also result in dilution. In addition, excessive sweating may stimulate thirst and intake of large amounts of water, which dilute sodium; this condition may be associated with endurance exercise in which there is only pure water replacement.

Hyponatremia may cause hypotonic or hypertonic alterations. During acute oliguric renal failure, severe congestive heart failure, or cirrhosis, renal excretion of water is impaired. Both TBW and sodium levels are increased, but TBW level exceeds the increase in sodium level, producing a **hypotonic hyponatremia. Hypertonic hyponatremia** develops with the shift of water from the ICF to the ECF as occurs with hyperglycemia, hyperlipidemia, and hyperproteinemia. The osmotic fluid shift to the ECF in turn dilutes the concentration of sodium and other electrolytes.

CLINICAL MANIFESTATIONS. Cellular swelling and deficits of intracellular sodium alter the ability of cells to depolarize and repolarize normally (see Chapter 1). Neurologic changes characteristic of hyponatremia include lethargy, headache, confusion, apprehension, seizures, and coma. Pure sodium losses may be accompanied by loss of ECF, causing hypovolemia with symptoms of hypotension, tachycardia, and decreased urine output. Dilutional hyponatremia is accompanied by weight gain, edema, ascites, and jugular vein distention. Cerebral edema can be a life-threatening complication of hypervolemic hyponatremia caused by increases in intracranial pressure.

EVALUATION AND TREATMENT. In hyponatremic states, serum sodium concentration falls to less than 135 mEq/L. With pure sodium deficits, the hematocrit and plasma protein levels may be elevated. Urine specific gravity is less than 1.010 when renal function is normal because sodium is maximally conserved.

Treatment of hyponatremia is related to the contributing disorder. Losses of sodium and water volume are calculated from the clinical evaluation, and appropriate solutions then are selected for replacement. Restriction of water intake is required in most cases of dilutional hyponatremia because body sodium levels may be normal or increased even though serum concentrations are low. Hypertonic saline solutions are used cautiously with severe hyponatremia or the presence of symptoms such as seizures.[9]

Hypochloremia

Hypochloremia, a low level of serum chloride (less than 97 mEq/L), usually occurs with hyponatremia or an elevated bicarbonate concentration, as in metabolic alkalosis (see p. 128). Sodium deficit related to restricted intake, use of diuretics, and vomiting are accompanied by chloride deficiency. Cystic fibrosis is a genetic disease characterized by hypochloremia (see Chapters 36 and 42). In all cases, treatment of the underlying cause is required.

Water Excess

PATHOPHYSIOLOGY. When the body is functioning normally, it is almost impossible to produce an excess of TBW since water balance is regulated by the kidneys. However, some individuals with psychogenic disorders develop **water intoxication** from compulsive water drinking. Intensive exercise with replacement of large volumes of electrolyte-free water also causes overhydration. Acute renal failure, severe congestive heart failure, and cirrhosis are clinical conditions that can precipitate water excess. **Decreased urine formation** from renal disease or decreased renal blood flow contributes to water excess. The overall effect is dilution of the ECF with the movement of water to the intracellular space by osmosis. The syndrome of inappropriate

secretion of ADH (SIADH), also known as vasopressin dysregulation, enhances water retention because ADH levels are elevated (see Chapter 22, p. 718). Water excess is usually accompanied by hyponatremia.

CLINICAL MANIFESTATIONS. The symptoms of water excess are related to the rate at which water loading has occurred. Acute excesses cause cerebral edema with confusion and convulsions. Weakness, nausea, muscle twitching, headache, and weight gain are common symptoms of chronic water accumulation.

EVALUATION AND TREATMENT. Serum sodium concentration can be decreased, but this also can occur with a pure sodium deficit. Serum and urine osmolalities are decreased because water concentration will be in excess of sodium concentration. Urine sodium concentration will be reduced. The hematocrit value is reduced from the dilutional effect of water excess.

Fluid restriction for 24 hours is an effective treatment if there are no severe neurologic symptoms or convulsions. Small amounts of intravenous hypertonic sodium chloride (i.e., 3% sodium chloride) can be given when neurologic symptoms are severe.

ALTERATIONS IN POTASSIUM, CALCIUM, PHOSPHATE, AND MAGNESIUM BALANCE

Potassium

Potassium (K^+) is the major intracellular electrolyte and is found in most body fluids (see Table 3-5, p. 108). The ICF concentration of K^+ is 150 to 160 mEq/L; the ECF concentration is 3.5 to 5.0 mEq/L. Total body potassium content is about 4000 mEq, with most of it located in the cells. Daily dietary intake of potassium is 40 to 150 mEq/day, with an average of 1.5 mEq/kg body weight.

Potassium balance is maintained by renal excretion of K^+ absorbed from the gastrointestinal tract. Absorbed dietary K^+ moves rapidly into cells. However, the distribution of K^+ between intracellular and extracellular fluids can fluctuate and is influenced by several factors. Aldosterone, insulin, epinephrine (β-adrenergic stimulation), and alkalosis facilitate the shift of K^+ into cells. Insulin deficiency, aldosterone deficiency, acidosis, and strenuous exercise facilitate the shift of K^+ out of cells. α-Adrenergics impair K^+ entry into cells. Glucagon blocks entry of K^+ into cells, and glucocorticoids promote K^+ excretion. Potassium also will move out of cells along with water when there is increased ECF osmolarity (number of osmoles of solute per liter of fluid). If cells lyse, they release their intracellular K^+ into the ECF, which can cause an acute rise in plasma K^+ levels.

Besides acting to conserve sodium, *aldosterone is a major factor in potassium regulation.* Elevated plasma K^+ concentration causes adrenal secretion of aldosterone. Aldosterone then stimulates the release of K^+ into the urine by the distal renal tubules.

Insulin contributes to the regulation of plasma potassium levels by stimulating the Na^+-K^+-ATPase pump, thereby promoting the movement of K^+ into liver and muscle cells simultaneously with glucose transport. The intracellular movement of K^+ prevents an acute hyperkalemia related to food intake. Insulin also can be used to treat hyperkalemia. However, dangerously low levels of plasma K^+ can result from the administration of insulin when K^+ levels are depressed. Potassium balance is especially significant in the treatment of conditions requiring insulin administration, such as insulin-dependent diabetes mellitus (type 1).

The difference in the K^+ intracellular to extracellular concentration is maintained by a sodium-potassium active transport system (Na^+-K^+-ATPase pump). The ratio of ICF K^+ concentration to ECF K^+ concentration is the major determinant of the resting membrane potential, which is necessary for the transmission and conduction of nervous impulses, maintenance of normal cardiac rhythms, and contraction of skeletal and smooth muscles (see Figure 1-35, p. 35). The constant diffusion of positively charged K^+ out of the cell (i.e., down its concentration gradient) makes the interior of cells electronegative in relation to the ECF. Changes in the ratio of ICF to ECF potassium are responsible for many of the symptoms associated with K^+ imbalance.

As the predominant ICF ion, K^+ exerts a major influence on the regulation of ICF osmolality and fluid balance, as well as on intracellular electrical neutrality in relation to hydrogen (H^+) and Na^+ levels. Potassium is also necessary for a variety of metabolic functions and is required for glycogen deposition in liver and skeletal muscle cells.

The kidney provides the most efficient regulation of K^+ level balance over time. The amount of K^+ excreted varies in proportion to the dietary intake (40 to 120 mEq/day). Potassium is freely filtered by the renal glomerulus, and 90% is reabsorbed by the proximal tubule and loop of Henle. **Principal cells** in the collecting duct secrete K^+ and **intercalated cells** in the collecting duct reabsorb K^+. Dietary K^+ intake, aldosterone level, and distal tubule urine flow determine the amount of K^+ excreted from the body. Unlike sodium, the renal mechanism for conserving K^+ is weak, even when total body K^+ stores are depleted. The gut also may sense the amount of K^+ ingested and stimulate renal K^+ excretion.[10] However, a low K^+ intake also suppresses renal K^+ excretion.

Renal regulation of potassium level includes:

1. The concentration gradient for K^+ at the distal tubule and collecting duct
2. The distal tubule flow rate and distal tubule sodium delivery
3. The action of aldosterone
4. Changes in pH (causing acidosis or alkalosis)

The concentration of K^+ in the distal tubular cells is determined primarily by the plasma concentration in the peritubular capillaries. When plasma K^+ concentration increases because of increased dietary intake or shifts from the ICF to the ECF occur, K^+ is secreted into the urine by principal cells in the collecting ducts. Decreased levels of plasma K^+ result in decreased collecting duct secretion and reabsorption by intercalated cells, although K^+ losses of approximately 5 to 15 mEq/day will continue.

Changes in distal tubule flow rate and distal tubule sodium delivery also influence the concentration gradient for K^+ secretion. When the flow rate and sodium delivery are high, as occurs with the administration of diuretics, the concentration of K^+ in the distal tubular urine is lower, favoring the secretion

of K^+ into the tubule. Potassium secretion decreases when distal tubule flow rate and sodium delivery are low. However, aldosterone stimulates K^+ secretion by the distal tubule and serves to preserve K^+ secretion and K^+ balance during dehydration and extracellular volume depletion, when tubular delivery of Na^+ and flow rate are reduced.

Changes in pH and thus in hydrogen ion concentration also affect K^+ balance.[11] Hydrogen ions move from the ECF to the ICF during states of acidosis. When hydrogen is moving into the cell, K^+ shifts out of the cell to the ECF to maintain a balance of cations across the cell membrane. This occurs in part because of a decrease in Na^+-K^+-ATPase pump activity. The decreased ICF K^+ level in the distal tubular cells results in decreased secretion of K^+ into the urine, contributing to hyperkalemia (hyperkalemic acidosis), although total body K^+ level may not change. In contrast, intracellular fluid levels of hydrogen are diminished during states of alkalosis. Alkalosis causes K^+ to shift into the cell, so the distal tubular cells increase their secretion of K^+ into the urine, contributing to hypokalemia (hypokalemic alkalosis). The management of alterations associated with acid-base imbalances requires that the acid-base imbalances must be treated before or concurrently with treatment of changes in K^+ concentration.

Potassium adaptation is the ability of the body to adapt to increased levels of K^+ intake over time. A sudden increase in K^+ level may be fatal, but if the intake is slowly increased by amounts of more than 120 mEq/day, the kidney can increase the urinary excretion of K^+ and maintain K^+ concentration balance.

Hypokalemia

PATHOPHYSIOLOGY. Potassium deficiency, or **hypokalemia,** develops when the serum K^+ concentration decreases to less than 3.5 mEq/L. Because intracellular and total body stores of K^+ are difficult to measure, changes in K^+ balance are described by the plasma concentration, although changes in total body K^+ level are not always reflected in the plasma K^+ concentration. Generally, lowered serum K^+ level indicates a loss of total body K^+. Because K^+ is lost from the ECF, the change in the concentration gradient favors movement of K^+ from the cell to the ECF. The ICF/ECF concentration ratio is maintained, but the amount of total body K^+ is depleted.[12]

Factors contributing to the development of hypokalemia include *reduced intake of potassium,* increased entry of K^+ into cells, and increased losses of body K^+. Dietary deficiency of K^+ is a rare cause but may occur in elderly individuals with both low protein intake (meat) and inadequate intake of fruits and vegetables, and in individuals with alcoholism or anorexia nervosa. Reduced K^+ intake generally becomes a problem when combined with other causes of K^+ depletion.

ECF hypokalemia can develop without losses of total body K^+ when K^+ is redistributed between the ECF and ICF. Alkalosis, particularly respiratory alkalosis, is the most common clinical cause of these shifts. In alkalosis, ECF hydrogen moves out of the cell to correct the alkalosis, which causes K^+ to move into the cell to maintain an ionic balance. Insulin also promotes cellular uptake of K^+ and can cause an ECF potassium deficit, particularly with the intake of high carbohydrate loads. Severe, even fatal, hypokalemia may occur if insulin is administered without also providing K^+ supplements.

Treatment of pernicious anemia with vitamin B_{12} or folate also may precipitate hypokalemia if the formation of new red blood cells causes enough K^+ uptake to effect an extracellular decrease in K^+ concentration. **Familial hypokalemic periodic paralysis** is a rare genetically transmitted disease that also causes K^+ to shift into the intracellular space.

Hypokalemia also can occur when K^+ shifts from the ICF to the ECF, as occurs in conjunction with renal losses. For example, in diabetic ketoacidosis, the increased hydrogen ion concentration in the ECF causes H^+ to shift into the cell in exchange for K^+ at the same time diuresis is occurring. A normal level of K^+ is maintained in the plasma, but K^+ continues to be lost in the urine, causing a deficit in the amount of total body potassium. Total body K^+ depletion becomes evident when insulin treatment and rehydration therapy are initiated.

Potassium loss also occurs through normal body functions, but without causing hypokalemia. Average daily losses of K^+ are as follows:

Location	Daily Loss (mEq/L)
Stool	5-10
Sweat	0-20
Urine	40-120

Losses of K^+ from body stores are most commonly caused by gastrointestinal and renal disorders. Diarrhea (from any cause), intestinal drainage tubes or fistulae, and laxative abuse also may result in hypokalemia. Normally, only 5 to 10 mEq of potassium and 100 to 150 ml of water are excreted in the stool each day. With diarrhea, fluid and electrolyte losses can be voluminous, with several liters of fluid and 100 to 200 mEq of K^+ lost per day. Vomiting or applying continuous nasogastric suction frequently is associated with K^+ depletion, partly because of the K^+ lost from the gastric fluid but principally because of renal compensation for volume depletion and the metabolic alkalosis (elevated bicarbonate levels) that occurs from sodium, chloride, and hydrogen ion losses. The loss of fluid and sodium stimulates the secretion of aldosterone and ADH, which in turn causes renal loss of K^+. The elevated flow of bicarbonate at the distal tubule contributes to renal excretion of K^+ because of increased tubular lumen electronegativity.

Renal losses of K^+ are related to increased secretion of K^+ by the distal tubule. Use of diuretics, excessive aldosterone secretion, increased distal tubular flow rate, and low plasma magnesium concentration all may contribute to urinary losses of K^+. Many diuretics, including thiazides, furosemide, ethacrynic acid, and osmotic diuretics, inhibit the reabsorption of sodium chloride, causing the diuretic effect. The distal tubular flow rate then increases, promoting K^+ excretion. If sodium loss is severe, the compensating aldosterone secretion (which causes secondary hyperaldosteronism) may further deplete K^+ stores. Primary hyperaldosteronism with excessive secretion of aldosterone from an adrenal adenoma also causes K^+ wasting. Many kidney diseases result in a reduced ability to conserve sodium. The disordered

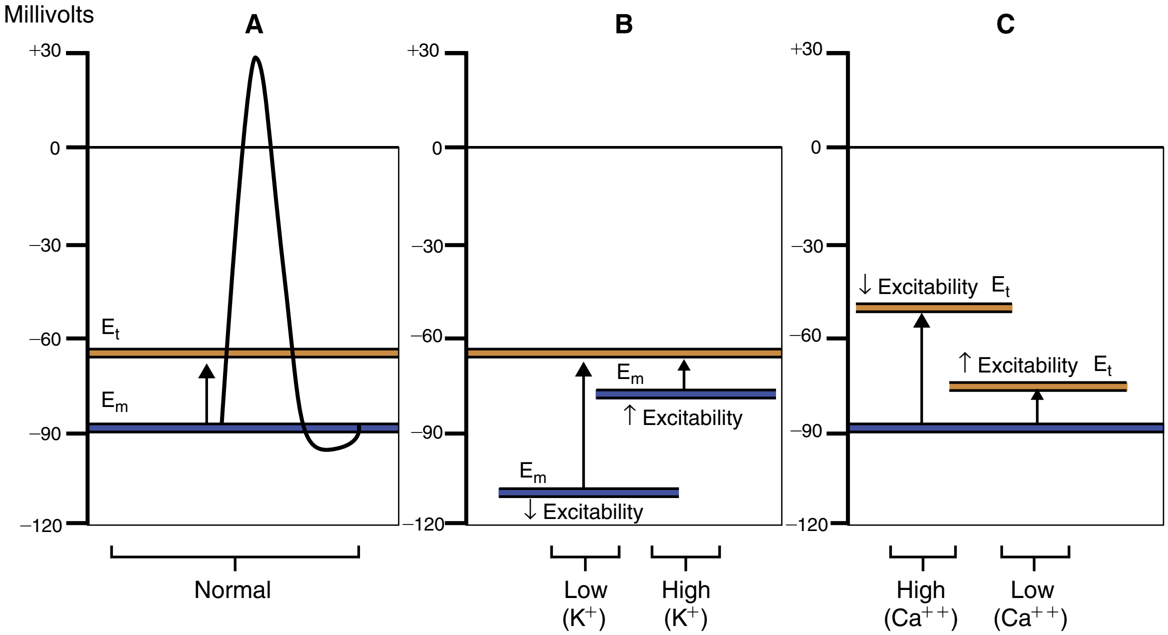

FIGURE 3-7 **Effects of Potassium (K^+) and Calcium (Ca^{++}) on Membrane Excitability. A,** Normal membrane excitability: Potassium affects resting membrane potential (E_m), and calcium affects threshold potential (E_t). **B,** Effects of potassium (K^+) changes on membrane potential. **C,** Effect of calcium (Ca^{++}) on threshold potential. **Note:** *Hyperpolarization* can be caused by either hypokalemia (E_m more negative) or hypercalcemia (E_t less negative)–distance between E_m and E_t is increased (decreased excitability); and *hypopolarization* can be caused by either hyperkalemia (E_m less negative) or hypocalcemia (E_t more negative)—distance between E_m and E_t is decreased (increased excitabillity).

sodium reabsorption produces a diuretic effect, and the increased distal tubule flow rate favors the secretion of K^+. Magnesium deficits stimulate renin release and hyperaldosteronism, causing hypokalemia. Several antibiotics, including amphotericin B, gentamicin, and carbenicillin, are known to cause hypokalemia.

CLINICAL MANIFESTATIONS. Mild losses of K^+ are usually asymptomatic. A wide range of dysfunctions may result from severe hypokalemia (<2.5 mEq/L). *Neuromuscular and cardiac effects* of hypokalemia produce the most common symptoms.[13] Neuromuscular excitability is decreased, causing skeletal muscle weakness, smooth muscle atony, and cardiac dysrhythmias. As Chapter 1 describes, the resting membrane potential (E_m) is determined by the *ratio* of extracellular to intracellular K^+ ion concentration. Because the concentration of K^+ in the ECF is small, only small changes in ECF potassium level are required to influence the resting membrane potential and affect neuromuscular excitability (the difference between resting membrane and threshold potentials)[1] (Figure 3-7, *A*). When extracellular K^+ levels decrease rapidly, intracellular K^+ diffuses more readily out of the cell and the resting membrane potential becomes more negative (i.e., from −90 to −100 millivolts). If the threshold potential (E_t) remains stable, the difference between resting membrane potential and threshold potential increases and the cell membrane becomes **hyperpolarized,** requiring a stronger stimulus (decreased excitability) to initiate depolarization and an action potential (Figure 3-7, *B* [low K^+]).

The *cardiac effects of hypokalemia* are related to decreased membrane excitability (see Figure 3-7, *B*). Because K^+ contributes to the repolarization phase of the action potential, hypokalemia delays ventricular repolarization and the frequency of action potentials. The membrane potential remains partially depolarized with slowed conduction and abnormal pacemaker activity. A variety of dysrhythmias may occur, including sinus bradycardia, atrioventricular block, and paroxysmal atrial tachycardia. The characteristic changes in the electrocardiogram reflect delayed repolarization. For instance, the amplitude of the T wave is decreased, the amplitude of the U wave is increased, and the ST segment is depressed (Figure 3-8). In severe states of hypokalemia, P waves peak and the QRS complex is prolonged. Hypokalemia also increases the risk of digitalis toxicity by slowing the sodium-potassium pump, which augments the action of digitalis in cardiac muscle by excessively increasing intracellular calcium and sodium concentrations.

Plasma calcium concentration also contributes to changes in neuromuscular excitability associated with hypokalemia. Increases in ECF calcium concentration tend to make the threshold potential (E_t) less negative and decrease membrane excitability, potentiating hyperpolarization, decreased excitability, and the neuromuscular effects of hypokalemia (Figure 3-7, *C*).

Carbohydrate metabolism is affected because hypokalemia depresses insulin secretion and alters hepatic and skeletal muscle glycogen synthesis. Renal function is impaired, with a decreased ability to concentrate urine. Polyuria (increased urine) and polydipsia (increased thirst) are associated with decreased responsiveness to ADH. Chronic potassium deficits lasting more than 1 month may damage renal tissue, with resulting interstitial fibrosis and tubular atrophy.

The onset of symptoms is related to the *rate of potassium depletion*. Because the body can accommodate slow losses of K^+, the decrease in ECF concentration may be slow enough to allow K^+ to shift from the intracellular space. The extracellular to intracellular K^+ concentration gradient then is restored toward normal,

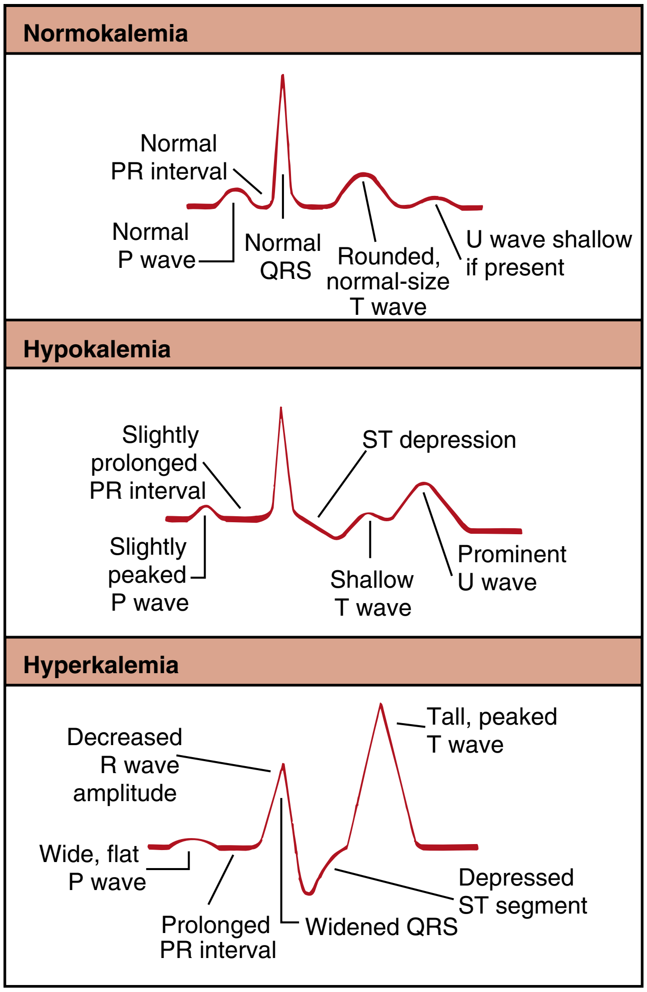

FIGURE 3-8 Electrocardiogram (ECG) Changes with Potassium Imbalance.

with less severe neuromuscular changes. With acute losses of K^+, changes in neuromuscular excitability are more profound. Skeletal muscle weakness initially occurs in the larger muscles of the legs and arms and ultimately affects the diaphragm and depresses ventilation. Paralysis and respiratory arrest then can occur. Loss of smooth muscle tone is manifested by orthostatic hypotension, constipation, intestinal distention, anorexia, nausea, vomiting, and paralytic ileus. Table 3-9 contains a summary of K^+ alterations.

EVALUATION AND TREATMENT. The diagnosis of hypokalemia is based on serum K^+ levels; however, it is important to examine the medical history and identify disorders associated with K^+ loss or shifts of extracellular K^+ to the intracellular space. Treatment involves an estimation of total body K^+ losses and correction of acid-base imbalances. Further losses of K^+ should be prevented, and the individual should be encouraged to eat foods rich in K^+. Potassium replacement is instituted cautiously to prevent hyperkalemia. The maximal rate of oral replacement is 40 to 80 mEq/day if renal function is normal. A maximal safe rate of intravenous replacement is 20 mEq/hr for adults. Because K^+ is irritating to blood vessels, a maximal concentration of 40 mEq/100 ml should be used. Serum K^+ values can be monitored until normokalemia is achieved.

Hyperkalemia

PATHOPHYSIOLOGY. An elevation of ECF potassium concentration *above 5.5 mEq/L* constitutes **hyperkalemia.** Because of efficient renal excretion, excesses of total body potassium are relatively rare. Acute increases in serum K^+ concentration are handled quickly through an increase in cellular uptake and renal excretion of body K^+ excesses.

Excesses of serum K^+ may be caused by *excessive intake,* a *shift of potassium from the ICF to the ECF,* or *decreased renal excretion.*[14] If renal function is normal, slow, long-term increases in K^+ intake are usually well tolerated through K^+ adaptation, although acute K^+ loading can exceed renal excretion rates. Use of stored whole blood, administration of intravenous boluses of penicillin G, or replacement of K^+ can precipitate hyperkalemia, particularly if renal function is impaired. Dietary excesses of K^+ are uncommon, but accidental ingestion of K^+ salt substitutes can cause toxicity.

Potassium shifts from the ICF to the ECF occur with a *change in cell membrane permeability* (e.g., from cell hypoxia, acidosis, or insulin deficiency). Burns, massive crush injuries, and extensive surgeries can cause cell trauma and loss of ICF potassium to the ECF. If renal function is sustained, K^+ will be excreted. As cell repair begins, hypokalemia develops if the excreted K^+ is not replaced.

Hypoxia can lead to hyperkalemia by diminishing the efficiency of cell membrane active transport, resulting in the escape of K^+ to the ECF. In states of *acidosis,* hydrogen ions shift into the cells in exchange for ICF potassium; hyperkalemia and acidosis therefore often occur together. Because insulin promotes cellular entry of K^+, *insulin deficits,* which occur with conditions such as diabetic ketoacidosis, are accompanied by hyperkalemia. *Digitalis overdose* may cause hyperkalemia by inhibiting the Na^+-K^+-ATPase pump. This pump normally maintains intracellular K^+ concentration and moves sodium and calcium to the ECF (see Chapter 1).

Decreased renal excretion of potassium is commonly associated with hyperkalemia. Renal failure that results in oliguria (urine output <30 ml/hr) is accompanied by elevations of serum K^+ concentration. The severity of hyperkalemia is related to the severity of renal dysfunction, the amount of K^+ intake, and the degree of acidosis from the renal failure. In acute renal failure K^+ levels rise more rapidly with more serious consequences than the slower rises associated with chronic renal failure. Hypoaldosteronism also can cause decreases in the urinary excretion of K^+. For example, Addison disease results in decreased production and secretion of aldosterone and thus contributes to hyperkalemia. Drugs that decrease renal potassium excretion (i.e., ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists) also may contribute to hyperkalemia. Frequently, however, these drugs are used in combination with diuretics that cause K^+ wasting in an attempt to balance renal K^+ gains and losses.

CLINICAL MANIFESTATIONS. Symptoms of hyperkalemia vary, but common characteristics are muscle weakness or paralysis and dysrhythmias with changes in the electrocardiogram. During mild attacks, increased neuromuscular irritability may be manifested as tingling of lips and fingers, restlessness, intestinal

TABLE 3-9 POTASSIUM ALTERATIONS

CAUSES	HYPOKALEMIA <3.5 mEq/L	HYPERKALEMIA >5.0 mEq/L
Intake	Decreased intake: starvation or anorexia nervosa, inadequate replacement	Excess dietary or intravenous intake
Loss	Increased renal loss: renal tubular failure, K^+-losing diuretics, hyperaldosteronism, vomiting, diarrhea, use of selected antibiotics	Decreased renal loss: renal failure, K^+-sparing diuretics, hypoaldosteronism
Cellular shifts	Shift from ECF to ICF: metabolic alkalosis, insulin administration	Shift from ICF to ECF: metabolic acidosis, cell injury
	ORGAN SYSTEM MANIFESTATIONS	
Cardiovascular	Postural hypotension Dysrhythmias ECG changes (flattened T waves, U waves, ST depression, peaked P wave, prolonged QT interval) Weak, irregular pulse rate Ventricular fibrillation Cardiac arrest	Dysrhythmias ECG changes (peaked T waves, prolonged PR interval, absent P wave with widened QRS complex) Bradycardia Heart block Cardiac arrest
Nervous	Lethargy Fatigue Confusion Paresthesias Decreased tendon reflexes	Anxiety Tingling Numbness
Gastrointestinal	Nausea and vomiting Decreased motility Distention Decreased bowel sounds Ileus	Nausea and vomiting Diarrhea Colicky pain
Kidney	Inability to concentrate urine Water loss Thirst Kidney damage	Oliguria Kidney damage
Skeletal and smooth muscle	Weakness Flaccid paralysis Respiratory arrest Constipation Bladder dysfunction	Early: hyperactive muscles Late: weakness and flaccid paralysis

cramping, and diarrhea. Severe hyperkalemia causes muscle weakness, loss of muscle tone, and paralysis. In mild states of hyperkalemia, the more rapid repolarization is reflected in the electrocardiogram as narrow and taller T waves with a shortened QT interval. Severe hyperkalemia (serum levels ≥6 mEq/L) depresses the ST segment, prolongs the PR interval, and widens the QRS complex (loss of atrial activity) (see Figure 3-8). Delayed conduction and bradydysrhythmias are common in hyperkalemia, with alterations in cardiac conduction causing ventricular fibrillation or cardiac arrest.

As with hypokalemia, changes in the ratio of intracellular to extracellular K^+ concentration contribute to the symptoms of hyperkalemia. If extracellular K^+ concentration increases without a significant change in intracellular K^+ concentration, the resting membrane potential becomes more positive (i.e., changes from −90 to −80 millivolts) and the cell membrane is **hypopolarized** (the inside of the cell becomes less negative or partially depolarized [increased excitability]) (see Figure 3-7, *B*). (Electrical properties of cells are discussed in Chapter 1.) With relatively mild elevations in extracellular K^+ concentration, the cell more rapidly repolarizes and becomes more irritable (peaked T waves). An action potential then is initiated more rapidly because the distance between the resting membrane potential and the threshold potential has been shortened. With more severe hyperkalemia, the resting membrane potential approaches or exceeds the threshold potential (wide QRS merging with T wave). In this case the cell is not able to repolarize and therefore does not respond to excitation stimuli. The most serious consequence is cardiac standstill.

Like the effects of hypokalemia, the neuromuscular effects of hyperkalemia are related to the rate of increase in the ECF potassium concentration and the presence of other contributing factors, such as acidosis and calcium balance. Long-term increases in ECF potassium concentration result in shifts of K^+ into the cell because the tendency is to maintain a normal ratio of intracellular/extracellular potassium concentrations. Acute elevations of extracellular K^+ concentration affect neuromuscular irritability because this ratio is disrupted.

Because calcium influences the threshold potential, changes in extracellular fluid calcium concentration can augment or override the effects of hyperkalemia. With hypocalcemia the threshold potential becomes more negative, enhancing the neuromuscular effects of hyperkalemia. Hypercalcemia causes the threshold potential to become less negative, counteracting the effects of hyperkalemia on resting membrane potential (see Figure 3-7, *C*). See Table 3-9 for a summary of potassium alteration.

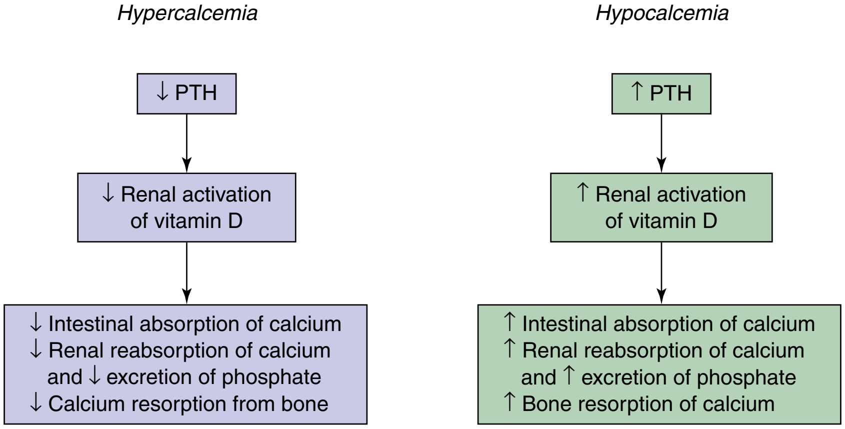

FIGURE 3-9 Hormonal Regulation of Calcium Balance. *PTH,* Parathyroid hormone.

EVALUATION AND TREATMENT. Hyperkalemia should be investigated when there is a history of renal disease, massive trauma, insulin deficiency, Addison disease, use of potassium salt substitutes, or metabolic acidosis. The acuity of the onset of symptoms may be related to the underlying cause.

Management of hyperkalemia is related to treating the contributing causes and correcting the potassium excess. Normalizing the extracellular potassium concentration can be achieved with a variety of methods; the treatment chosen is related to the cause and severity of the problem. Calcium gluconate can be administered to restore normal neuromuscular irritability when serum potassium levels are dangerously high. Administration of glucose, which readily stimulates insulin secretion, or administration of glucose and insulin for those with diabetes, facilitates cellular entry of potassium. Buffered solutions correct metabolic acidosis and lower serum potassium level. Oral or rectal administration of cation exchange resins, which exchange sodium for potassium in the intestine, can be effective. Dialysis effectively removes potassium when renal failure has occurred.

Calcium and Phosphate

The total body content of calcium is about 1200 g. Most calcium (99%) is located in bone as hydroxyapatite (an inorganic compound that contributes to bone rigidity), and the remainder is in the plasma and body cells. The total fraction of calcium circulating in the blood is small (9.0 to 10.5 mg/dl) and about 50% is bound to plasma proteins, primarily albumin. About 40% is in the free or ionized form (5.5 to 5.6 mg/dl). Ionized calcium has the most important physiologic functions.

Calcium (Ca^{++}) is a necessary ion for many fundamental metabolic processes. It is the major cation associated with the structure of bones and teeth. It serves as an enzymatic cofactor for blood clotting and is required for hormone secretion and the function of cell receptors. Plasma membrane stability and permeability are directly related to calcium ions, as is the transmission of nerve impulses and the contraction of muscles. Intracellular calcium is located primarily in the mitochondria.

Phosphate ($HPO_4^=$) is found primarily in bone (85%), with smaller amounts found within the intracellular and extracellular spaces. In the plasma, phosphate exists in phospholipids and phosphate esters and as inorganic phosphate, which is the ionized form. The normal serum levels of inorganic phosphate range from 2.5 to 4.5 mg/dl and may be as high as 6.0 to 7.0 mg/dl in infants and young children. Intracellular phosphate has many metabolic forms, including the high-energy structures creatine phosphate and adenosine triphosphate (ATP). Phosphate acts as an intracellular and extracellular anion buffer in the regulation of acid-base balance; in the form of ATP it provides energy for muscle contraction.

Calcium and phosphate concentrations are rigidly controlled. They are related by the product of calcium (Ca^{++}) and phosphate ($HPO_4^=$), which is a constant (K) [$Ca^{++} \times HPO_4^= = K$]. Thus, if the concentration of one ion increases or decreases, that of the other increases or decreases.

Calcium and phosphate balance is regulated by three hormones: parathyroid hormone (PTH), vitamin D, and calcitonin. Acting together, these substances determine the amount of dietary calcium and phosphate absorbed from the intestine, the deposition and absorption of calcium and phosphate from bone, and the renal reabsorption and excretion of calcium and phosphate by the kidney.

The parathyroid glands secrete PTH in response to low levels of serum calcium. (The specific actions of PTH in relation to calcium and phosphate are described in Chapter 21.) **Parathyroid hormone** controls levels of ionized calcium and phosphate in the blood and other extracellular fluids. The renal regulation of calcium and phosphate balance requires PTH. PTH stimulates reabsorption of calcium along the distal tubule of the nephron and inhibits phosphate reabsorption by the proximal tubule of the nephron. The net result is an increase in serum calcium concentration and increased urinary excretion of phosphate. Figure 3-9 summarizes hormonal regulation of calcium.

Another compound important to calcium and phosphate regulation is vitamin D. **Vitamin D** (cholecalciferol) is a fat-soluble steroid ingested in food or synthesized in the skin in the presence of ultraviolet light. Several steps of activation are required before vitamin D can act on target tissues. The first step occurs in the liver; final activation is in the kidney. The renal activation of vitamin D begins when the serum calcium level decreases and stimulates secretion of PTH. PTH then acts to increase calcium reabsorption and enhance renal excretion of

phosphate, producing decreased phosphate levels. The combination of low calcium level and increased PTH secretion causes the renal activation of vitamin D. The activated vitamin D (vitamin D_3—calcitriol) then circulates as a hormone in the plasma and acts to increase absorption of calcium and phosphate in the small intestine, enhance bone calcification, and increase renal tubular reabsorption of calcium and phosphate. When renal failure occurs, vitamin D is not activated; serum calcium levels decrease; and phosphate levels increase.

As calcium levels increase, an opposite adaptation occurs, leading to suppression of PTH secretion, decreased renal vitamin D activation, decreased intestinal calcium absorption, and increased renal phosphate reabsorption. **Calcitonin** (produced by C cells of the thyroid gland) primarily decreases calcium levels by inhibiting osteoclastic activity in bone.

The fractions of serum calcium that are freely ionized or bound to plasma proteins are influenced by pH. In states of acidosis, levels of ionized calcium increase. When alkalosis develops, with an increase in pH, the amount of protein-bound calcium increases and the physiologically active, ionized calcium level decreases. The decreased concentration of ionized calcium may be great enough to cause symptoms of hypocalcemia, such as tetany.

Hypocalcemia

PATHOPHYSIOLOGY. **Hypocalcemia** occurs when serum total calcium concentrations are less than 8.5 mg/dl and ionized levels are less than 4.0 mg/dl. In general, deficits in calcium are related to inadequate intestinal absorption, decreases in levels of PTH and vitamin D, or deposition of ionized calcium into bone or soft tissue.

Nutritional deficiencies of calcium can occur in the instance of inadequate sources of dairy products or green, leafy vegetables. Excessive amounts of dietary phosphorus also bind with calcium, so neither mineral is absorbed when such an excess occurs. Removal of the parathyroid glands (e.g., during total thyroidectomy) with the resulting loss of PTH also causes hypocalcemia. Vitamin D deficiency, which can result from inadequate intake or avoidance of sunlight, causes decreased intestinal absorption of calcium. Malabsorption of fat, including fat-soluble vitamin D, also may contribute to calcium deficiency. Neoplastic bone metastases tend to inhibit bone resorption and increase calcium deposition into bone, thereby decreasing serum calcium levels.

Blood transfusions are also a common cause of hypocalcemia because the citrate solution used in storing whole blood binds with calcium and makes it unavailable to the tissues. Pancreatitis causes release of lipases into soft tissue spaces, so the free fatty acids that are formed bind calcium, causing a decrease in the concentration of ionized calcium. Metabolic or respiratory alkalosis causes symptoms of hypocalcemia because the change in pH enhances protein binding of ionized calcium. Hypoalbuminemia lowers total serum calcium levels by decreasing the amount of bound calcium in the plasma.

CLINICAL MANIFESTATIONS. The clinical manifestations of hypocalcemia are caused primarily by an increase in neuromuscular excitability. Calcium deficits cause partial depolarization of nerves and muscle as the threshold potential becomes more negative and approaches the resting membrane potential (hypopolarization) (see Figure 3-7, *C*). Therefore, a smaller stimulus is required for initiating the action potential. The symptoms are related to neuromuscular irritability and include paresthesias around the mouth and in the digits, carpopedal spasm (muscle spasms in the hands and feet), laryngospasm, hyperreflexia, seizures, and dysrhythmias.

Two clinical signs are Chvostek sign and Trousseau sign. *Chvostek sign* is elicited by tapping on the facial nerve just below the temple. A positive sign is a twitch of the nose or lip. *Trousseau sign* is contraction of the hand and fingers when the arterial blood flow in the arm is occluded for 5 minutes.

Severe symptoms include convulsions and *tetany,* a continuous severe muscle spasm that can interfere with breathing and cause death. The characteristic electrocardiogram (ECG) change is a prolonged QT interval, indicating prolonged ventricular depolarization and decreased cardiac contractility. Intestinal cramping and hyperactive bowel sounds also may be present because hypocalcemia affects the smooth muscles of the gastrointestinal tract. Table 3-10 contains a summary of the manifestations of calcium level alterations.

EVALUATION AND TREATMENT. The health history may signify underlying pathologic conditions that require further evaluation and treatment. Severe symptoms of hypocalcemia require emergency treatment with intravenous 10% calcium gluconate. Oral calcium replacement should be initiated, and serum calcium levels should be monitored. Decreasing phosphate intake facilitates long-term management of hypocalcemia.[14a]

Hypercalcemia

PATHOPHYSIOLOGY. **Hypercalcemia** with total serum calcium concentrations exceeding 12 mg/dl can be caused by a number of diseases. The most common among these are hyperparathyroidism; bone metastases with calcium resorption from breast, prostate, or cervical cancer, or hematologic malignancy; sarcoidosis; and excess vitamin D. Many tumors produce PTH and elevate the serum calcium levels. Sarcoidosis appears to increase vitamin D levels. Prolonged immobilization can also lead to hypercalcemia from enhanced bone resorption and decreased calcium deposition into bone. Acidosis decreases serum binding of calcium to albumin, increasing ionized calcium levels.

CLINICAL MANIFESTATIONS. Many symptoms of hypercalcemia are nonspecific. Because serum calcium levels are increased, a greater amount of calcium is also contained inside the cells. The threshold potential becomes more positive (hyperpolarized) (e.g., moves from −60 to −50 millivolts) and the cell membrane becomes refractory to depolarization (decreased excitability) because there is a greater difference between threshold potential and resting membrane potential (see Figure 3-7, *C*). Thus many of the symptoms are related to loss of cell membrane excitability. (Membrane potentials and membrane excitability are discussed in Chapter 1.) Fatigue, weakness, lethargy, anorexia, nausea, and constipation are common.

Mental status changes and confusion may occur. Impaired renal function frequently develops, and kidney stones form as precipitates of calcium salts. A shortened QT segment and

TABLE 3-10 ALTERATIONS IN CALCIUM, PHOSPHATE, AND MAGNESIUM LEVELS

CAUSES	MANIFESTATIONS
Hypocalcemia (<8.5 mg/dl)	
Inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreases in PTH and vitamin D levels; nutritional deficiencies occur with inadequate sources of dairy products or green, leafy vegetables; alkalosis, elevated calcitonin level	Increased neuromuscular excitability; tingling, muscle spasms (particularly in hands, feet, and facial muscles), intestinal cramping, hyperactive bowel sounds; osteoporosis and fractures; severe cases show convulsions and tetany; prolonged QT interval, cardiac arrest
Hypercalcemia (>10-12 mg/dl)	
Hyperparathyroidism; bone metastases with calcium resorption from breast, prostate, renal, and cervical cancer; sarcoidosis; excess vitamin D; many tumors that produce PTH; calcium-containing antacids	Many nonspecific; fatigue, weakness, lethargy, anorexia, nausea, constipation; impaired renal function, kidney stones; dysrhythmias, bradycardia, cardiac arrest; bone pain, osteoporosis, fractures
Hypophosphatemia (<2.0 mg/dl)	
Intestinal malabsorption related to vitamin D deficiency, use of magnesium- and aluminum-containing antacids, long-term alcohol abuse, and malabsorption syndromes; respiratory alkalosis; increased renal excretion of phosphate associated with hyperparathyroidism	Conditions related to reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism; leukocyte and platelet dysfunction; deranged nerve and muscle function; in severe cases, irritability, confusion, numbness, coma, convulsions; possibly respiratory failure (because of muscle weakness), cardiomyopathies, bone resorption (leading to rickets or osteomalacia)
Hyperphosphatemia (>4.7 mg/dl)	
Acute or chronic renal failure with significant loss of glomerular filtration; treatment of metastatic tumors with chemotherapy that releases large amounts of phosphate into serum; long-term use of laxatives or enemas containing phosphates; hypoparathyroidism	Symptoms primarily related to low serum calcium levels (caused by high phosphate levels) similar to symptoms of hypocalcemia; when prolonged, calcification of soft tissues in lungs, kidneys, joints
Hypomagnesemia (<1.5 mEq/L)	
Malnutrition, malabsorption syndromes, alcoholism, urinary losses (renal tubular dysfunction, loop diuretics)	Behavioral changes, irritability, increased reflexes, muscle cramps, ataxia, nystagmus, tetany, convulsions, tachycardia, hypotension
Hypermagnesemia (>3.0 mEq/L)	
Usually renal insufficiency or failure; also excessive intake of magnesium-containing antacids, adrenal insufficiency	Lethargy, drowsiness; loss of deep tendon reflexes; nausea and vomiting; muscle weakness; hypotension; bradycardia; respiratory distress; heart block, cardiac arrest

PTH, Parathyroid hormone.

depressed widened T waves also may be observed on the ECG, with bradycardia and varying degrees of heart block.

EVALUATION AND TREATMENT. With elevated serum calcium levels, often a reciprocal decrease in serum phosphate values occurs. Specific diagnostic procedures to identify the contributing pathologic condition are required.

Treatment is related to the severity of symptoms and the underlying disease. When renal function is normal, oral phosphate administration is effective. When acute illness and high calcium levels are present, treatment options include intravenous administration of large amounts of normal saline to enhance renal excretion of calcium, administration of bisphosphonates in the absence of renal failure, and administration of calcitonin. Corticosteroids and the cytotoxic drug mithramycin (blocks osteoclastic function) also are used to treat hypercalcemia. Ultimately, the underlying pathologic condition must be treated. (Table 3-10 contains a summary of the manifestations of alterations in calcium levels.)

Hypophosphatemia

PATHOPHYSIOLOGY. Hypophosphatemia is a serum phosphate level less than 2.5 mg/dl and is usually an indication of phosphate deficiency. In some conditions, total body phosphate is normal but serum concentrations are low. The most common causes are intestinal malabsorption and increased renal excretion of phosphate. Inadequate absorption is associated with vitamin D deficiency, use of magnesium- and aluminum-containing antacids (which bind with phosphorus), long-term alcohol abuse, and malabsorption syndromes. Respiratory alkalosis can cause severe hypophosphatemia because of cellular use of phosphorus for accelerated glycolysis (ATP) formation. Increased renal excretion of phosphorus is associated with hyperparathyroidism.

CLINICAL MANIFESTATIONS. The consequences of phosphate deficiency are not clinically evident until hypophosphatemia is severe. There is reduced capacity for oxygen transport by red blood cells and disturbed energy metabolism. Transport and release of oxygen are associated with 2,3-diphosphoglycerate (2,3-DPG) and ATP levels. When phosphate is depleted, 2,3-DPG and ATP levels become low and diminish release of oxygen to the tissues. The oxyhemoglobin curve shifts to the left (see Chapter 34), and hypoxia can occur with bradycardia and varying degrees of heart block.

Leukocyte and platelet dysfunctions also are associated with hypophosphatemia. There is a greater risk of infection and blood-clotting impairment, with potential for hemorrhage. Nerve and muscle function can be affected because of

derangement in energy metabolism. Muscle weakness may become serious enough to cause respiratory failure, and cardiomyopathies also can develop. Irritability, confusion, numbness, coma, and convulsions develop with severe phosphate losses. In response to low phosphate levels, bone resorption occurs and may lead to rickets or osteomalacia. (Table 3-10 contains a summary of the manifestations of phosphate level alterations.)

EVALUATION AND TREATMENT. To correct the condition, the underlying cause must be identified and treated. The rate and amount of replacement are determined by the cause and presenting symptoms.[15] (Table 3-10 contains a summary of the manifestations of alterations in phosphate levels.)

Hyperphosphatemia

PATHOPHYSIOLOGY. **Hyperphosphatemia,** or an elevated serum phosphate level of more than 4.5 mg/dl, develops with exogenous or endogenous addition of phosphorus to the ECF or with significant loss of glomerular filtration.[16] Because most phosphate is located in cells, the cell destruction associated with treatment of metastatic tumors with chemotherapy can release large amounts of phosphate into the ECF. Long-term use of phosphate-containing enemas or laxatives also may lead to hyperphosphatemia. Hypoparathyroidism can cause elevated phosphate levels by increasing renal tubular reabsorption of phosphate.

High levels of serum phosphate also lower serum calcium levels, and increased amounts of phosphate and calcium are deposited in bone and soft tissues. Serum calcium levels may become low enough to cause symptoms of hypocalcemia, including tetany.

CLINICAL MANIFESTATIONS. Symptoms of hyperphosphatemia are related primarily to low serum calcium levels and thus are comparable to symptoms of hypocalcemia. With prolonged hyperphosphatemia, calcification of soft tissues occurs in the lungs, kidneys, and joints.

EVALUATION AND TREATMENT. To correct hyperphosphatemia, the underlying pathologic condition must be identified and treated. Aluminum hydroxide may be administered because it binds phosphate in the gastrointestinal tract and is then eliminated; however, aluminum can be toxic, causing encephalopathy and osteomalacia. Non-aluminum and non–calcium phosphate binders (lanthanum carbonate or sevelamer) are being evaluated but cost and toxicity are concerns.[17] Dialysis is required for management of renal failure. (Table 3-10 contains a summary of the manifestations of alterations in phosphate concentration.)

Magnesium

Magnesium (Mg^{++}) is a major intracellular cation, second to potassium. About 40% to 60% is stored in muscle and bone with 30% in the cells. A small amount (1%) is in the serum. Plasma concentration is 1.8 to 2.4 mg/dl with about one third bound to plasma proteins and the rest in ionized form. Regulation of magnesium metabolism is balanced by the small intestine and kidney. Low serum levels cause renal conservation of magnesium. Magnesium is a cofactor in intracellular enzymatic reactions, protein synthesis, nucleic acid stability, and neuromuscular excitability. Calcium and magnesium often interact in reactions at the cellular level.[18]

Hypomagnesemia occurs when serum magnesium concentration is less than 1.5 mEq/L and increases in neuromuscular excitability and tetany are present. Malnutrition, malabsorption syndromes, alcoholism, renal tubular dysfunction, metabolic acidosis, and use of loop and thiazide diuretics can cause magnesium losses. Hypomagnesemia is associated with insulin resistance, diabetes mellitus, left ventricular hypertrophy, systemic inflammation, hypoalbuminemia, and osteoporosis.[19] Because magnesium inhibits potassium channels, loss of magnesium results in movement of potassium out of the cell, with renal excretion resulting in hypokalemia. Signs and symptoms of hypomagnesemia are similar to those of hypocalcemia. Depression, confusion, irritability, increased reflexes, muscle weakness, ataxia, nystagmus, tetany, convulsions, and tachydysrhythmias may be observed.[20] Treatment is intramuscular or intravenous administration of magnesium sulfate.

Magnesium supplements have several benefits including improved myocardial metabolism and cell function; improved vascular smooth muscle tone and peripheral vascular resistance, afterload, and cardiac output; reduced cardiac dysrhythmias; and improved lipid and glucose metabolism. Magnesium also reduces vulnerability to oxygen-derived free radicals and systemic inflammation, improves human endothelial function, and inhibits platelet function, including platelet aggregation and adhesion.[19,20]

Hypermagnesemia, in which magnesium concentration is greater than 2.5 mEq/L, is rare and usually is caused by renal failure.[21] Magnesium-containing antacids (e.g., Gaviscon, Gelusil) can potentiate excess magnesium. Excess magnesium depresses skeletal muscle contraction and nerve function. Signs and symptoms include nausea and vomiting, muscle weakness, hypotension, bradycardia, and respiratory depression. Treatment is avoidance of magnesium-containing substances and removal of magnesium by dialysis. (Table 3-10 contains a summary of the manifestations of magnesium level alterations.)

ACID-BASE BALANCE

Acid-base balance and hydrogen ion concentration must be regulated within a narrow range for the body to function normally. Slight changes in amounts of hydrogen can significantly alter biologic processes in cells and tissues. Hydrogen ion is necessary to maintain membrane integrity and the speed of enzymatic reactions. Most pathologic conditions disturb acid-base balance, and the degree of severity may be more harmful than the disease process.

Hydrogen Ion and pH

The hydrogen ion concentration, $[H^+]$, is commonly expressed as the pH, the negative logarithm of hydrogen ions in solution. The symbol **pH** represents the acidity or alkalinity of a solution. The logarithmic value means that as the pH changes 1 unit (e.g., from 7.0 to 6.0), the $[H^+]$ changes tenfold (i.e., from 0.0000001 to 0.000001). The relationship is commonly expressed as follows:

$$\mathrm{pH} = \log \frac{1}{[H^+]} \text{ or } \mathrm{pH} = -\log_{10}[H^+]$$

As the $[H^+]$ increases, the pH decreases; likewise, as the $[H^+]$ decreases, the pH increases. The greater the $[H^+]$, the more acidic the solution and the lower the pH. The lower the $[H^+]$, the more basic the solution and the higher the pH. In biologic fluids, a pH of less than 7.4 is defined as acidic and a pH greater than 7.4 is defined as basic.

Different body fluids have different pH values as follows:

Body Fluid	pH
Gastric juices	1.0-3.0
Urine	5.0-6.0
Arterial blood	7.38-7.42
Venous blood	7.32-7.36
Cerebrospinal fluid	7.28-7.32
Pancreatic fluid	7.8-8.0

Body acids are formed as end products of cellular metabolism. The average person generates 50 to 100 mEq/day of acid from the metabolism of protein, carbohydrates, and fats and from loss of alkaline fluids in the stools. To maintain a normal pH, an equal amount of acid therefore must be neutralized or excreted. The lungs, kidneys, and bone are the major organs involved in the regulation of acid-base balance. The systems are interrelated and work together to regulate short- or long-term changes in acid-base status. Body acids exist in two forms: **volatile** (respiratory acids—eliminated as carbon dioxide [CO_2] gas) and **nonvolatile** (metabolic acids—eliminated by the kidney or metabolized by the liver). The volatile acid is carbonic acid (H_2CO_3), which is formed from the hydration of carbon dioxide:

Regulated by lung Regulated by kidney

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \quad \leftrightarrow \quad HCO_3^- + H^+$$

Carbonic acid is a weak acid, and in the presence of carbonic anhydrase, it readily dissociates into carbon dioxide and water. CO_2 is produced as an end product of oxidative metabolism. The more oxygen that is consumed, the more CO_2 is produced. The carbon dioxide is then eliminated by pulmonary ventilation. Sulfuric, phosphoric, and other metabolic acids (lactic acid, pyruvic acid, and keto acids [such as acetoacetic acid and β-hydroxybutyric acid, associated with diabetes mellitus]) are nonvolatile strong acids produced from the incomplete metabolism of proteins, carbohydrates, and fats. (Strong acids are those that readily give up their hydrogen; weak acids do not.) Nonvolatile acids are eliminated by the renal tubules in conjunction with the regulation of the concentration of HCO_3^-. Thus the lungs and kidneys, with the help of body buffer systems, are the prime regulators of acid-base balance.

Buffer Systems

Buffering occurs in response to changes in acid-base status. **Buffers** can absorb excessive H^+ (acid) or OH^- (base) to minimize fluctuations in pH. The buffer systems are located in both the ICF and ECF compartments, and they function at different rates. Buffer systems exist as buffer pairs, consisting of a weak acid and its conjugate base (Table 3-11). The most important plasma buffer systems are bicarbonate–carbonic acid and hemoglobin. Phosphate and protein are the most important intracellular buffers. Ammonia and phosphate are important renal buffers.

An important factor for effective buffering is a function known as the *pK value*, which represents the pH at which a buffer pair is half dissociated. Buffer pairs can associate and dissociate (see Table 3-11).

The pK provides a rate constant for the chemical reaction. A buffer system is most effective when the pK for the buffer is close to the pH of the fluid in which the buffer is acting. There is an equal concentration of acid and its conjugate base when pK equals pH. For the bicarbonate–carbonic acid buffer system, the pK is 6.1. This value is not as high as the pK for other buffer systems (see Table 3-11), but this buffer system is still very effective because carbon dioxide is rapidly removed from the blood by the lungs.

The pK value is also a term in the equation used to determine pH. The relationships among pH, pK, and the ratio of bicarbonate to carbonic acid can be expressed as follows by the *Henderson-Hasselbalch equation:*

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

TABLE 3-11 BUFFER SYSTEMS

BUFFER PAIRS	BUFFER SYSTEM	PK VALUES	REACTION	RATE
HCO_3^-/H_2CO_3	Bicarbonate	6.1	$H^+ + HCO_3^- \gtreqless H_2O + CO_2$	Instantaneous
Hb^-/HHb	Hemoglobin	7.3	$HHb \rightleftharpoons H^+ + Hb^-$	Instantaneous
$HPO_4^=/H_2PO_4^-$	Phosphate	6.8	$HPO^-_4 + H^+ \rightleftharpoons H_2PO_4^-$	Instantaneous
Pr^-/HPr	Plasma proteins	6.7	$HPr \rightleftharpoons H^+ + Pr^-$	Instantaneous
ORGANS	**MECHANISM**			**RATE**
Lungs	Regulates retention or elimination of CO_2 and therefore H_2CO_3 concentration			Minutes to hours
Ionic shifts	Exchange of intracellular potassium and sodium for hydrogen			2-4 hours
Kidneys	Bicarbonate reabsorption and regeneration, ammonia formation, phosphate buffering			Hours to days
Bone	Exchanges of calcium and phosphate, release of carbonate			Hours to days

H^+, Hydrogen ion; *HCO_3^-*, bicarbonate; *H_2CO_3*, carbonic acid; *Hb^-*, hemoglobin; *$H_2PO_4^-$*, monobasic phosphate; *$HPO_4^=$*, dibasic phosphate; *HPr*, hydrogenated protein; *HHb*, hydrogenated hemoglobin; *Pr^-*, protein.

The pH then can be determined when specific values are included in the equation:

$$\begin{aligned} pH &= pK + \log\frac{[HCO_3^-]}{[H_2CO_3]} \\ &= 6.1 + \log\frac{24}{1.2} \\ &= 6.1 + \log\frac{20}{1} \\ &= 6.1 + 1.3 \\ &= 7.40 \end{aligned}$$

Bicarbonate Buffering–Carbonic Acid

The bicarbonate–carbonic acid buffer pair operates in both the lung and the kidney. The greater the carbon dioxide partial pressure (Pco_2), the more carbonic acid is formed. The relationship that exists between carbonic acid concentration ($[H_2CO_3]$) and carbon dioxide partial pressure (Pco_2) can be expressed as follows:

$$[H_2CO_3] = 0.03 \times PCO_2\ (mmHg)$$

The 0.03 represents the solubility coefficient for carbon dioxide in water. The Pco_2 of arterial blood ($Paco_2$) is normally about 40 mmHg. Therefore the amount of H_2CO_3 is equal to about 1.2 mmol/L (0.03 × 40). As the amount of carbon dioxide increases or decreases, the amount of H_2CO_3 changes in the same direction.

The relationship between the levels of bicarbonate and carbonic acid is usually expressed as a ratio. When the pH is 7.40, this ratio is 20:1 (bicarbonate/carbonic acid) (Figure 3-10). The ratio is defined by the amount of bicarbonate and carbon dioxide (carbonic acid) in the arterial blood. Bicarbonate concentration ($[HCO_3^-]$) is normally about 24 mEq/L. Therefore, the 20:1 ratio can be developed as follows:

$$\frac{[HCO_3^-] = 24\ mEq/L}{[H_2CO_3] = (0.03 \times 40\ mmHg)} = \frac{24}{1.2} = \frac{20}{1}$$

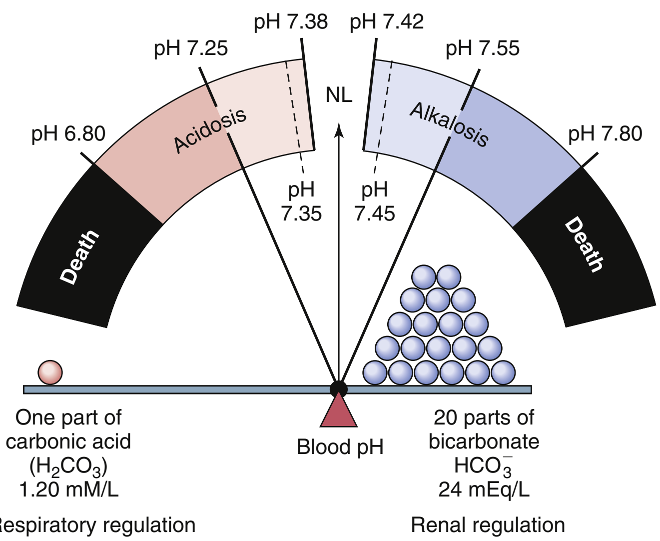

FIGURE 3-10 Ratio of Carbonic Acid and Bicarbonate Concentration in Maintaining pH within Normal Limits. An increase in H_2CO_3 or decrease in HCO_3^- concentration causes acidosis. A decrease in H_2CO_3 or increase in HCO_3^- concentration causes alkalosis. *NL,* Normal. (From Monahan FD et al: *Medical-surgical nursing: health and illness perspectives,* ed 8, St Louis, 2007, Mosby.)

The values for $[HCO_3^-]$ and $Paco_2$ ($[H_2CO_3]$) can increase or decrease proportionately, but the 20:1 ratio is maintained.

The lungs can decrease the amount of carbonic acid by exhaling CO_2 and leaving water. The kidneys can reabsorb bicarbonate or regenerate new bicarbonate from CO_2 and water. The renal mechanism does not act as rapidly as the lungs, but the two systems are very effective together because acid concentration can be rapidly adjusted by the lungs and bicarbonate is easily reabsorbed or regenerated by the kidneys. The pH equation can be symbolically expressed as follows:

$$pH = \frac{\text{Base}}{\text{Acid}} \quad \text{or} \quad pH = \frac{\text{Renal regulation (slow)}}{\text{Pulmonary regulation (fast)}}$$

or

$$pH = \frac{\text{Metabolic acid-base function}}{\text{Respiratory acid-base function}}$$

Changes in either the numerator or the denominator will change the pH. For example, if the amount of bicarbonate is decreased, the pH also decreases, causing a state of acidosis. The pH can be returned to a normal range if the value of the denominator or the amount of carbonic acid also decreases. When a disease process causes an alteration in the bicarbonate/carbonic acid ratio, the kidneys or lungs (i.e., the organ not responsible for causing the alteration) respond to restore the ratio and maintain

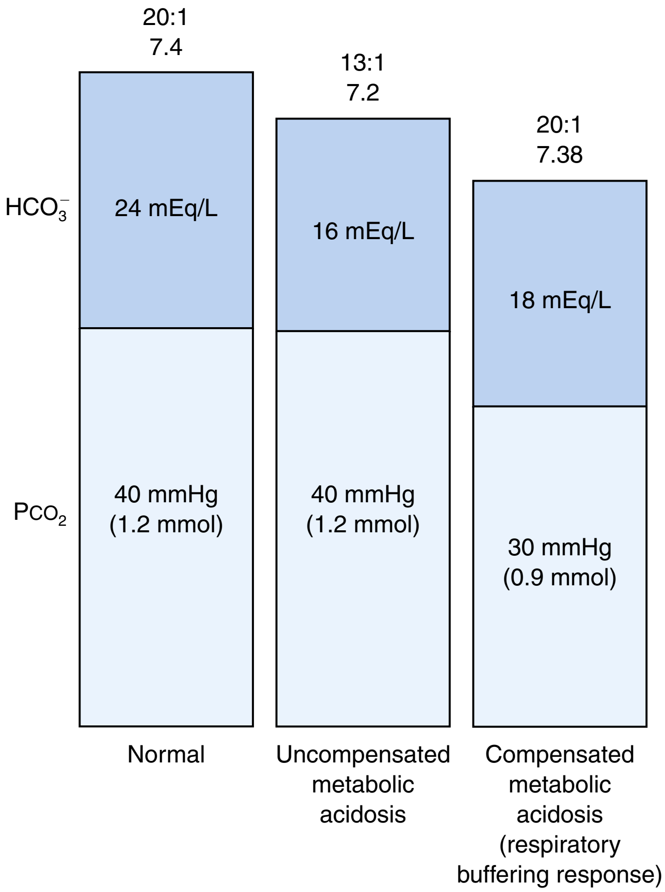

FIGURE 3-11 Compensated Maintenance of $[HCO_3^-]/Pco_2$ (H_2CO_3) Ratio in Metabolic Acidosis.

a normal pH. Renal and respiratory adjustments to *primary* changes in pH are known as **compensation.** With compensation, a 20:1 ratio may be achieved, but the actual values for HCO_3^- and H_2CO_3 concentrations are not normal. The respiratory system compensates for changes in pH by increasing or decreasing ventilation, a rapid response occurring within minutes to hours. The renal system compensates by producing more acidic or more alkaline urine, which may take hours to days. **Correction** occurs when the values for both components of the buffer pair ratio (bicarbonate and carbonic acid) return to normal (Figure 3-11).

Protein Buffering

Both intracellular and extracellular proteins have negative charges and can serve as buffers for H^+, but because most proteins are inside cells, they are primarily an intracellular buffer system. Hemoglobin (Hb) is an excellent intracellular blood buffer because of its ability to bind with H^+ (forming HHb) and carbon dioxide (forming $HHbCO_2$). Hemoglobin bound to H^+ becomes a weak acid. Less saturated hemoglobin (venous blood) is a better buffer than hemoglobin saturated with oxygen (arterial blood). The pH control system is illustrated in Figure 3-12.

Respiratory and Renal Buffering

The respiratory system regulates acid-base balance by controlling the rate of ventilation when there is metabolic acidosis or alkalosis. Central chemoreceptors sense increases or decreases in pH and $Paco_2$ (see Figure 32-11). When acidemia exists, the respiratory rate increases (eliminating CO_2 and reducing

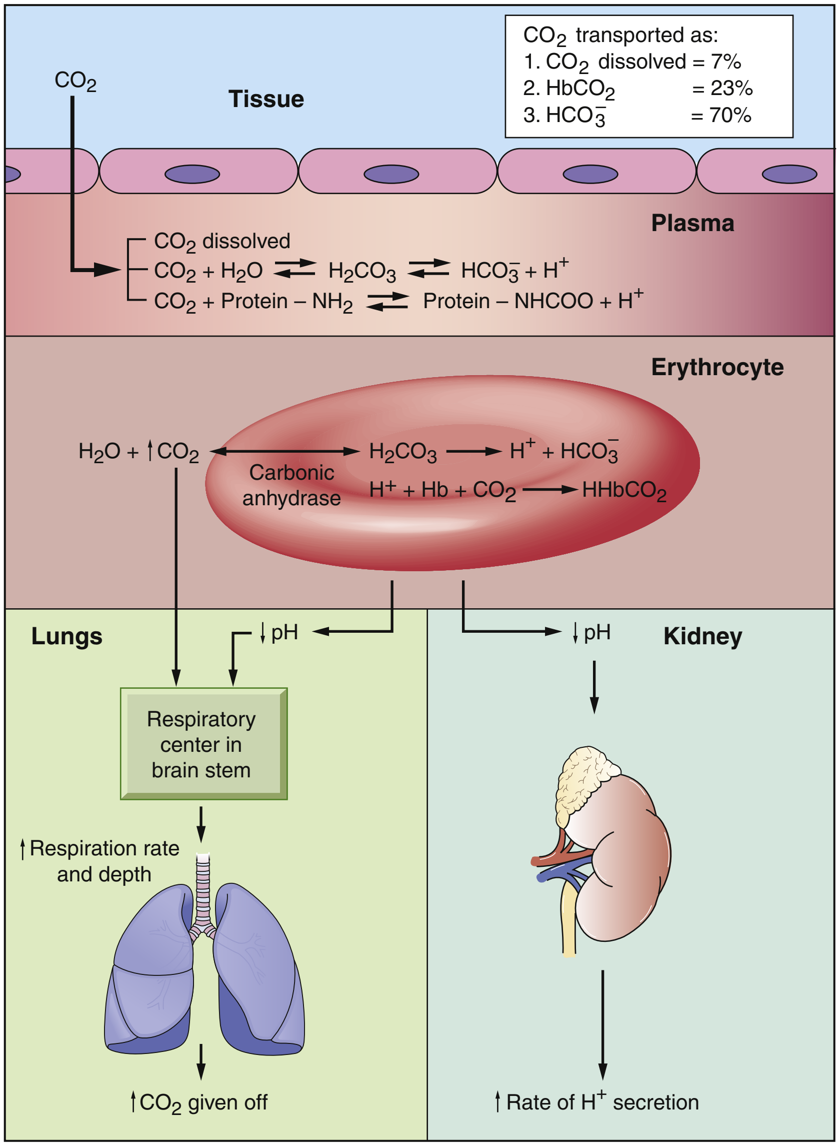

FIGURE 3-12 Integration of pH Control Mechanisms. CO_2 is produced in tissue cells and diffuses to plasma, where it is transported as dissolved CO_2, or it combines with water to form carbonic acid (H_2CO_3), or it combines with protein from which hydrogen has been released. Most of the CO_2 diffuses into the red blood cells and combines with water to form H_2CO_3. The H_2CO_3 dissociates to form hydrogen ion (H^+) and bicarbonate (HCO_3^-). Hydrogen ion combines with hemoglobin that has released its oxygen to form HHb, which buffers the hydrogen ion and makes venous blood slightly more acidic than arterial blood. The increase in H^+ concentration coupled with elevated CO_2 levels results in $HHbCO_3$ and an increase in the respiratory rate (eliminates CO_2) and secretion of H^+ by the kidneys.

carbonic acid concentration) (see Figure 3-12). When alkalemia occurs, the respiratory rate decreases (retaining CO_2 and increasing carbonic acid concentration).

The distal tubule of the kidney regulates acid-base balance by secreting hydrogen into the urine and regenerating bicarbonate with a maximum urine acidity of about pH 4.4 to 4.7. Buffers in the tubular fluid combine with hydrogen ions, allowing more H^+ to be secreted before the limiting pH value is reached. Dibasic phosphate ($HPO_4^=$) and ammonia (NH_3) are two important renal buffers. Dibasic phosphate is filtered at the glomerulus. About 75% is reabsorbed, and the remainder is available for buffering H^+. Secreted H^+ combines with $HPO_4^=$ to form monobasic phosphate ($H_2PO_4^-$). The remaining negative charge on the molecule makes it lipid insoluble, preventing it from diffusing back across the tubular cells and into the blood. Thus the $H_2PO_4^-$ containing the secreted H^+ is excreted in the urine (Figure 3-13).

Ammonia (NH_3) is an important renal buffer; it is not ionized (does not carry a charge), and therefore it is lipid soluble and can cross the tubular cell membrane. The presence of NH_3 in the tubular cells creates a concentration gradient, and it diffuses into the renal tubular fluid, where it combines with hydrogen to form ammonium ion (NH_4^+), which is eliminated in the urine (see Figure 3-13). NH_4^+ is lipid insoluble and does not readily diffuse back into the tubular cells. The renal buffering of hydrogen ions requires the use of CO_2 and H_2O to form H_2CO_3. The enzyme carbonic anhydrase catalyzes the formation of H^+ + HCO_3^-. The hydrogen is secreted from the tubular cell and buffered in the lumen by phosphate and ammonia. The bicarbonate is reabsorbed. The end effect is the addition of new bicarbonate, which contributes to the alkalinity of the plasma, because the hydrogen ion is excreted from the body (see Figure 3-13).

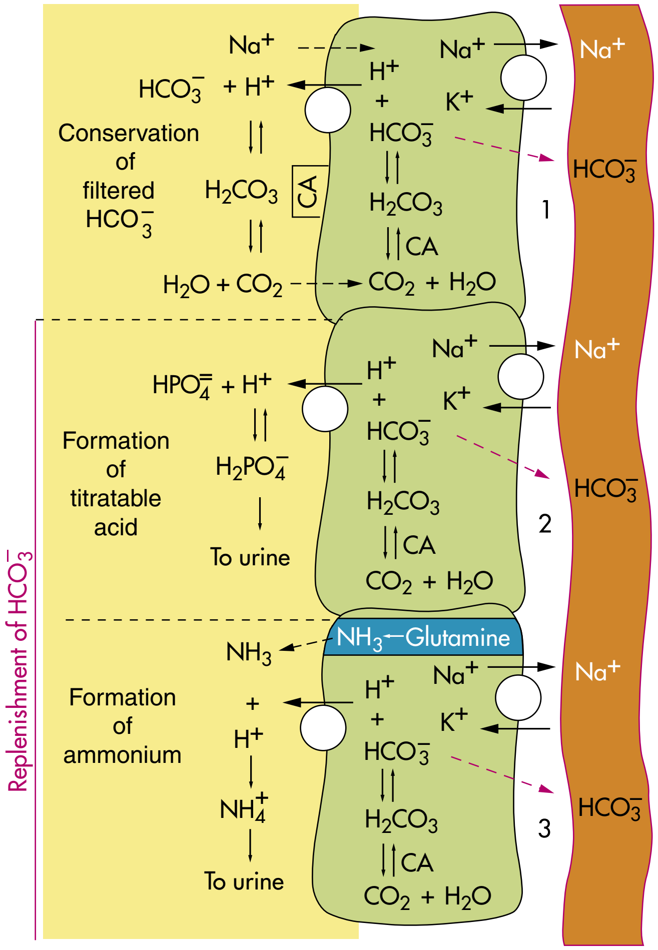

FIGURE 3-13 Renal excretion of acid. **1,** *Conservation of Filtered Bicarbonate.* Filtered bicarbonate combines with secreted hydrogen ion in the presence of carbon anhydrase *(CA)* to form carbonic acid (H_2CO_3), which then dissociates to water (H_2O) and carbon dioxide (CO_2); both diffuse into the epithelial cell. The CO_2 and H_2O combine to form H_2CO_3 in the presence of CA, and the resulting bicarbonate ion (HCO_3^-) is reabsorbed into the capillary. **2,** *Formation of Titratable Acid.* Hydrogen ion is secreted and combines with dibasic phosphate ($HPO_4^=$) to form monobasic phosphate ($H_2PO_4^-$). The secreted hydrogen ion is formed from the dissociation of H_2CO_3, and the remaining HCO_3^- is reabsorbed into the capillary. **3,** *Formation of Ammonium.* Ammonia (NH_3) is produced from glutamine in the epithelial cell and diffuses to the tubular lumen, where it combines with H^+ to form ammonium ion (NH_4^+). Once NH_4^+ has been formed, it cannot return to the epithelial cell (diffusional trapping), and the bicarbonate remaining in the epithelial cell is reabsorbed into the capillary.

Other Buffers

A cellular ion exchange mechanism is also an important buffering system. The best example is the shift of potassium in exchange for hydrogen during states of acidosis or alkalosis. During acidosis, potassium tends to leave the intracellular space in exchange for hydrogen. The reverse occurs during alkalosis. Although the ionic shifts facilitate buffering, the changes in intracellular or extracellular potassium concentrations may have serious consequences (e.g., hyperkalemia or hypokalemia).

Acid-Base Imbalances

Pathophysiologic changes in the concentration of hydrogen ion or base in the blood lead to acid-base imbalances. **Acidemia** is a state in which the pH of arterial blood is less than 7.35. A systemic increase in hydrogen ion concentration or loss of base is termed **acidosis. Alkalemia** is a state in which the pH of arterial blood is greater than 7.45. A systemic decrease in hydrogen ion concentration or an excess of base is termed **alkalosis.** Acid-base imbalances may have a metabolic or respiratory etiology or may be of mixed etiology. Acid-base imbalances are assessed using a measurement of arterial blood gases that includes the reporting of pH, $Paco_2$, and HCO_3^- concentration. The medical history is important to determining the cause of the disorder. Figure 3-14 summarizes the relationships among pH, $Paco_2$, and bicarbonate concentration during different acid-base alterations.

Metabolic Acidosis

PATHOPHYSIOLOGY. In **metabolic acidosis,** the concentration of non-carbonic acids increases or bicarbonate (base) is lost from the extracellular fluid or cannot be regenerated by the kidney (Table 3-12). This can occur quickly, as in lactic acidosis from poor perfusion or hypoxemia, or more slowly, as in renal failure (failure to excrete acid) or diabetic ketoacidosis (excess production of keto acids from lack of insulin) (see Chapter 23).

The buffer systems compensate for the excess acid and attempt to maintain the arterial pH within a normal range.

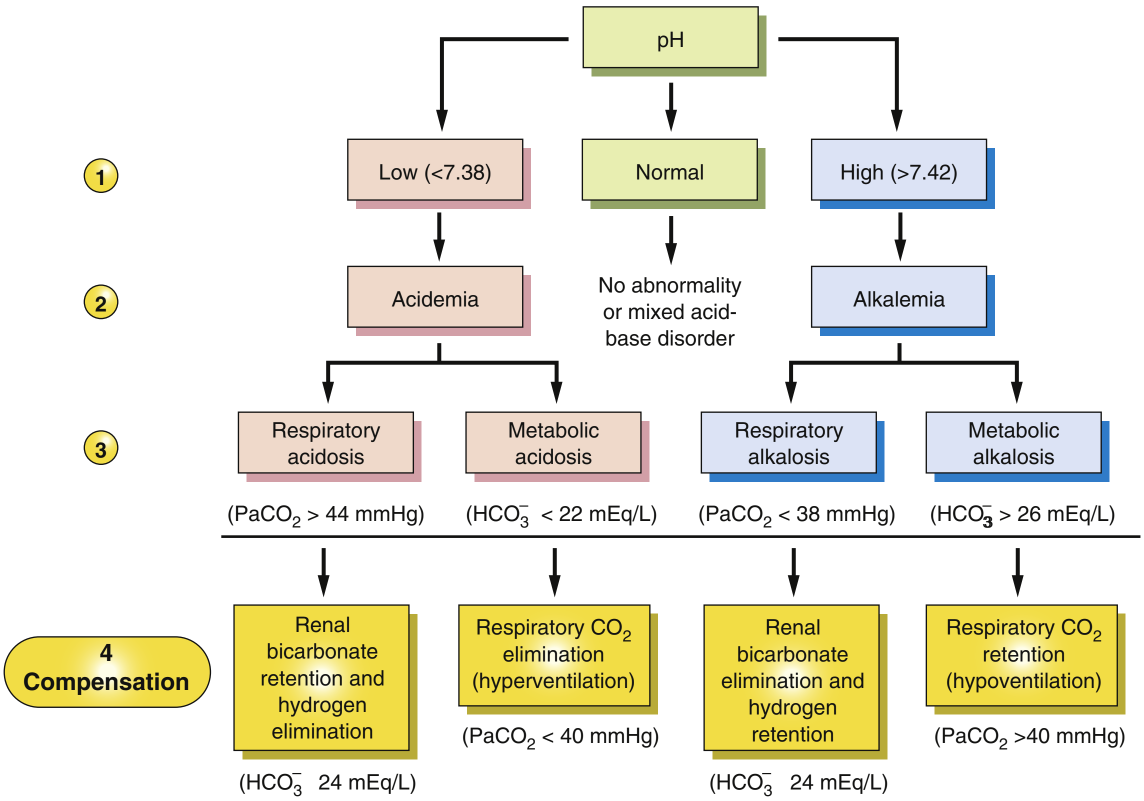

FIGURE 3-14 **Primary and Compensatory Acid-base Changes.** A systematic approach can be used to interpret the cause of an acid-base imbalance. **1,** Is the pH low or high? **2,** If the pH is low there is acidemia; if the pH is high there is alkalemia. **3,** If the pH is low (acidemia), is the cause respiratory (high $Paco_2$) or metabolic (low HCO_3^-)? If the pH is high (alkalemia), is the cause respiratory (low $Paco_2$) or metabolic (high HCO_3^-)? **4,** Is there compensation for the primary acid-base disorder? *(a)* HCO_3^- will be ≥24 mEq/L if there is renal compensation for a primary respiratory acidosis; *(b)* $Paco_2$ will be <40 mmHg if there is respiratory compensation of a primary metabolic acidosis; *(c)* HCO_3^- will ≤24 mEq/L if there is renal compensation for primary respiratory alkalosis; *(d)* $Paco_2$ will be >40 mmHg if there is respiratory compensation for primary metabolic alkalosis. **NOTE:** Examine the pH first. Then examine the changes in HCO_3^- and $Paco_2$. HCO_3^- will be elevated when there is primary metabolic alkalosis or renal compensation for primary respiratory acidosis. HCO_3^- will be decreased when there is primary metabolic acidosis or renal compensation for primary respiratory alkalosis. $Paco_2$ will be elevated when there is primary respiratory acidosis or respiratory compensation for primary metabolic alkalosis. $Paco_2$ will be decreased when there is primary respiratory alkalosis or respiratory compensation for metabolic acidosis.

TABLE 3-12 CAUSES OF METABOLIC ACIDOSIS

INCREASED NON–CARBONIC ACIDS (ELEVATED ANION GAP)	BICARBONATE LOSS (NORMAL ANION GAP)
Increased H+ load	Diarrhea
Ketoacidosis (e.g., diabetes mellitus, starvation)	Ureterosigmoidoscopy
Lactic acidosis (e.g., shock)	Renal failure
Ingestions (e.g., ammonium chloride, ethylene glycol, methanol, salicylates, paraldehyde)	Proximal renal tubule acidosis
Decreased H+ excretion	
Uremia	
Distal renal tubule acidosis	

Hydrogen ions will move to the intracellular space, and potassium will move to the extracellular space to maintain an ionic balance (see p. 115). Buffering by bicarbonate lowers the serum value of hydrogen ions and increases the pH. The respiratory system compensates for a metabolic acidosis as the reduced pH stimulates hyperventilation, lowering the $Paco_2$ and the amount of H_2CO_3 circulating in the blood. The kidneys excrete the excess acid as NH_4^+ and titratable acid ($H_2PO_4^-$). When acidosis is severe, buffers become depleted and cannot compensate for the increasing H^+ load and the pH continues to decrease. The ratio of bicarbonate to carbonic acid decreases to less than 20:1 (Figure 3-15). In states of metabolic acidosis, potassium is redistributed from the intracellular to the extracellular space, and is reabsorbed at the apical membrane of the renal collecting tubule (see p. 114). There is also an increase in the levels of ionized calcium because acidosis decreases the amount of calcium bound to albumin (see p. 114).

The evaluation of the **anion gap** can be helpful when used cautiously to distinguish different types of metabolic acidosis.[22]

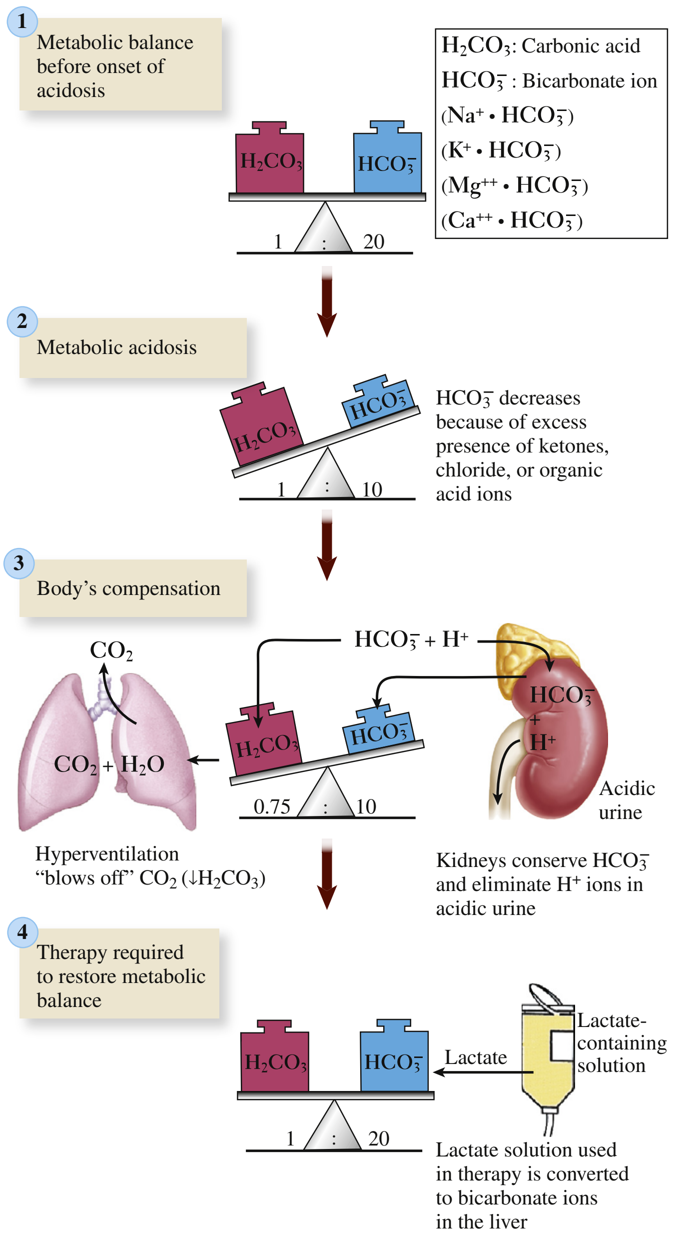

FIGURE 3-15 Metabolic Acidosis with Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

Normally, the concentrations of cations and anions in the plasma are equivalent. Some anions, such as protein, sulfates, phosphates, and organic acids, however, are not measured in the common laboratory evaluations of the blood. Therefore the normal anion gap represents these unmeasured negative ions (sulfate, phosphate, lactate, keto acids, albumin). A convenient measure of the anion gap is the difference between the sum of Na^+ and K^+ and the sum of HCO_3^- and Cl^-, or about 10 to 12 mEq/L:

$$\text{Anion gap} = [Na^+\ (140) + K^+\ (4.0)] - [HCO_3^-\ (24) + Cl^-\ (110)] = 10 - 12\ \text{mEq/L}$$

In metabolic acidosis a **normal anion gap** is characteristic of conditions related to bicarbonate loss with retention of chloride to maintain an ionic balance. This is called **hyperchloremic metabolic acidosis** and it occurs with renal failure, diabetic ketoacidosis, or prolonged diarrhea with bicarbonate loss. An elevated anion gap is characteristic of acidosis associated with accumulation of anions other than chloride (see Table 3-12).

CLINICAL MANIFESTATIONS. Metabolic acidosis is manifested by changes in the neurologic, respiratory, gastrointestinal, and cardiovascular systems. Headache and lethargy are early symptoms, which progress to coma with severe acidosis. Deep, rapid respirations (Kussmaul respirations) are indicative of respiratory compensation. Anorexia, nausea, vomiting, diarrhea, and abdominal discomfort are common. Severe acidosis can compromise ventricular contraction and produce life-threatening dysrhythmias.

EVALUATION AND TREATMENT. The diagnosis of metabolic acidosis is established from the health history, clinical symptoms, and laboratory findings. Arterial blood pH is below 7.35, and bicarbonate concentration is less than 24 mEq/L. The anion gap can isolate the specific cause. The oxyhemoglobin curve is shifted to the right (see Figure 34-18), reducing hemoglobin affinity for oxygen.

The underlying condition must be diagnosed to establish effective treatment of a buffering solution. During severe acidosis (pH ≤7.1), administration is required to elevate the pH to a safe level, particularly if there is renal failure. Accompanying sodium and water deficits must also be corrected.[22]

Metabolic Alkalosis

PATHOPHYSIOLOGY. **Metabolic alkalosis** occurs when bicarbonate concentration is increased, usually caused by excessive loss of metabolic acids. Conditions that can result in metabolic alkalosis are prolonged vomiting, gastric suctioning, excessive bicarbonate intake, hyperaldosteronism with hypokalemia, and diuretic therapy.[23]

Respiratory compensation for metabolic alkalosis occurs when the elevated pH inhibits the respiratory center. The rate and depth of ventilation are decreased, causing retention of carbon dioxide. The ratio of HCO_3^- concentration to H_2CO_3 concentration is reduced toward normal. Respiratory compensation is not very efficient, however, and chronic or severe metabolic alkalosis requires therapeutic intervention (Figure 3-16).

Hypochloremic metabolic alkalosis occurs when acid loss is caused by vomiting or gastric suctioning with depletion of ECF sodium, chloride, and potassium. Renal compensation is not very effective because the volume depletion and loss of electrolytes stimulate a paradoxical response by the kidneys. The kidneys increase bicarbonate reabsorption to maintain an anionic balance because the ECF chloride concentration is decreased. The resulting excretion of H^+ and reabsorption of bicarbonate prevent correction of the alkalosis (Figure 3-17). The kidneys also increase sodium reabsorption. When potassium concentration is depleted, hydrogen ion moves to the intracellular space and is excreted to maintain an electrochemical balance.

With alkalemia, hydrogen ions are redistributed from the intracellular to the extracellular space and potassium moves to the intracellular space to preserve electroneutrality. With

hyperaldosteronism, the excess aldosterone causes sodium retention and loss of hydrogen and potassium ions. Mild volume expansion ensues, and bicarbonate is retained along with the sodium, thereby causing alkalosis. Diuretics, such as thiazides, ethacrynic acid, and furosemide, produce mild alkalosis by enhancing sodium, potassium, and chloride excretion more than bicarbonate excretion.

CLINICAL MANIFESTATIONS. Because of the many causes of metabolic alkalosis, the symptoms vary. Some common symptoms, such as weakness, muscle cramps, and hyperactive reflexes, are related to volume depletion and electrolyte losses. Because alkalosis increases binding of Ca^{++} to plasma proteins (albumin), ionized calcium concentration decreases, causing excitable cells to become hypopolarized, which initiates an action potential

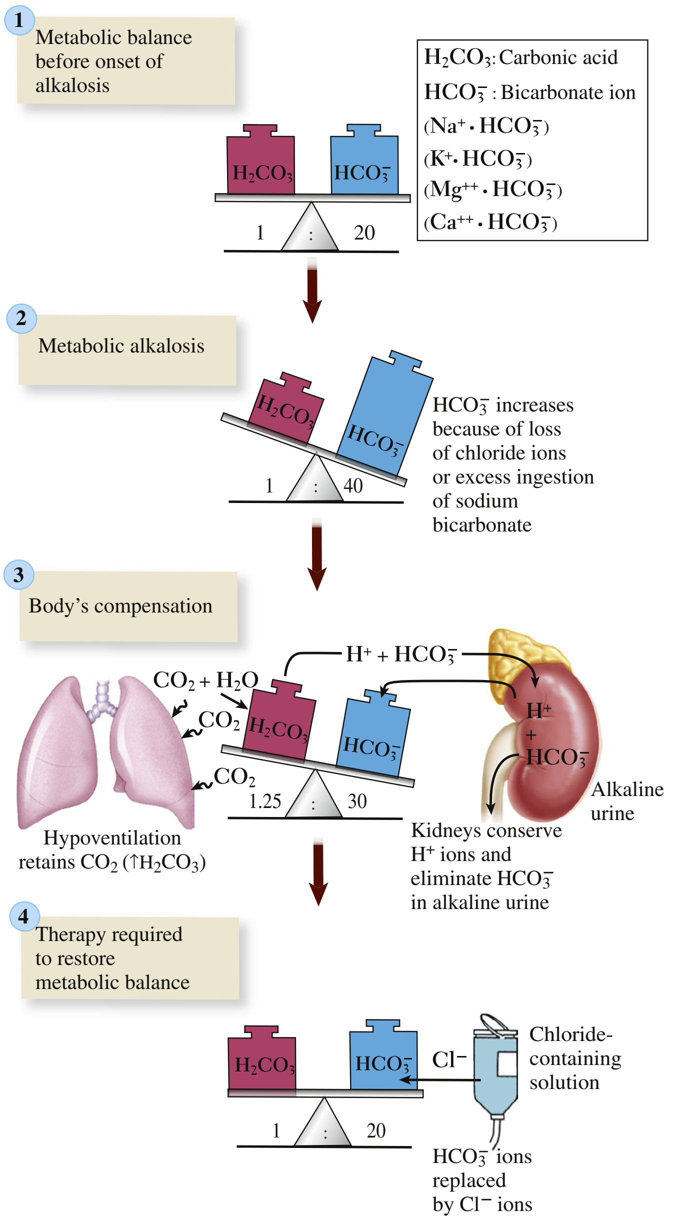

FIGURE 3-16 Metabolic Alkalosis with Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

more easily. Paresthesias (especially numbness/tingling of the fingertips and perioral area), tetany, and seizures may develop (see Hypocalcemia, p. 120).

Respirations are slow and shallow to increase carbon dioxide retention. Confusion and convulsions occur with severe alkalosis. Atrial tachycardia is a potential problem. The oxyhemoglobin curve is shifted to the left (see Figure 34-18), decreasing the dissociation of oxyhemoglobin and increasing the risk of dysrhythmias.

EVALUATION AND TREATMENT. The health history provides significant clues to the diagnosis of metabolic alkalosis. The arterial pH is greater than 7.45, and bicarbonate levels exceed 26 mEq/L. With respiratory compensation, the $Paco_2$ rises above 40 mmHg. With hypochloremic metabolic alkalosis, serum chloride values are below normal. Serum potassium levels are usually depleted because hydrogen is released from the cells in exchange for potassium to help regulate the pH level. The potassium is then secreted from renal distal tubule cells into the urine.

With hypochloremic alkalosis or contraction alkalosis with volume depletion, a sodium chloride solution is required for *correction*. The renal stimulus to increase ECF volume by retaining Na^+ is diminished, and HCO_3^- can be excreted as $NaHCO_3$ in the urine. The administration of potassium corrects alkalosis caused by hyperaldosteronism or hypokalemia. The potassium causes hydrogen to move back into the ECF and decreases loss of hydrogen from the distal tubule.

Respiratory Acidosis

PATHOPHYSIOLOGY. Respiratory disorders of acid-base balance are caused by increases or decreases of alveolar ventilation in relation to the metabolic production of carbon dioxide. **Respiratory acidosis** occurs when there is alveolar hypoventilation. Carbon dioxide is retained, increasing $[H^+]$ (as H_2CO_3) and producing acidosis. Carbon dioxide excess in the blood is called **hypercapnia.** The common causes include depression of the respiratory center (brainstem trauma, oversedation), paralysis of the respiratory muscles, disorders of the chest wall (kyphoscoliosis, pickwickian syndrome, flail chest), and disorders of the lung parenchyma (pneumonitis, pulmonary edema, emphysema, asthma, bronchitis).

Respiratory acidosis may be acute or chronic. Airway obstruction is the most common cause of acute respiratory acidosis. Acute compensation for respiratory acidosis is not effective because the renal buffer mechanism takes time to function. Further, the protein buffers provide marginal compensation, and HCO_3^- is not a good buffer for CO_2. Acute uncompensated respiratory acidosis is characterized by decreased arterial pH, elevated $Paco_2$, and normal or slightly increased bicarbonate concentration.

Chronic respiratory acidosis is commonly associated with chronic obstructive pulmonary disease and deformities of the chest wall or neuromuscular disorders. Renal compensation is effective and is established over several days. The acidosis produced from CO_2 retention stimulates the kidney to secrete hydrogen ions and regenerate bicarbonate. Serum bicarbonate and $Paco_2$ levels are elevated, and pH is restored toward normal (Figure 3-18).

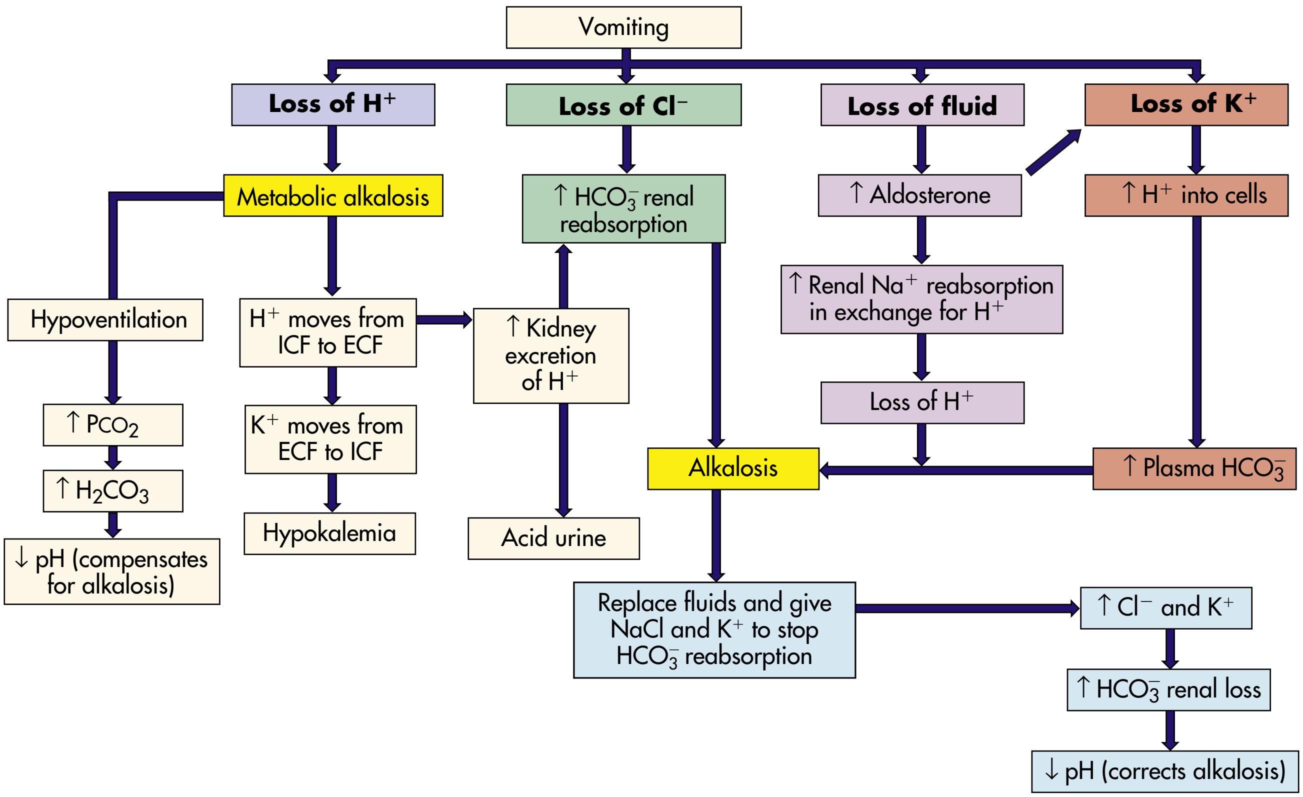

FIGURE 3-17 Hypochloremic Metabolic Alkalosis. See text for abbreviations.

CLINICAL MANIFESTATIONS. The symptoms of respiratory acidosis are related to acuity of onset and severity of $Paco_2$ retention. Initial symptoms include headache, restlessness, blurred vision, and apprehension followed by lethargy, muscle twitching, tremors, convulsions, and coma. Neurologic symptoms are caused by a decrease in the pH of cerebrospinal fluid and vasodilation because CO_2 readily crosses the blood-brain barrier. The respiratory rate is rapid at first and gradually becomes depressed because over time, the respiratory center adapts to increasing levels of CO_2. Cyanosis does not occur unless there is an accompanying hypoxemia, and the skin may instead be pink from vasodilation caused by the elevated CO_2 level.

EVALUATION AND TREATMENT. The primary diagnostic indicators are an arterial pH less than 7.35 and hypercapnia. Acute respiratory acidosis must be distinguished from chronic acidosis; the health history and clinical laboratory data are therefore helpful.

In many cases, restoration of adequate alveolar ventilation removes excess CO_2. If alveolar ventilation cannot be maintained spontaneously because of drug overdose or neuromuscular disorders, mechanical ventilation is required. When the hypercapnea is caused by alterations in gas diffusion at the alveolar-capillary membrane, ventilation may not be effective. The values of arterial pH, Pco_2, Po_2, and HCO_3^- must be carefully monitored. Rapid reduction of $Paco_2$ can cause respiratory alkalosis with seizures and death.

The underlying diseases are treated to achieve maximal ventilation. In the presence of hypoxemia and hypercapnia, oxygen can function as a respiratory depressant when the respiratory center is no longer stimulated by the lower pH and elevated $Paco_2$ value. Therefore, oxygen should be given cautiously.

Respiratory Alkalosis

PATHOPHYSIOLOGY. **Respiratory alkalosis** occurs when there is alveolar hyperventilation and decreased concentration of plasma carbon dioxide (termed **hypocapnia**). Stimulation of ventilation is precipitated by hypoxemia (i.e., high altitudes); hypermetabolic states such as fever, anemia, and thyrotoxicosis; early salicylate intoxication; or anxiety or panic disorder. Improper use of mechanical ventilators can cause iatrogenic respiratory alkalosis. Secondary respiratory alkalosis may develop from hyperventilation stimulated by metabolic acidosis, causing a mixed acid-base disorder.

The onset of acute respiratory alkalosis occurs within minutes of hyperventilation. Cellular buffers provide immediate compensation (i.e., protein and shifts of H^+ from ICF to ECF). The H^+ shifts are not very effective, however, if the $Paco_2$ level is significantly decreased. When chronic respiratory alkalosis is present, renal compensation restores pH toward normal by decreasing H^+ excretion and bicarbonate absorption (Figure 3-19).

CLINICAL MANIFESTATIONS. Respiratory alkalosis, like metabolic alkalosis, is irritating to the central and peripheral nervous systems. Symptoms include dizziness, confusion, tingling of extremities (paresthesias), convulsions, and coma. Carpopedal

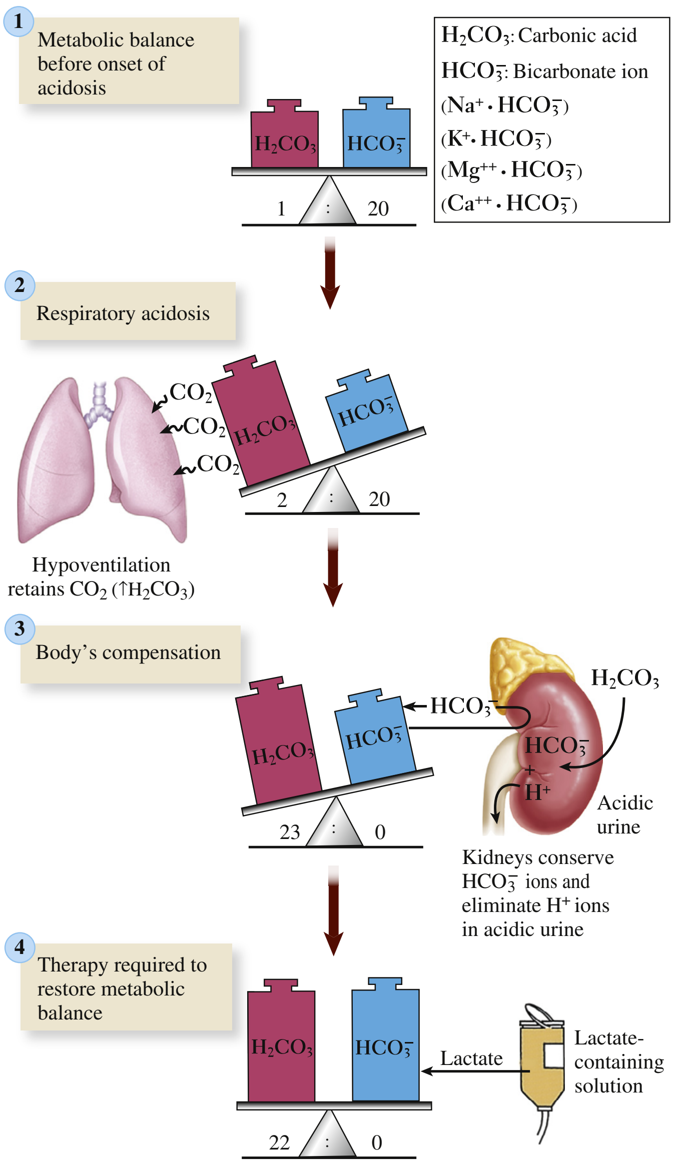

FIGURE 3-18 Respiratory Acidosis with Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

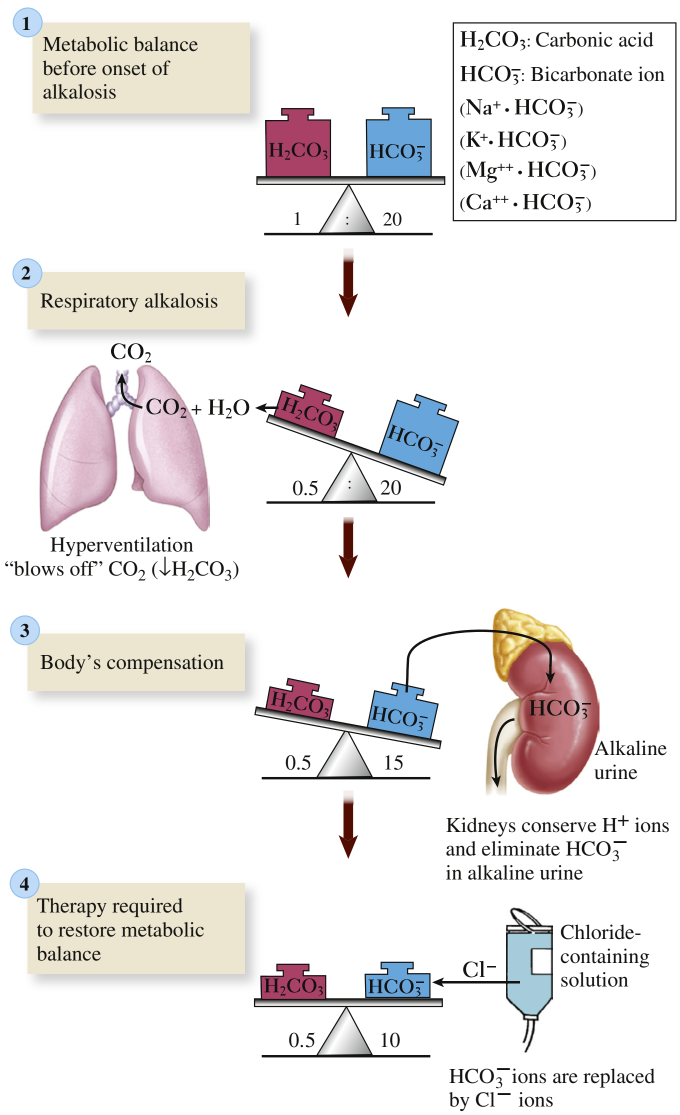

FIGURE 3-19 Respiratory Alkalosis with Compensation and Correction. See text for abbreviations. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

spasm and other symptoms of hypocalcemia are similar to those of metabolic alkalosis (see p. 128). Deep and rapid respirations (tachypnea) are primary symptoms of the disorders that cause respiratory alkalosis.

EVALUATION AND TREATMENT. The underlying disturbance must be identified. The arterial pH is greater than 7.45, and the $Pa{CO_2}$ is less than 38 mmHg. In acute states, bicarbonate levels are normal. With chronic respiratory alkalosis, a compensatory decrease in the bicarbonate level occurs and the pH is closer to normal.

Treating the underlying disturbance is the most effective treatment. Hypoxemia must be corrected and hypermetabolic states reversed. Symptoms from hysterical hyperventilation can be corrected by rebreathing from a paper bag, which increases the concentration of inspired carbon dioxide and reverses the respiratory alkalosis.

SUMMARY REVIEW

Distribution of Body Fluids

1. Body fluids are distributed among functional compartments and are classified as ICF or ECF.
2. The sum of all fluids is the TBW, which varies with age and amount of body fat.
3. Water moves between the ICF and ECF compartments principally by osmosis.
4. Water moves between the plasma and interstitial fluid by osmosis and hydrostatic pressure, which occur across the capillary membrane.
5. Movement across the capillary wall is called *net filtration* and is described according to the Starling law.

Alterations in Water Movement

1. Edema is a problem of fluid distribution that results in accumulation of fluid within the interstitial spaces.
2. Edema is caused by venous or lymphatic obstruction, plasma protein losses, increased capillary permeability, and increased vascular volume.
3. The pathophysiologic process that leads to edema is related to an increase in forces favoring fluid filtration from the capillaries into the tissues.
4. Edema may be localized or generalized and usually is associated with swelling and puffiness, tighter-fitting clothes and shoes, limited movement of the affected area, and, in severe cases, weight gain.

Sodium, Chloride, and Water Balance

1. Sodium balance and water balance are intimately related; chloride levels are generally proportional to changes in sodium levels.
2. Sodium balance is regulated by aldosterone, which increases reabsorption of sodium by the distal tubule of the kidney.
3. Renin and angiotensin are enzymes that promote or inhibit secretion of aldosterone and thus regulate sodium and water balance.
4. Atrial natriuretic hormone is also involved in decreasing tubular resorption and promoting urinary excretion of sodium.
5. Water balance is regulated by the sensation of thirst and by the level of antidiuretic hormone, which is initiated by an increase in plasma osmolality or a decrease in circulating blood volume.

Alterations in Sodium, Chloride, and Water Balance

1. Alterations in water balance may be classified as isotonic, hypertonic, or hypotonic.
2. Isotonic alterations occur when changes in TBW are accompanied by proportional changes in concentrations of electrolytes.
3. Hypertonic alterations develop when the osmolality of the ECF is elevated above normal, usually because of an increased concentration of ECF sodium or a deficit of ECF water.
4. Hypernatremia (sodium levels >147 mEq/L) may be caused by an acute increase in sodium level or a loss of water.
5. Water deficit, or hypertonic dehydration, can be caused by lack of access to water, pure water losses, hyperventilation, arid climates, or increased renal clearance.
6. Hyperchloremia is caused by an excess of sodium or a deficit of bicarbonate.
7. Hypotonic alterations occur when the osmolality of the ECF is less than normal.
8. Hyponatremia may be caused by loss of sodium, inadequate intake of sodium, or dilution of the body's sodium level.
9. Water excess is rare but can be caused by compulsive water drinking, decreased urine formation, or the syndrome of inappropriate secretion of ADH.
10. Hyponatremia (serum sodium concentration <135 mEq/L) usually causes movement of water into cells.
11. Hypochloremia is usually the result of hyponatremia or elevated bicarbonate concentrations.

Alterations in Potassium, Calcium, Phosphate, and Magnesium Balance

1. Potassium is the predominant ICF ion; it functions to regulate ICF osmolality, maintain the resting membrane potential, and deposit glycogen in liver and skeletal muscle cells.
2. Potassium balance is regulated by the kidney, by aldosterone and insulin secretion, and by changes in pH.
3. A mechanism known as *potassium adaptation* allows the body to accommodate slowly to increased levels of potassium intake.
4. Hypokalemia (serum potassium concentration <3.5 mEq/L) indicates loss of total body potassium, although ECF hypokalemia can develop without losses of total body potassium and plasma K^+ levels may be normal or elevated when total body potassium is depleted.
5. Hypokalemia may be caused by reduced potassium intake, increased ICF-to-ECF potassium concentration, loss of potassium from body stores, increased aldosterone secretion (e.g., caused by hypernatremia), and increased renal excretion.
6. Hyperkalemia (potassium levels >5.5 mEq/L) may be caused by increased potassium intake, a shift from ICF to ECF potassium, or decreased renal excretion.
7. Calcium is a necessary ion in the structure of bones and teeth, in blood clotting, in hormone secretion and the function of cell receptors, and in membrane stability.
8. Phosphate acts as a buffer in acid-base regulation and provides energy for muscle contraction.
9. Calcium and phosphate concentrations are rigidly controlled by PTH, vitamin D, and calcitonin.
10. Hypocalcemia (serum calcium concentration <8.5 mg/dl) is related to inadequate intestinal absorption, deposition of ionized calcium into bone or soft tissue, blood administration, or decreased PTH and vitamin D levels.
11. Hypercalcemia (serum calcium concentration >12 mg/dl) can be caused by a number of diseases, including hyperparathyroidism, bone metastases, sarcoidosis, and excess vitamin D.

SUMMARY REVIEW—cont'd

12. Hypophosphatemia is usually caused by intestinal malabsorption and increased renal excretion of phosphate.
13. Hyperphosphatemia develops with acute or chronic renal failure with significant loss of glomerular filtration.
14. Magnesium is a major intracellular cation and is principally regulated by PTH.
15. Magnesium functions in enzymatic reactions and often interacts with calcium at the cellular level.
16. Hypomagnesemia (serum magnesium concentrations <1.5 mEq/L) may be caused by malabsorption syndromes.
17. Hypermagnesemia (serum magnesium concentrations >2.5 mEq/L) is rare and is usually caused by renal failure.

Acid-Base Balance

1. Hydrogen ions, which maintain membrane integrity and the speed of enzymatic reactions, must be concentrated within a narrow range if the body is to function normally.
2. Hydrogen ion concentration is expressed as pH, which represents the negative logarithm of hydrogen ions in solution.
3. Different body fluids have different pH values.
4. The renal and respiratory systems, together with the body's buffer systems, are the principal regulators of acid-base balance.
5. Buffers are substances that can absorb excessive acid or base to minimize fluctuations in pH.
6. Buffers exist as acid-base pairs; the principal plasma buffers are bicarbonate, protein (hemoglobin), and phosphate.
7. Buffer pairs can associate and dissociate; the pK value is the pH at which a buffer pair is half dissociated.
8. The lungs and kidneys act to compensate for changes in pH by increasing or decreasing ventilation and by producing more acidic or more alkaline urine.
9. Correction is a process different from compensation; correction occurs when the values for both components of the buffer pair are returned to normal.
10. Acid-base imbalances are caused by changes in the concentration of H^+ in the blood; an increase causes acidosis, and a decrease causes alkalosis.
11. An abnormal increase or decrease in bicarbonate concentration causes metabolic acidosis or metabolic alkalosis; changes in the rate of alveolar ventilation produce respiratory acidosis or respiratory alkalosis.
12. Metabolic acidosis is caused by an increase in the concentrations of non-carbonic acids or by loss of bicarbonate from the extracellular fluid.
13. Metabolic alkalosis occurs with an increase in bicarbonate concentration usually caused by loss of metabolic acids from conditions such as vomiting, gastrointestinal suctioning, excessive bicarbonate intake, hyperaldosteronism, and diuretic therapy.
14. Respiratory acidosis occurs with a decrease of alveolar ventilation and an increase in levels of carbon dioxide, or hypercapnia.
15. Respiratory alkalosis occurs with alveolar hyperventilation and excessive reduction of carbon dioxide concentration, or hypocapnia.

CHAPTER OUTLINE

In the nineteenth century, microscopic studies of cells led scientists to suspect that the nucleus of the cell contained the important mechanisms of inheritance. Scientists found that chromatin, the substance that gives the nucleus a granular appearance, is observable in nondividing cells (also see Chapter 6). Just before the cell divides, the chromatin condenses to form microscopically observable, threadlike structures called chromosomes. (Cell division and chromosomes are discussed in Chapter 1.) With the rediscovery of Gregor Mendel's important breeding experiments at the turn of the twentieth century, it soon became apparent that the chromosomes contained **genes,** the basic units of inheritance. Genes are composed of sequences of **deoxyribonucleic acid (DNA),** a primary constituent of chromosomes; the other primary constituent consists of proteins, such as histones, that cause the DNA to coil into a highly compressed structure (Figure 1-2, Chapter 1). By serving as the blueprints of proteins in the body, genes ultimately influence all aspects of body structure and function. Humans have approximately 20,000 to 25,000 genes. An error in one of these genes can lead to a recognizable genetic disease. The composition of genes at a given locus is known as the ***genotype.*** The outward appearance of an individual, which is the result of both genotype and environment, is the ***phenotype*** (p. 151).

To date, more than 21,000 human genetic traits have been identified and cataloged.[1] About one third of pediatric inpatients are children with genetic diseases.[2] In addition, many common diseases that affect primarily adults, such as hypertension, coronary heart disease, diabetes, and cancer, are now known to have important genetic components. (These diseases are also affected by environmental factors. The interaction between genetic and environmental components is discussed in Chapter 5.)

BOX 4-1 GENETIC TESTING

The genetic causes of several thousand different diseases have now been identified and the pace of discovery is accelerating. Consequently, it is now possible to perform genetic tests to help determine whether an individual carries specific disease-causing mutations. Chromosome disorders, such as trisomy 21, are routinely detected using karyotypes or other, more automated approaches. More than 2700 diseases can now be diagnosed by testing for specific mutations (www.ncbi.nlm.nih.gov/sites/GeneTests/). In addition, genetic tests have been developed to help predict susceptibility for a number of common, genetically complex diseases.

Genetic testing can be applied in a variety of contexts, including:

1. *Carrier screening.* Genetic tests can identify heterozygous carriers for many recessive diseases, such as cystic fibrosis, sickle cell disease, and Tay-Sachs disease. It is becoming increasingly common for couples to undergo carrier screening to help make reproductive decisions, especially in populations in which specific diseases are relatively common (e.g., Tay-Sachs disease in the Ashkenazi Jewish population, β-thalassemia in Mediterranean populations). As a result, the prevalence of some of these diseases has declined dramatically in the past two decades.
2. *Prenatal diagnosis.* Several forms of prenatal genetic diagnosis are available, including:
   a. *Amniocentesis.* This procedure, which is usually carried out at about 16 weeks' gestation, involves the withdrawal of a small amount of amniotic fluid from the uterus. This fluid contains fetal cells, which can be cultured and karyotyped to detect chromosome abnormalities. In addition, genetic testing for single-gene disorders can be undertaken using DNA from these cells. Neural tube defects (spina bifida and anencephaly) can be detected as an elevation of α-fetoprotein level in amniotic fluid. Because there is a risk of fetal loss as a result of this procedure (estimated to be less than 1/200 above the background loss rate), it is usually recommended for women whose age is greater than 30 to 35 years or for couples who have a known increased risk of a specific genetic disease.
   b. *Chorionic villus sampling (CVS).* Carried out at 10 to 12 weeks' gestation, CVS is performed by extracting a small amount of villous tissue directly from the chorion. This procedure does not require in vitro culturing of cells for chromosome analysis because sufficient numbers are directly available in the extracted tissue. Chorionic villus sampling involves a slightly higher fetal loss rate (approximately 1%) than that of amniocentesis.
   c. *Preimplantation genetic diagnosis (PGD).* This relatively new procedure is carried out on early embryos (typically 8 to 12 cells) created by in vitro fertilization. One or two cells are removed from the embryo (which causes no damage), and these cells can be tested for chromosome abnormalities or single-gene disorders. If a genetic disorder is found in the cell, the embryo is not implanted in the mother's uterus.
   d. *Analysis of fetal DNA in maternal circulation.* By approximately 6 to 8 weeks' gestation, fetal cells can be found in the mother's bloodstream and these cells (or cell-free fetal DNA) can be tested for some disease-causing mutations. This approach is still largely experimental, but it is developing rapidly and has the advantages of early diagnosis and minimal risk to the mother and fetus. In addition to these diagnostic procedures, prenatal screening is now routinely carried out by measuring various analytes in maternal serum samples to assess the risk of conditions, such as trisomy 21, 13, and 18, and neural tube defects. Newborn screening also is commonly performed for a variety of genetic conditions such as PKU and galactosemia. A positive screening result is an indication for a subsequent diagnostic test (e.g., amniocentesis for a positive prenatal screening result or DNA sequencing for a positive newborn screening result).
3. *Presymptomatic diagnosis.* Many hereditary diseases, such as familial breast or colon cancer, can be tested genetically before an individual develops the disease. For some of these conditions, measures can be taken either to diagnose the disease early (e.g., colonoscopy) or to minimize the risk of developing the disease.
4. *Testing for drug efficacy or sensitivity.* A number of genes are now known to be associated with sensitivity to specific therapeutic drugs, and people are sometimes tested for variants in these genes to help guide drug treatment. For example, abacavir, an antiviral drug used in treating human immunodeficiency virus (HIV) infection, can cause severe adverse reactions in those who have a specific HLA-B variant (HLA-B*57:01), and the FDA now recommends testing for this variant before administering abacavir. For other drugs, such as warfarin, genetic testing for variants in specific genes (*CYP2C9* and *VKORC1*) may help to guide drug dosage.

Although genetic testing can be very informative, it also has limitations. Genetic testing usually reveals the presence or absence of a disease-causing mutation, but many genetic diseases have incomplete penetrance. For example, a woman who carries a mutation in the *BRCA1* or *BRCA2* genes has a lifetime breast cancer risk of approximately 70% to 80% (but not 100%). In addition, the absence of a disease-causing mutation does not guarantee that the disease in question will not occur (e.g., a woman who does not have a *BRCA1* or *BRCA2* mutation still has nearly the same risk of developing breast cancer as do other women because these genes account for only a few percent of all cases of breast cancer). Individuals and families should be advised of these and other limitations of genetic testing.

Data from Harper JC, Sengupta SB: *Hum Genet* 131(2):175–186, 2012; South ST et al: *Clin Obstet Gynecol* 51(1):62–73, 2008.

Great progress is being made in the diagnosis of genetic diseases and the understanding of genetic mechanisms underlying them. Genetic testing is used increasingly to guide drug choice and dosage, and gene therapy—the direct alteration of genes in cells—is now carried out effectively for some diseases. Genetics is now one of the most rapidly advancing fields of medicine (Boxes 4-1 and 4-2).

DNA, RNA, AND PROTEINS: HEREDITY AT THE MOLECULAR LEVEL

DNA

Composition and Structure

Genes are composed of DNA and the most important constituent of DNA is four types of nitrogenous bases (Figure 4-1). The four bases, **adenine, cytosine, guanine,** and **thymine,** are commonly represented by their first letters: A, C, G, and T, respectively.

In the early 1950s, James Watson and Francis Crick determined the physical structure of DNA. They proposed the now-famous **double-helix** model, in which DNA can be envisioned as a twisted ladder with chemical bonds as its rungs (see Figure 4-1). Projecting from each side of the ladder, at regular intervals, are the nitrogenous bases. The base projecting from one side is bound to the base projecting from the other by a weak hydrogen bond. Therefore, the nitrogenous bases form the rungs of the ladder; adenine pairs with thymine, and guanine pairs with cytosine. Each DNA subunit—consisting of one deoxyribose molecule, one phosphate group, and one base (see Figure 4-1)—is called a **nucleotide.**

BOX 4-2 GENE THERAPY

Gene therapy, in which the harmful effects of a disease-causing mutation are corrected by altering the person's DNA, has been a long-sought goal in human genetics. Hundreds of individuals are currently enrolled in dozens of clinical trials of gene therapy. Many technical challenges have arisen, but gene therapy is now beginning to yield positive therapeutic results.

In somatic cell gene therapy, the DNA of a specific set of an individual's somatic cells is altered (it is also possible to perform germline therapy, which affects all cells, including reproductive cells; however, for technical and ethical reasons, this is not being pursued in humans). Most commonly, somatic cell therapy is used for conditions in which a mutation has caused the absence of a gene product in a cell (e.g., adenosine deaminase in T cells, which leads to immunodeficiency). A "vector" is used to carry a normal copy of the mutated gene into the individual's cells. These vectors are usually viruses, such as retroviruses or adenoviruses, which have been genetically modified so that they contain the normal human gene and cannot make copies of themselves (otherwise they could cause a viral infection). Once inside the individual's cells, the normal human gene begins to encode the missing gene product.

This approach faces a number of technical hurdles, including immune responses against the vector and difficulties in producing sufficient quantities of the desired gene product. In one case, an immune response against an adenoviral vector proved fatal, and several cases of leukemia have resulted from the insertion of a modified retrovirus near an oncogene. Nevertheless, gene therapy has now been successful in treating a number of inherited conditions, including two forms of severe combined immunodeficiency (SCID), β-thalassemia, and X-linked adrenoleukodystrophy. In some cases, symptoms have been completely reversed through gene therapy. In addition to the treatment of hereditary diseases, gene therapy is being used to alter tumor cells in the treatment of various types of cancer. It is hoped that further research will lead to safe, efficient, and cost-effective treatment of many human diseases through gene therapy.

Data from Kay MA: *Nat Rev Genet* 12(5):316–328, 2011.

DNA as the Genetic Code

To serve as the basis of genetic inheritance DNA must be able to provide a code for all the body's proteins. Proteins are composed of one or more **polypeptides** (intermediate protein compounds), which are in turn composed of sequences of **amino acids** (organic acids containing NH_2). The body contains 20 different types of amino acids, and the amino acid sequences that make up polypeptides must in some way be specified by the DNA molecule.

Because there are 20 possible amino acids and only four bases, each single nucleotide cannot specify an amino acid. Similarly, the amino acids cannot be specified by couplets of bases (e.g., adenine-guanine, thymine-guanine, guanine-cytosine) because there are only 4×4, or 16, possible couplets. If series of 3 bases are translated into amino acids, however, there are $4 \times 4 \times 4$, or 64, possible combinations—more than enough to specify each different amino acid. By manufacturing synthetic nucleotide sequences and allowing them to direct the formation of amino acids in the laboratory, it was proved that amino acids were specified by these triplets of bases, or **codons.**

Of the 64 possible codons, three signal the end of a gene and are known as **termination,** or **nonsense, codons.** The remaining 61 all specify amino acids, which means that most amino acids can be specified by more than one codon. The genetic code is thus said to be redundant, although each codon can specify only one amino acid.

Another significant feature of the genetic code is that it is nearly universal: with the exception of ciliated protozoa and some plants, all organisms use precisely the same DNA codes to specify proteins. An important general exception to this rule occurs in mitochondria—cytoplasmic organelles that are the sites of cellular respiration (see Chapter 1). The mitochondria have their own extranuclear DNA. Several codons of mitochondrial DNA encode different amino acids than do the same nuclear DNA codons.

Replication

In addition to having the ability to specify amino acid sequences, DNA must be able to replicate itself accurately during cell division if it is to serve as the basic genetic material. DNA replication consists of the breaking of the weak hydrogen bonds between the bases, leaving a single strand with each base unpaired. The consistent pairing of adenine with thymine and of guanine with cytosine, known as **complementary base pairing,** is the key to accurate replication. The principle of complementary base pairing dictates that the unpaired base will attract a free nucleotide only if the nucleotide has the proper complementary base. Thus a portion of a single strand with a sequence of bases labeled ATTGCT will bond with a series of free nucleotides with the bases TAACGA. When replication is complete, a new double-stranded molecule identical to the original is formed (Figure 4-2, *A*). The single strand is said to be a **template (guide),** or molecule on which a complementary molecule is built, and is the basis for synthesizing the new double strand.

Several different proteins are involved in DNA replication. One protein unwinds the double helix, one holds the strands apart, and others perform different distinct functions. The most important of these proteins is the enzyme known as **DNA polymerase.** This enzyme travels along the single DNA strand, adding the correct nucleotides to the free end of the new strand (see Figure 4-2, *B*). Besides adding the new nucleotides, the DNA polymerase performs a proofreading procedure. After the new nucleotide has been added to the chain, the DNA polymerase checks to make sure that its base is actually complementary to the template base. If it is not, the incorrect nucleotide is excised and replaced with a correct one. This procedure, one of the mechanisms of DNA repair, substantially enhances the accuracy of DNA replication.

Mutation

A **mutation** is any inherited alteration of genetic material. Microscopically observable alterations of chromosome number or structure are examples of mutations. Some mutations are much too small to be observed under a microscope. An example is the **base pair substitution,** in which one base pair is replaced by another. This mutation is sometimes called **missense mutation** because the "sense" of the codon produced after transcription of the mutant gene is altered (Figure 4-3). This substitution sometimes results in a change in amino acid sequence, but because of the redundancy of the genetic code, it may have no consequence. Profound consequences can result

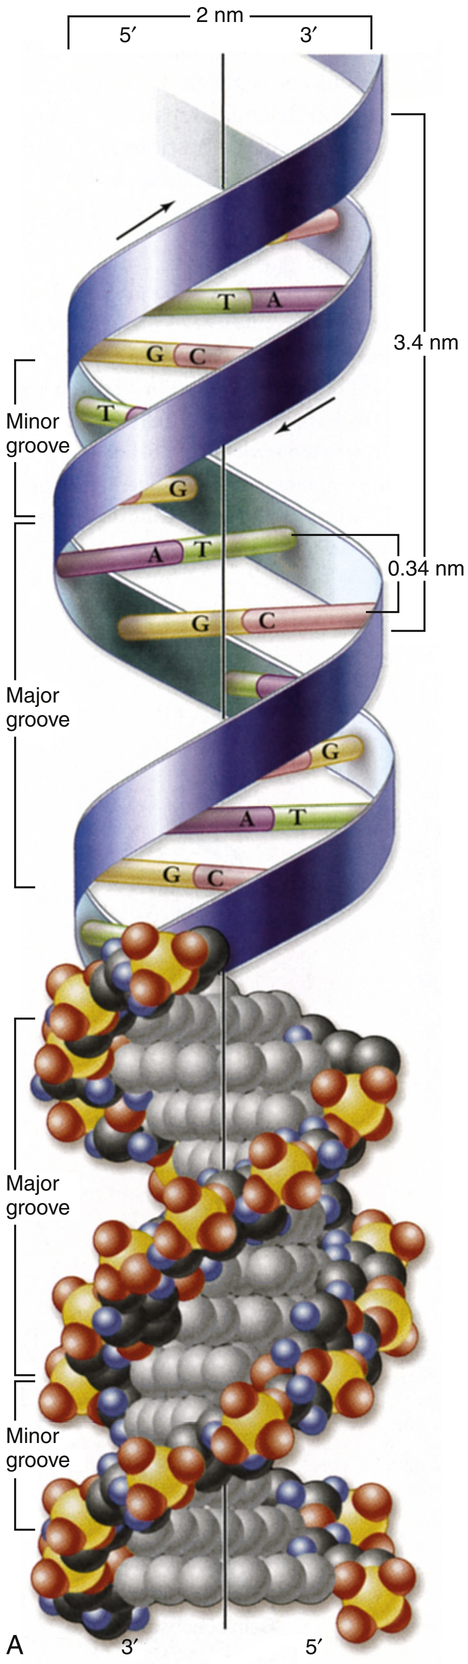

FIGURE 4-1 Structure of DNA. **A,** Double helix. Shown with the phosphodiester backbone as a ribbon on top and a space-filling model on the bottom. The bases protrude into the interior of the helix where they hold it together by base pairing. The backbone forms two grooves, the larger major groove and the smaller minor groove. **B,** Base pairing holds strands together. The H-bonds that form between A and T and between G and C are shown with dashed lines. These produce AT and GC base pairs that hold the two strands together. This always pairs a purine with a pyrimidine, keeping the diameter of the double helix constant. *A,* Adenine; *C,* cytosine; *G,* guanine; *T,* thymine. (From Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

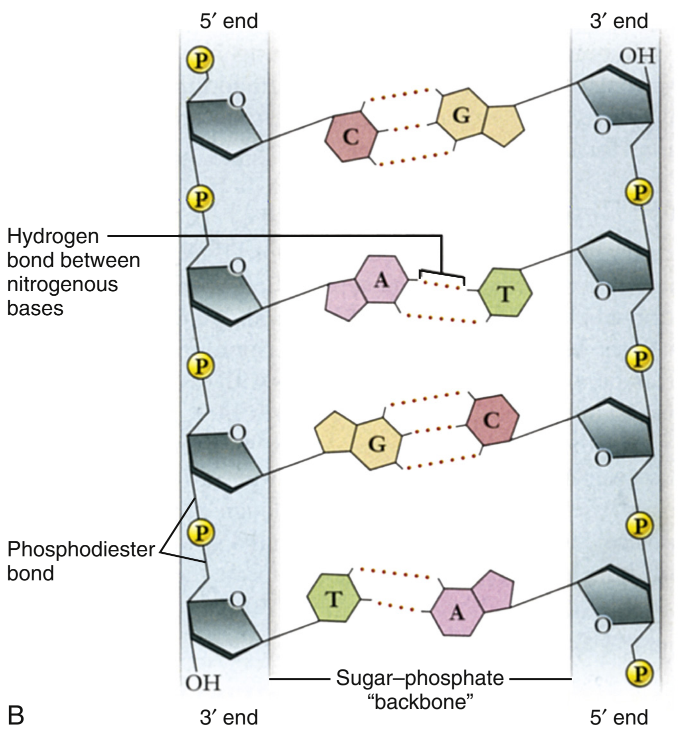

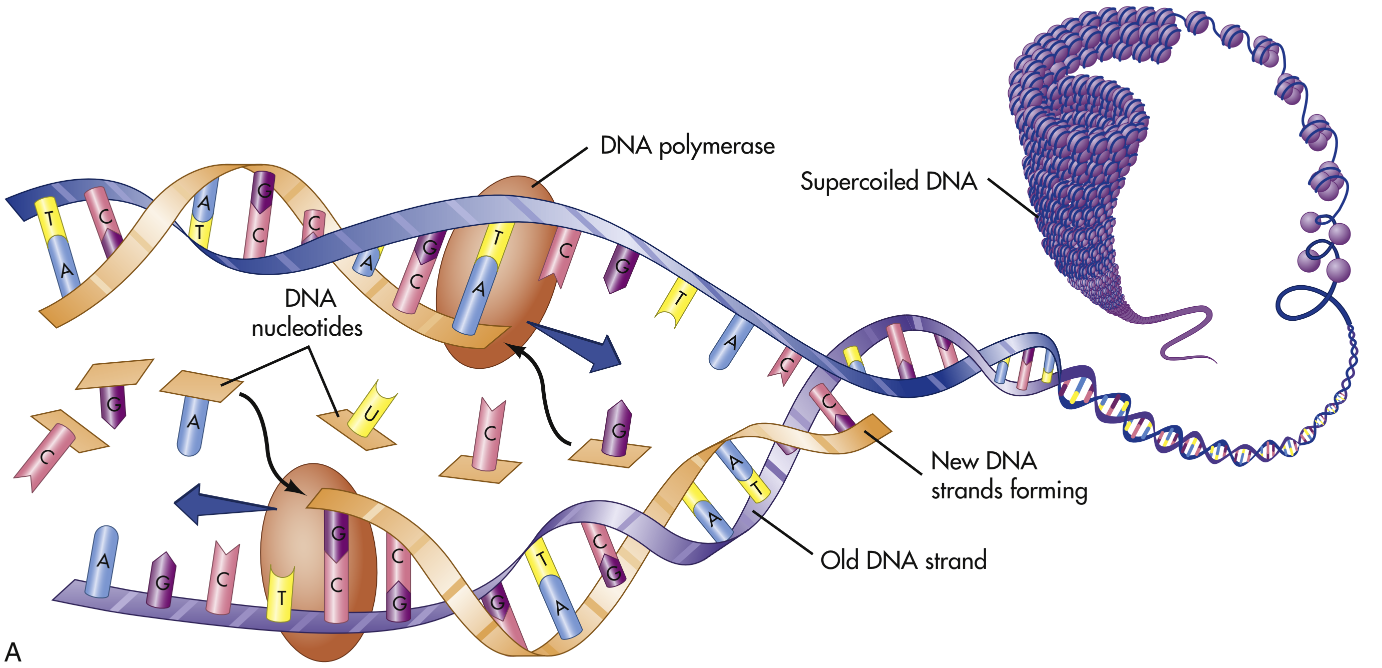

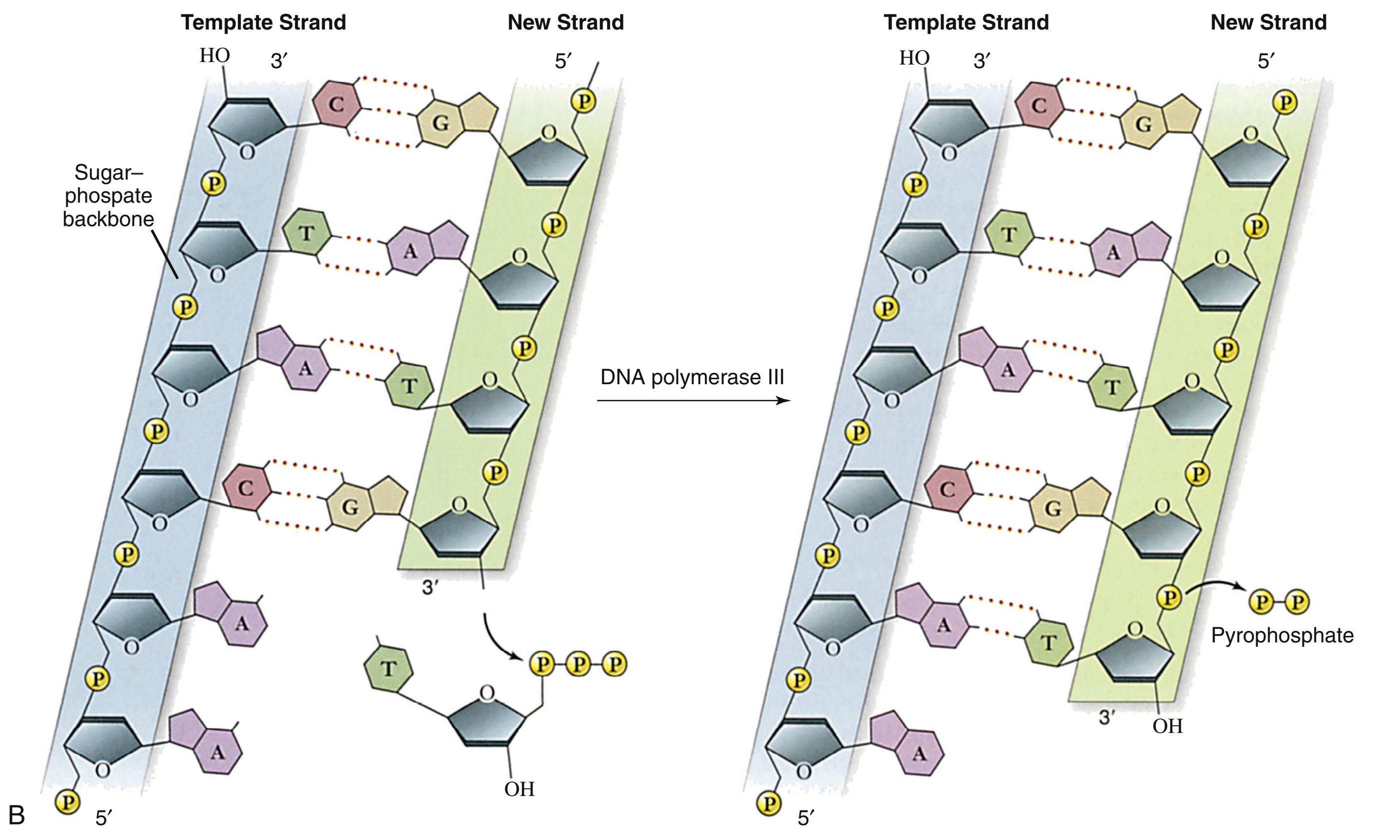

FIGURE 4-2 **Replication and Action of DNA. A,** Replication of DNA. **B,** Action of DNA polymerase. DNA polymerases add nucleotides to the 3′ end of a growing chain. The nucleotide added depends on the base that is in the template strand. Each new base must be complementary to the base in the template strand. With the addition of each new nucleotide, triphosphate, two of its phosphates are cleaved off as pyrophosphate. *A,* Adenine; *T,* thymine; *G,* guanine; *C,* cytosine. (**A** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby; **B** adapted from Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

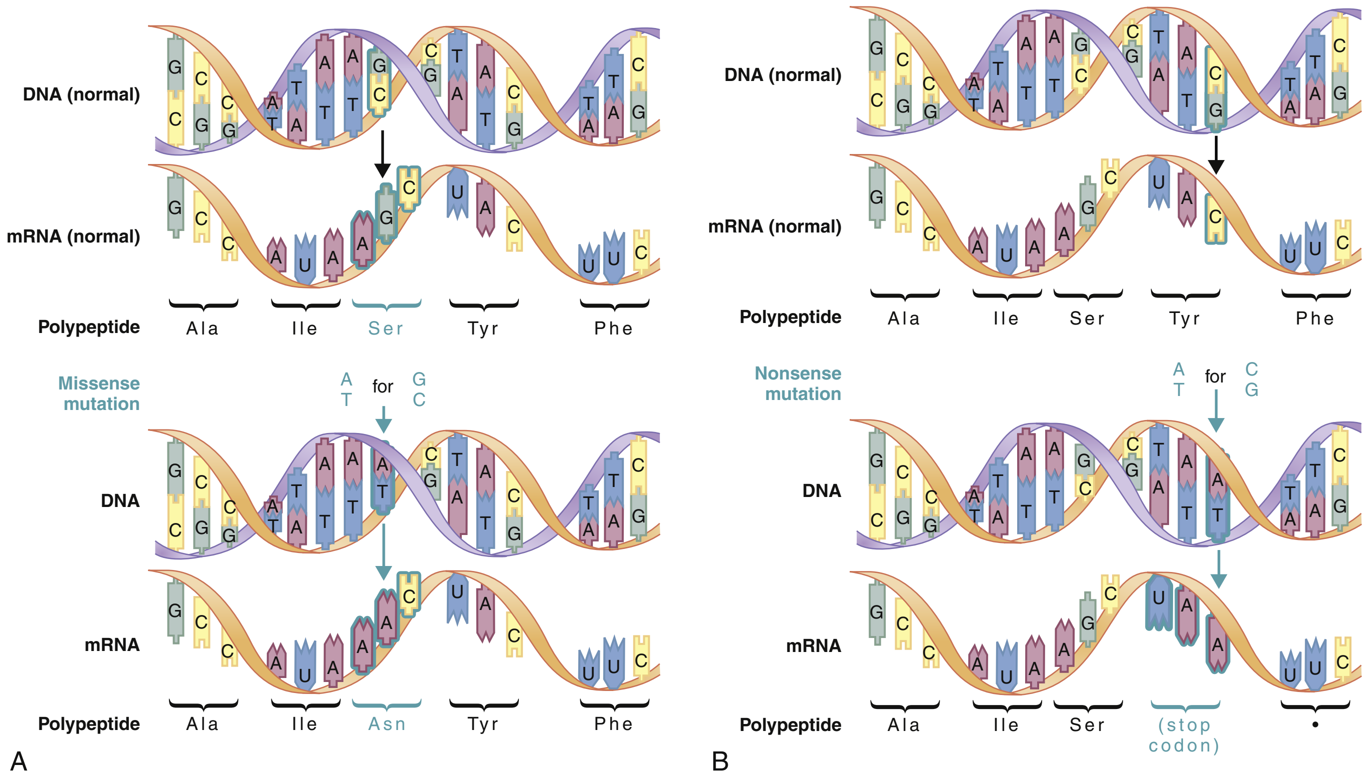

FIGURE 4-3 **Base Pair Substitution.** Missense mutations **(A)** produce a single amino acid change, whereas nonsense mutations **(B)** produce a stop codon in the mRNA. Stop codons terminate translation of the polypeptide. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

when an amino acid sequence is altered by a base pair substitution. (Many of the serious genetic diseases discussed later are the result of base pair substitutions.)

A second major type of mutation is the **frameshift mutation.** This alteration involves the insertion or deletion of one or more base pairs to the DNA molecule. As Figure 4-4 shows, these mutations can change the entire "reading frame" of the DNA sequence because codons consist of groups of three base pairs. A frameshift mutation thus can greatly alter the resulting amino acid sequence.

A large number of agents are known to increase the frequency of mutations. These agents are known collectively as **mutagens.** Radiation, such as that produced by x-rays and nuclear fallout, is an important mutagen and is known to cause cell damage (see Chapter 12). Radiation can fragment the DNA molecule and it can cause chemical reactions that can alter a DNA base. A variety of chemicals also can induce mutations, often because they are chemically similar to DNA bases. Other chemicals mimic the effects of ionizing radiation, and still others interfere with the process of base pairing. Hundreds of chemicals are now known to be mutagenic in humans or laboratory animals, such as nitrogen mustard, vinyl chloride, alkylating agents, formaldehyde, and sodium nitrite. Some of these chemicals, however, are much more potent mutagens than others. Nitrogen mustard, for example, is extremely mutagenic, whereas sodium nitrate is a weak mutagen.

Measurement of the mutation rate in humans is difficult, in part because mutations are very rare events. Current estimates

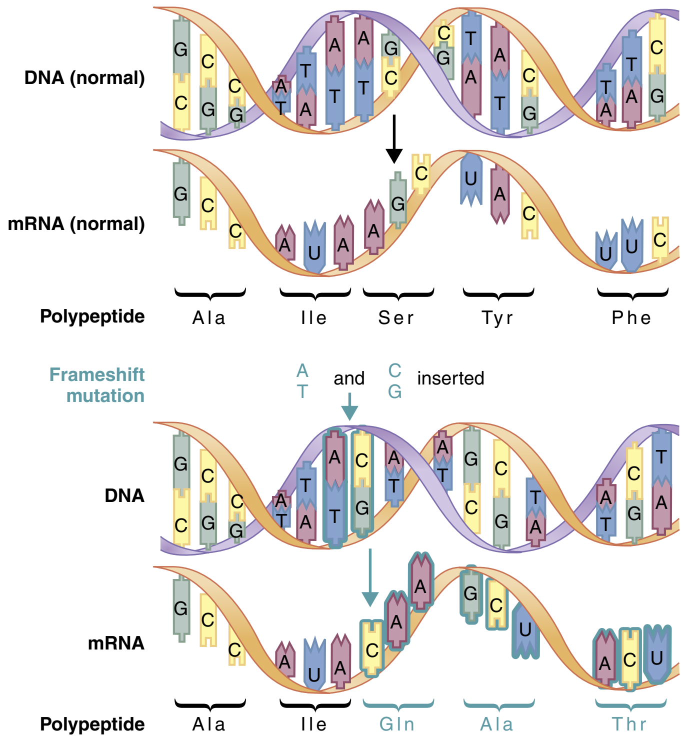

FIGURE 4-4 **Frameshift Mutations.** Frameshift mutations result from the addition or deletion of a number of bases that is not a multiple of 3. This mutation alters all of the codons downstream from the site of insertion or deletion. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

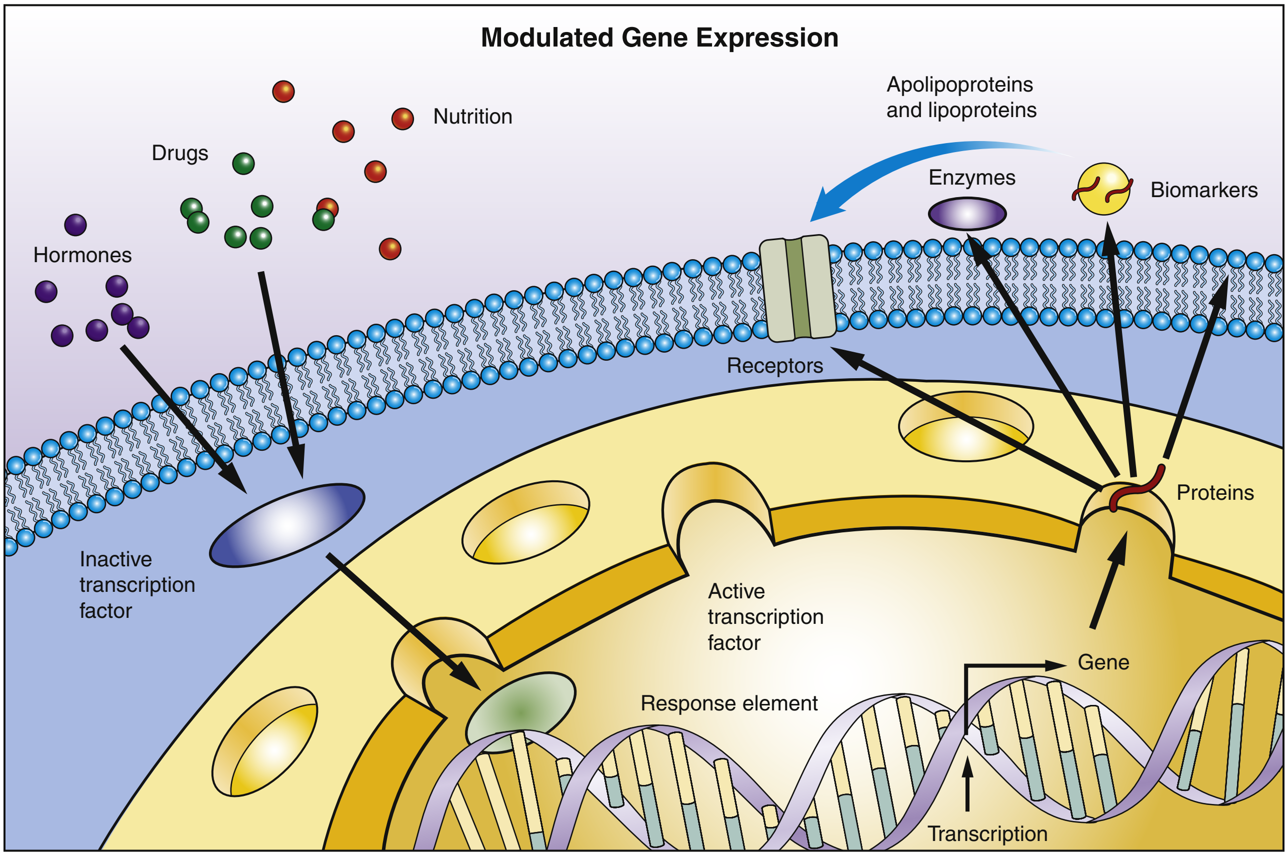

FIGURE 4-5 Transcription Factors and Simplified Schematic of Gene Expression. Transcription factors are proteins and bind to specific sites on DNA. They read and interpret the genetic blueprint of the DNA thereby controlling transcription or the flow of genetic information from DNA to mRNA. Transcription factors are essential for gene expression; for example, proteins that function as receptors, enzymes, or biomarkers. Environmental stimuli: for example, hormones involve signaling cascades that can involve transcription factors. Transcription factors can alter gene expression to promote pathophysiology.

are that the **mutation rate** in humans is about 10^{-4} to 10^{-7} per gene per generation. This rate appears to vary from one gene to another, with greater mutation rates for larger genes. At the nucleotide level, the human mutation rate is approximately 10^{-8} per nucleotide per generation. Certain DNA sequences have particularly high mutation rates and are known as **mutational hot spots.** In particular, sequences consisting of a cytosine base followed by a guanine base (CG) are highly susceptible to mutation and are known to account for a disproportionately large percentage of disease-causing mutations.[3]

From Genes to Proteins

Whereas DNA is formed and replicated in the cell nucleus, protein synthesis takes place in the cytoplasm. The transport of the DNA code from nucleus to cytoplasm and the subsequent protein formation involve two basic processes: transcription and translation. Both of these processes are mediated by **ribonucleic acid (RNA),** a type of nucleic acid that is chemically very similar to DNA. RNA differs from DNA in that uracil rather than thymine is one of the four nitrogenous bases. The other bases of RNA, as in DNA, are adenine, cytosine, and guanine. Uracil is structurally very similar to thymine, so it also can pair with adenine. Whereas DNA usually occurs as a double strand, RNA usually occurs as a single strand.

Transcription

Transcription is the process by which RNA is synthesized from a DNA template. The result is the formation of **messenger RNA (mRNA)** from the base sequence specified by the DNA molecule. Transcription of a gene begins when an enzyme called **RNA polymerase** binds to a **promoter site** on the DNA. A promoter site is a sequence of DNA that specifies the beginning of a gene. In addition to RNA polymerase, proteins called **transcription factors** bind to DNA sequences called **transcription factor binding sites** near genes to regulate the timing of transcription, as well as the specific tissues in which genes are actively transcribed (e.g., clotting factor VIII primarily in hepatocytes) (Figure 4-5). Transcription factors can either activate or repress the expression of genes. In addition, transcription is sometimes up-regulated by the binding of nearby DNA sequences called **enhancers.** The RNA polymerase pulls a portion of the DNA strands apart from one another, allowing unattached DNA bases to be exposed. One of the DNA strands then provides the template for the sequence of mRNA nucleotides.

The sequence of bases in the mRNA is thus complementary to that of the template strand, and with the exception of the presence of uracil instead of thymine, the mRNA sequence is identical to that of the other DNA strand. Transcription continues until a DNA sequence called a **termination sequence** is

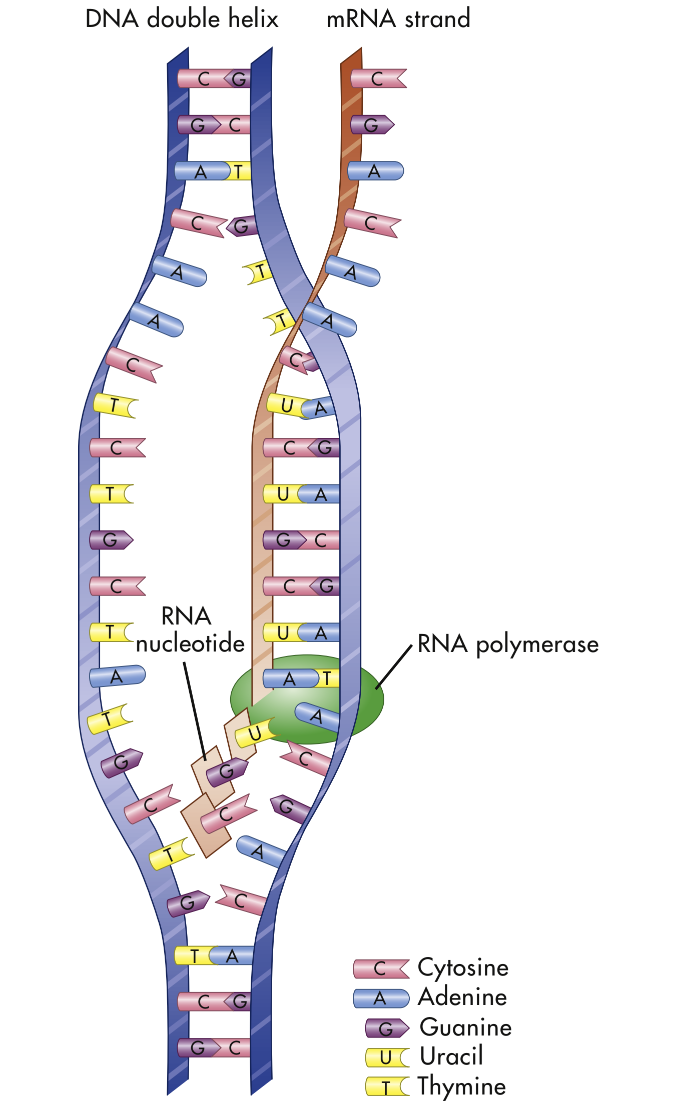

FIGURE 4-6 General Scheme of RNA Transcription. See text for explanation. (From Patton KT, Thibodeau GA: *Anatomy & physiology*, ed 8, St Louis, 2013, Mosby.)

reached. Then the RNA polymerase detaches from the DNA, and the transcribed mRNA is freed to move out of the nucleus and into the cytoplasm. Figure 4-6 summarizes the process of transcription.

RNA Splicing

After the mRNA first has been transcribed from the DNA template, it reflects exactly the base sequence of the DNA. In eukaryotes an important step takes place before this RNA leaves the nucleus. Many of the RNA sequences are removed and the remaining sequences are spliced together to form the functional mRNA that will migrate to the cytoplasm. The excised sequences are called **introns,** and the sequences that are left to code for proteins are called **exons.** The functions of most introns remain poorly understood.

Translation

Translation is the process by which RNA directs the synthesis of a polypeptide (Figure 4-7). However, mRNA cannot code directly for amino acids. Instead, it interacts with **transfer RNA (tRNA),** a cloverleaf-shaped strand of about 80 nucleotides. The tRNA molecule has a site for the attachment of an amino acid. At the opposite side of the cloverleaf is a sequence of three nucleotides called the **anticodon.** The anticodon undergoes complementary base pairing with an appropriate codon in the mRNA. The mRNA thus specifies the sequence of amino acids by acting through the tRNA. As each codon is processed, an amino acid is translated by the interaction of mRNA and tRNA, which is aided by cytoplasmic structures called **ribosomes.** Bonds are formed between adjacent amino acids to make a growing polypeptide. When the ribosome arrives at a termination signal on the mRNA sequence, translation and polypeptide formation cease. The mRNA, ribosome, and polypeptide separate from one another and the polypeptide is released into the cytoplasm to perform its required function.

CHROMOSOMES

Human cells can be categorized into two types: **gametes** (sperm and egg cells) and **somatic cells,** which include all cells other than gametes. Each somatic cell has 46 chromosomes in its nucleus. These are **diploid cells,** meaning that the chromosomes occur in pairs. Thus each cell actually contains 23 pairs of chromosomes. One member of each pair comes from an individual's mother, and one comes from the father. New somatic cells are formed through mitosis and cytokinesis, through which the cell nucleus and cytoplasm are replicated. (The division process that creates new copies of somatic cells is described in Chapter 1.) Gametes are **haploid cells:** they have only one member of each chromosome pair, giving them a total of 23 chromosomes. The process by which these haploid cells are formed from diploid cells is called **meiosis** (Figure 4-8).

In 22 of the 23 chromosome pairs, the two members of each pair are virtually identical in microscopic appearance and DNA sequence and are thus said to be **homologous** to one another. These 22 chromosome pairs are homologous in both males and females and are termed **autosomes.** The remaining pair of chromosomes, the **sex chromosomes,** consists of two homologous X chromosomes in females and a nonhomologous pair, X and Y, in males.

Figure 4-9, *A,* illustrates a **metaphase spread,** which is a photograph of the chromosomes as they appear in the nucleus of a somatic cell during metaphase. (Chromosomes are easiest to visualize during this stage of mitosis.) A **karyotype** is an ordered display of chromosomes. In Figure 4-9, *B,* the chromosomes are arranged according to size, with the **homologous chromosomes** paired. The 22 autosomes are numbered according to length, with chromosome 1 as the longest and chromosome 22 as the shortest. Some natural variation in relative chromosome length can be expected from person to person, however, so it is not always possible to distinguish each chromosome by its length. Therefore, the position of the centromere is also used to classify the chromosomes (Figure 4-10).

The chromosomes in Figure 4-9, *A,* were stained with a substance that binds preferentially to certain areas of chromosomes. The resulting distinctive **chromosome bands** are

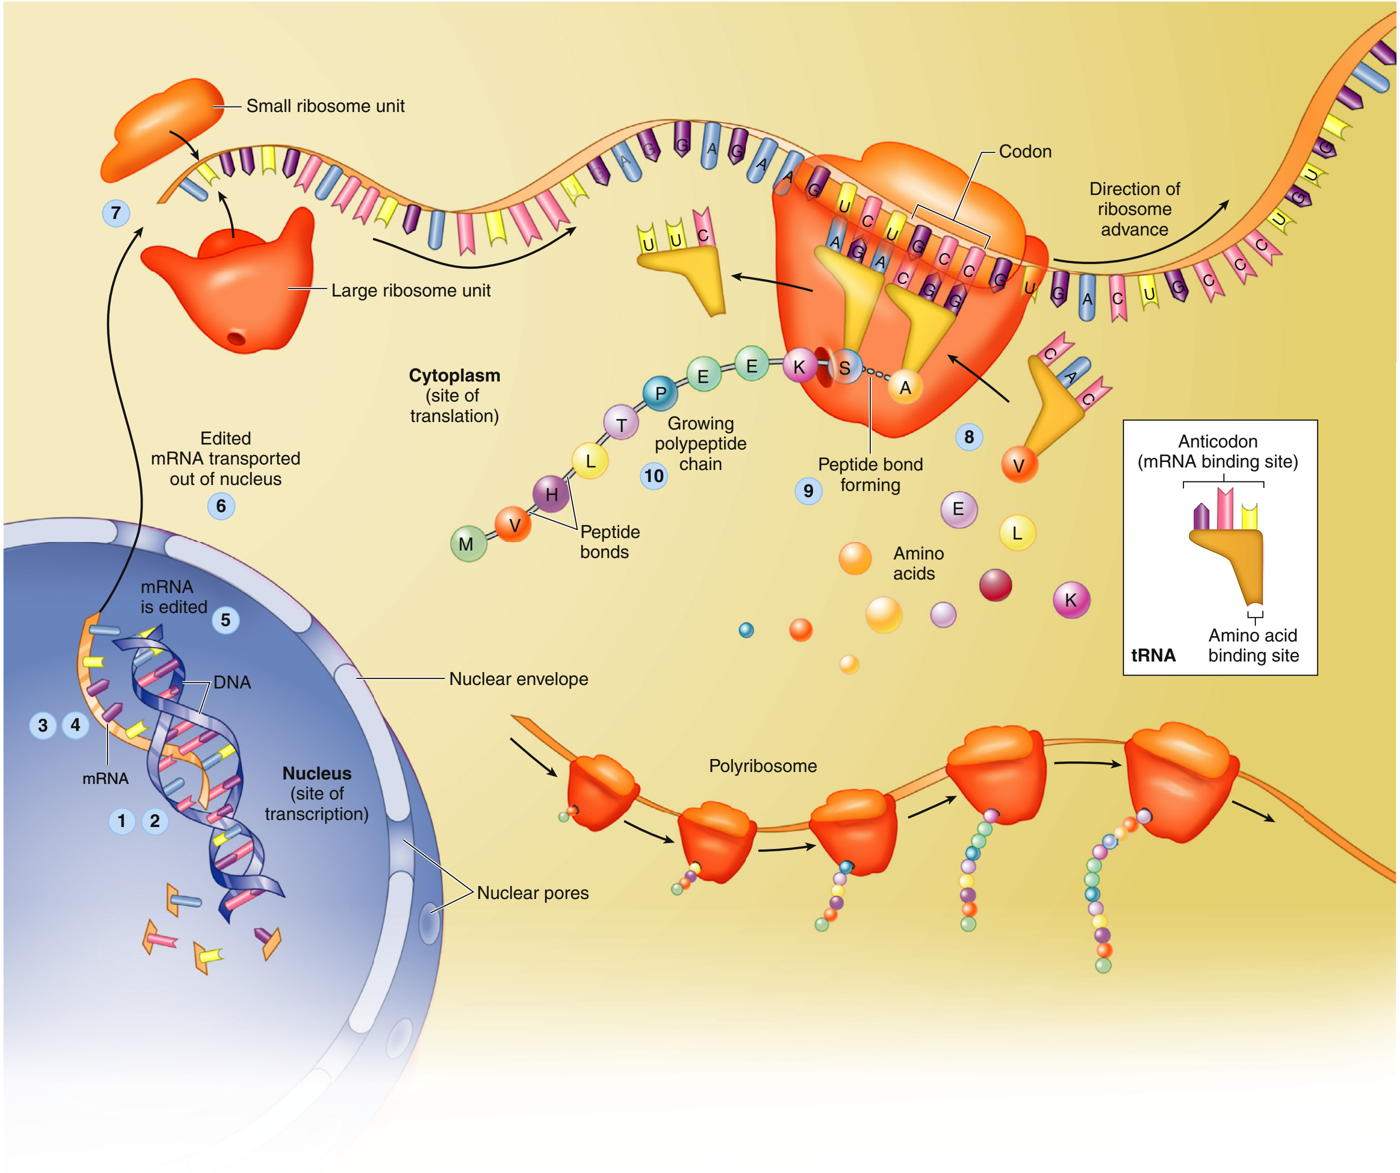

FIGURE 4-7 **Protein Synthesis.** Protein synthesis begins with *transcription,* a process in which an mRNA molecule forms along one gene sequence of a DNA molecule within the cell's nucleus **(1-3).** As it is formed, the mRNA molecule separates from the DNA molecule **(4),** is edited **(5),** and leaves the nucleus through the large nuclear pores **(6).** Outside the nucleus, ribosome subunits attach to the beginning of the mRNA molecule and begin the process of *translation* **(7).** In translation, transfer RNA (tRNA) molecules bring specific amino acids—encoded by each mRNA codon—into place at the ribosome site **(8).** As the amino acids are brought into the proper sequence, they are joined together by peptide bonds **(9)** to form long strands called *polypeptides* **(10).** Several polypeptide chains may be needed to make a complete protein molecule. *A,* Adenine; *C,* cytosine; *G,* guanine; *U,* uracil. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

evident in various patterns in the different chromosomes so that each chromosome can be distinguished easily. One of the most commonly used stains is **Giemsa stain.** By using banding techniques, chromosomes can be unambiguously numbered, and individual variation in chromosome composition can be studied. Missing or duplicated portions of chromosomes, which often result in serious diseases, also can be readily identified.

Chromosome Aberrations and Associated Diseases

Chromosome abnormalities are the leading known cause of mental retardation and miscarriage. A major chromosome aberration occurs in more than half of conceptions. Most of these fetuses do not survive to term; in fact, about 50% of all recovered first-trimester spontaneous abortuses have major chromosomal aberrations.[4] About 1 in 150 live births has a major diagnosable chromosome abnormality.[5]

Polyploidy

Cells that have a multiple of the normal number of chromosomes are said to be **euploid cells** (Greek *eu* = good or true). Because normal gametes are haploid and most normal somatic cells are diploid, they are both euploid forms. When a euploid

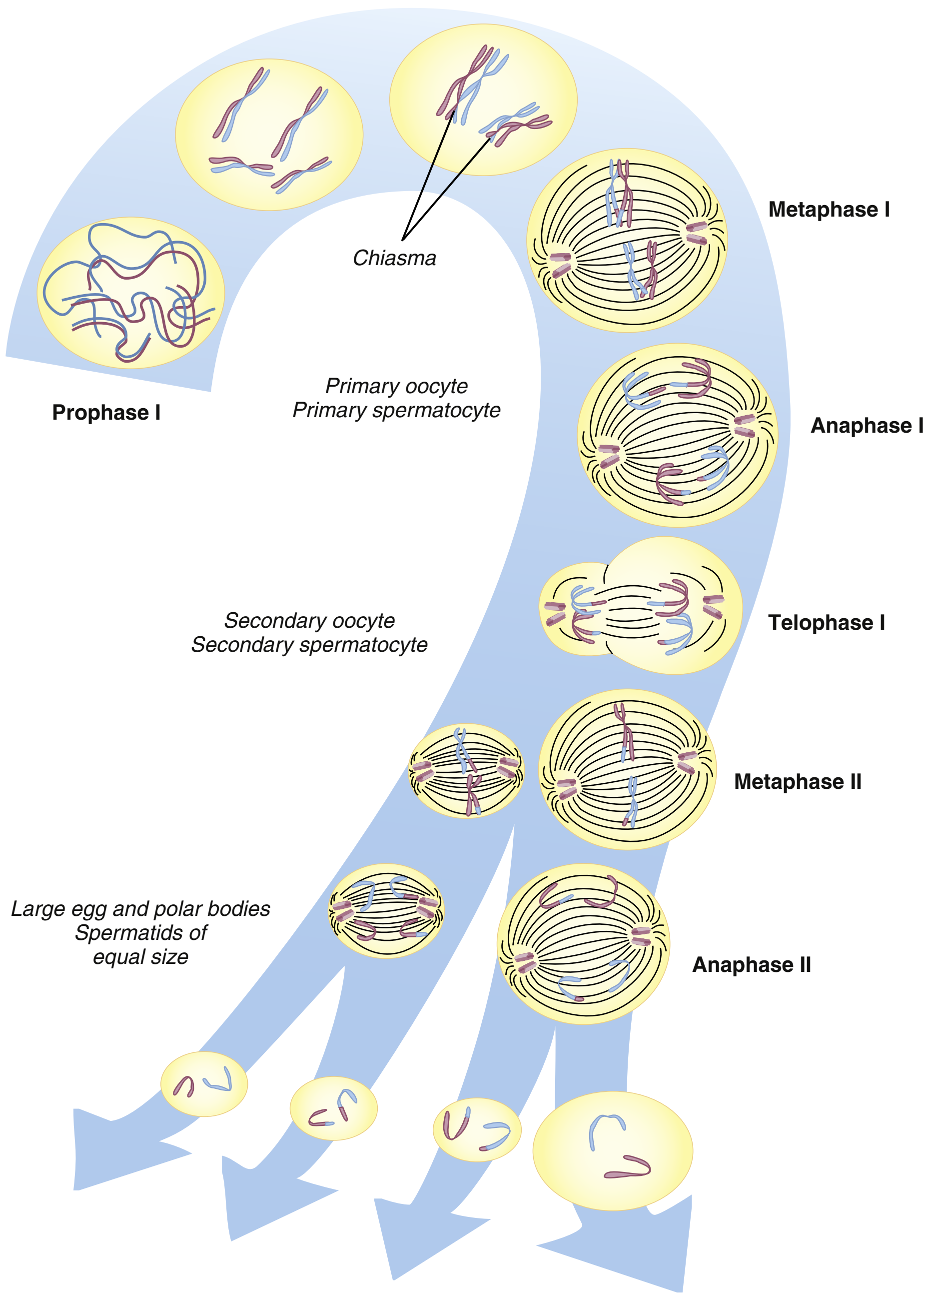

FIGURE 4-8 **Stages of Meiosis.** From these stages, haploid gametes are formed from a diploid stem cell. For brevity, prophase II and telophase II are not shown. Note the relationship between meiosis and spermatogenesis and oogenesis. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

cell has more than the diploid number of chromosomes, it is said to be a **polyploid cell.** Several types of body tissues, including some liver, bronchial, and epithelial tissues, are normally polyploid. A zygote having three copies of each chromosome, rather than the usual two, has a form of polyploidy called **triploidy. Tetraploidy,** a condition in which euploid cells have 92 chromosomes, also has been observed. Nearly all triploid and tetraploid conceptions are spontaneously aborted or stillborn, and the small proportion that survive to term die shortly after birth. Triploidy and tetraploidy are relatively common conditions at conception, accounting for approximately 10% of all known miscarriages.[4]

Aneuploidy

Aneuploid cells are defined as those that do not contain a multiple of 23 chromosomes. An aneuploid cell containing three copies of one chromosome is said to be trisomic (a condition termed **trisomy**). **Monosomy,** the presence of only one copy of a given chromosome in a diploid cell, is the other common form of aneuploidy. Among the autosomes, monosomy of any chromosome is lethal, but newborns with trisomy of chromosomes 13, 18, or 21 can survive. This difference illustrates an important principle: loss of chromosome material has more serious consequences than duplication of chromosome material.

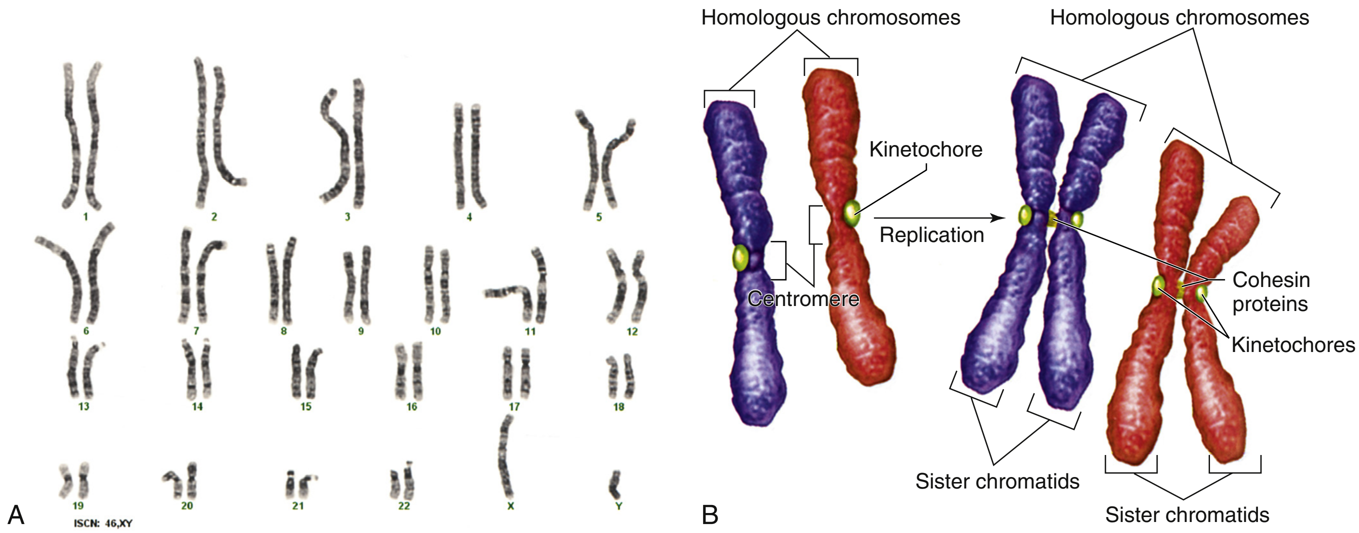

FIGURE 4-9 Karyotype of Chromosomes. **A,** Human karyotype. **B,** Homologous chromosomes and sister chromatids. (**A** courtesy of the Clinical Cytogenetics Section, Laboratory of Pathology, National Cancer Institute, National Institutes of Health, Bethesda, MD. **B** from Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

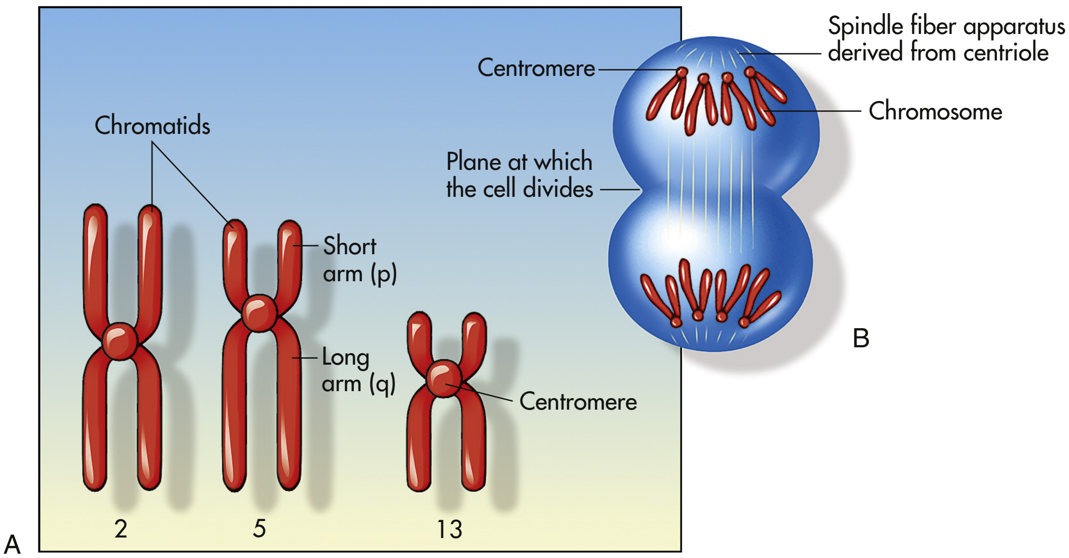

FIGURE 4-10 Structure of Chromosomes. **A,** Human chromosomes 2, 5, and 13. Each is replicated and consists of two chromatids. Chromosome 2 is a metacentric chromosome because the centromere is close to middle; chromosome 5 is submetacentric because the centromere is set off from the middle; chromosome 13 is acrocentric because the centromere is at or very near the end. **B,** During mitosis, the centromere divides and chromosomes move to opposite poles of the cell. At the time of centromere division, the chromatids are designated chromosomes.

Aneuploidy of the sex chromosomes is usually less serious than that of the autosomes. For the Y chromosome, this is true because very little genetic material is located on this chromosome. For the X chromosome, inactivation of extra chromosomes largely diminishes their effect. A zygote bearing *no* X chromosome, however, will not survive.

Aneuploidy is usually the result of **nondisjunction,** an error in which homologous chromosomes or sister chromatids fail to separate normally during meiosis or mitosis (Figure 4-11). Nondisjunction during either stage of meiosis produces some gametes that have two copies of a given chromosome and others that have no copies of the chromosome. When such gametes unite with normal haploid gametes, the resulting zygote is monosomic or trisomic for that chromosome.

Autosomal Aneuploidy. Trisomy can occur for any chromosome at conception, but the only forms seen with an appreciable frequency in live births are trisomies of the thirteenth, eighteenth, or twenty-first chromosome. Fetuses with most other chromosomal trisomies do not survive to term. Trisomy 16, for example, is the most commonly known trisomy among abortuses, but it is not seen in live births.[4]

Partial trisomy, in which only an extra portion of a chromosome is present in each cell, also can occur. The consequences of partial trisomies are not as severe as those of complete

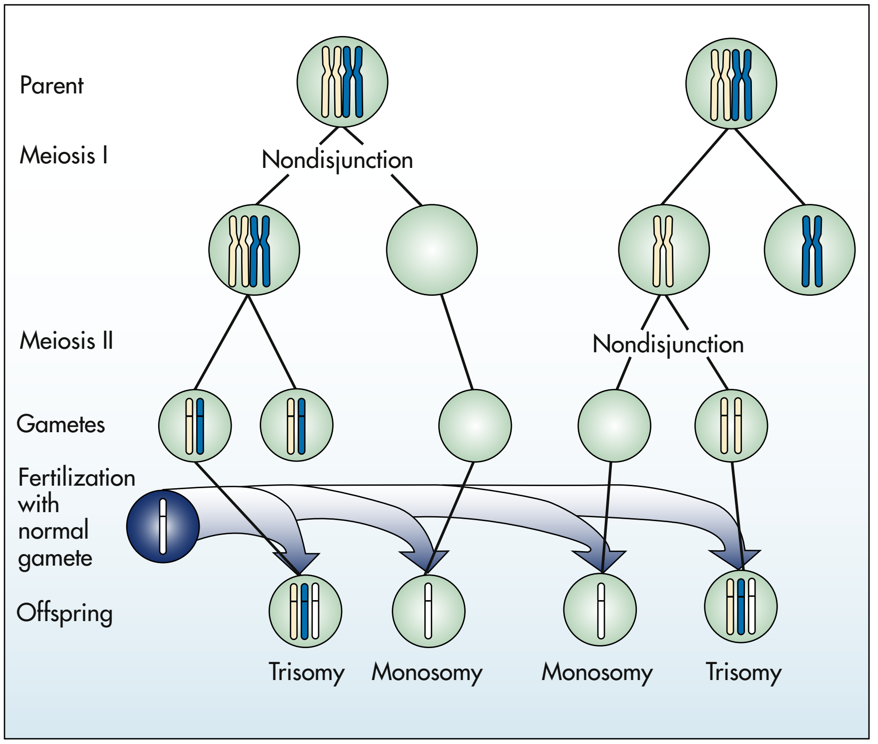

FIGURE 4-11 **Nondisjunction Causes Aneuploidy When Chromosomes or Sister Chromatids Fail to Divide Properly.** (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

FIGURE 4-12 **Down Syndrome. A,** The karyotype of Down syndrome consists of 47 chromosomes and shows trisomy 21. **B,** A child with Down syndrome. (**A** from Damjanov I: *Pathology for the health professions,* ed 4, Philadelphia, 2012, Saunders; **B** courtesy Olney A, MacDonald M, University of Nebraska Medical Center, Omaha.)

trisomies. Trisomies also may occur in only some cells of the body. Individuals thus affected are said to be **chromosomal mosaics,** meaning that the body has two or more different cell lines, each of which has a different karyotype. Mosaics are usually formed by early mitotic nondisjunction occurring in one embryonic cell but not in others.

The most well-known example of aneuploidy in an autosome is trisomy of the twenty-first chromosome, which causes **Down syndrome** (named after J. Langdon Down, who first described the disease in 1866). Down syndrome was formerly called *mongolism,* but this inappropriate term is no longer used. Down syndrome is seen in 1 in 800 live births.[4] Individuals with this disease typically have intelligence quotients (IQs) between 25 and 70. The facial appearance is distinctive (Figure 4-12), with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears. Poor muscle tone (hypotonia) and short stature are both characteristic. Congenital heart defects affect about one third to one half of liveborn children with Down syndrome; a reduced ability to fight respiratory tract infections and an increased susceptibility

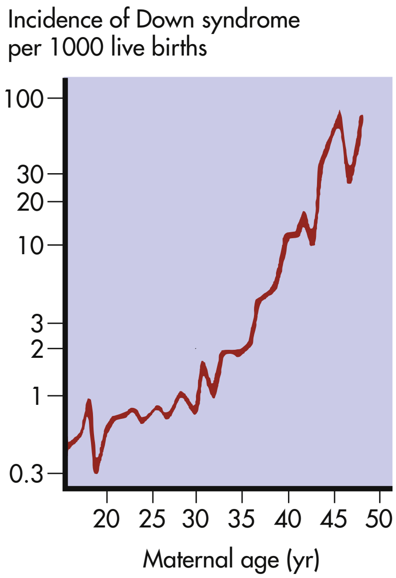

FIGURE 4-13 Down Syndrome Incidence Increases with Maternal Age. Rate is per 1000 live births related to maternal age.

to leukemia also contribute to reduced survival rate. By 40 years of age, individuals with Down syndrome virtually always develop symptoms that are nearly identical to those of Alzheimer disease because one of the genes that can cause Alzheimer disease is located on chromosome 21. About three fourths of fetuses known to have Down syndrome are spontaneously aborted or stillborn. About 20% of infants born with Down syndrome die during their first 10 years of life. For those who survive beyond 10 years, average life expectancy is now about 60 years.

About 97% of Down syndrome cases are caused by nondisjunction during the formation of one of the parent's gametes or during early embryonic development. The remaining 3% result from translocations (discussed later). In approximately 90% to 95% of cases, the nondisjunction occurs in the formation of the mother's egg cell. Paternal nondisjunction is responsible for the remaining cases. Among individuals with Down syndrome, about 1% are known to be mosaics. Because mosaics have a large number of normal cells, the effects of the trisomic cells are attenuated and symptoms are sometimes less severe.

The risk of having a child with Down syndrome increases greatly with maternal age. As Figure 4-13 demonstrates, women younger than 30 years have a risk ranging from about 1 in 1000 births to 1 in 2000 births. The risk begins to rise substantially after 35 years of age, and it reaches 3% to 5% for women older than 45 years of age. This dramatic increase in risk is a consequence of the age of maternal egg cells, which are held in an arrested state of prophase I from the time they are formed in the female embryo until they are shed in ovulation. Thus an egg cell formed by a 45-year-old woman is itself 45 years old. This long suspended state may allow for the accumulation of errors leading to nondisjunction. The risk of Down syndrome, as well as other trisomies, does not appear to increase with paternal age.[6]

Sex Chromosome Aneuploidy. Among live births, about 1 in 400 males and 1 in 650 females have a form of sex chromosome aneuploidy.[7] Because these conditions are generally less severe than autosomal aneuploidies, all forms except complete absence of an X chromosome allow at least some individuals to survive.

FIGURE 4-14 Turner Syndrome. A sex chromosome is missing, and the person's chromosomes are 45,X. Characteristic signs are short stature, female genitalia abnormality, webbed neck, shieldlike chest with underdeveloped breasts and widely spaced nipples, and imperfectly developed ovaries. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

One of the most common sex chromosome aneuploidies, affecting about 1 in 1000 newborn females, is trisomy X. Instead of two X chromosomes, these females have three X chromosomes in each cell. Most of them have no overt physical abnormalities, although sterility, menstrual irregularity, or cognitive deficits are sometimes seen. A very small proportion of females have four or even five X chromosomes, and their mental function is more severely compromised. Another sex chromosome aneuploidy is the presence of a single X chromosome and no homologous X or Y chromosome, resulting in a total of 45 chromosomes. The karyotype is designated 45,X, and it causes a set of symptoms known as **Turner syndrome** (Figure 4-14). Because they have no Y chromosome, only females are affected by Turner syndrome. They are usually sterile, however, and have gonadal streaks rather than ovaries. These streaks of connective tissue are susceptible to cancer in mosaics who have some cells containing a Y chromosome. Other features of the disorder include short stature, webbing of the neck in about half of cases, widely spaced nipples, coarctation (narrowing) of the aorta (in 15% to 20% of cases), edema of the feet in newborns, and sparse body hair. Their IQs are typically in the normal range, although they often have some impairment of spatial and mathematical reasoning ability. About three fourths of recognized 45,X conceptions inherit their X chromosome from the mother. Thus most cases are caused by a loss of the paternal X chromosome.

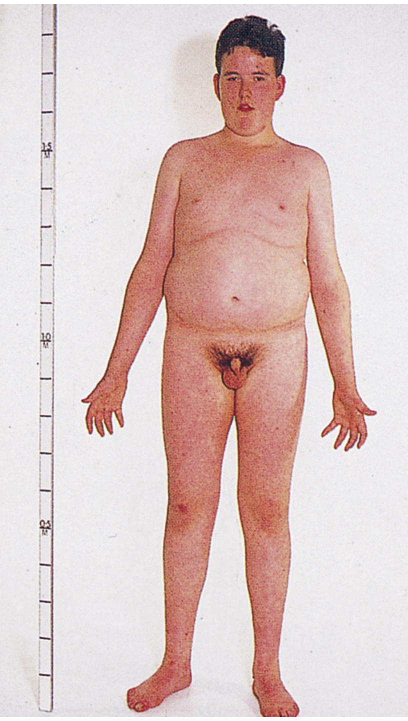

FIGURE 4-15 Klinefelter Syndrome. This young man exhibits many characteristics of Klinefelter syndrome: small testes, some development of the breasts, sparse body hair, and long limbs. This syndrome results from the presence of two or more X chromosomes with one Y chromosome (genotypes XXY or XXXY, for example). (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

The frequency of Turner syndrome is low compared with that of other sex chromosome aneuploidies: only about 1 in 2500 newborn females is affected.[8] The 45,X karyotype is more common among conceptions, however, and about 15% to 20% of spontaneous abortions with chromosome abnormalities have this karyotype, making it one of the most common single-chromosome aberrations. Thus the condition is highly lethal during gestation: less than 1% of 45,X conceptions survive to term. Most fetuses that survive to term are mosaics, with combinations of 45,X cells and XX, XXX, or XY cells. It is likely that the presence of some normal cells in mosaic fetuses enhances fetal survival.

Teenagers with Turner syndrome are typically treated with estrogen to promote the development of secondary sexual characteristics. The dose is then continued at a reduced level to maintain these characteristics and to help avoid osteoporosis. Human growth hormone is sometimes administered to increase stature.

Individuals with at least two X chromosomes and a Y chromosome in each cell (47,XXY karyotype) have a disorder known as **Klinefelter syndrome** (Figure 4-15). Because of the presence of a Y chromosome, these individuals have a male appearance, but they are usually sterile, and about half develop female-like breasts (a condition called *gynecomastia*). The testes are small, body hair is sparse, the voice is often somewhat high pitched, stature is elevated, and a moderate degree of mental impairment may be present. Klinefelter syndrome is found in about 1 in 1000 male births. About two thirds of the cases are caused by nondisjunction of the X chromosomes in the mother, and the frequency of the disorder rises with maternal age. Individuals with the XXXY and XXXXY karyotypes also are considered to have Klinefelter syndrome, and the degree of physical and mental impairment increases with each additional X chromosome. Regardless of the number of X chromosomes, however, these individuals have a male appearance. The presence of a single Y chromosome, which causes the undifferentiated gonads to become testes, always produces a male. Mosaicism is sometimes seen in Klinefelter syndrome and results in less severe disease; the most prevalent combination is XXY and XY cells.

About 1 in 1000 males has an extra Y chromosome, producing the 47,XYY karyotype. Individuals with this karyotype tend to be taller than average, and they have a 10- to 15-point reduction in average IQ. This condition, which causes few serious physical problems, achieved notoriety when it was found that its incidence was significantly elevated in prison populations. This discovery led to the suggestion that this chromosome might predispose affected individuals to violent, criminal behavior. Several dozen studies have addressed this issue, and they have shown that 47,XYY males are not inclined to commit violent crimes. However, even after adjusting for the effects of decreased IQ, some evidence exists for an increased incidence of behavioral disorders.

Abnormalities of Chromosome Structure

In addition to the loss or gain of whole chromosomes, parts of chromosomes can be lost or duplicated as gametes are formed, and the arrangement of genes on chromosomes can be altered. Unlike aneuploidy and polyploidy, these changes sometimes do not have serious consequences for an individual's health. Some of them can even remain entirely unnoticed, especially when very small pieces of chromosomes are involved. Nevertheless, abnormalities of chromosome structure also can produce serious disease in individuals or their offspring.

During meiosis and mitosis, chromosomes usually maintain their structural integrity very well, but **chromosome breakage** occasionally does occur. Mechanisms exist to "heal" these breaks, and generally the break is repaired perfectly with no damage resulting to the daughter cell. Sometimes, however, the breaks remain, or they heal in a fashion that alters the structure of the chromosome. Chromosome breakage occurs spontaneously, but it also can be caused by ionizing radiation, some viral infections, and certain chemicals.

Deletions. Broken chromosomes and loss of DNA cause **deletions** (Figure 4-16, *A*). Usually a gamete with a deletion unites with a normal gamete to form a zygote. The zygote thus has one chromosome with the normal complement of genes and one with some missing genes. Because a fairly large number of genes can be lost in a deletion, serious consequences can result even though one copy of the chromosome is normal. An often cited example of a disease caused by a chromosomal deletion is the **cri du chat syndrome** (Figure 4-17). The term, which literally means "cry of the cat," describes the characteristic cry of the affected child. Other symptoms include low birth weight, severe mental retardation, microcephaly (smaller than normal

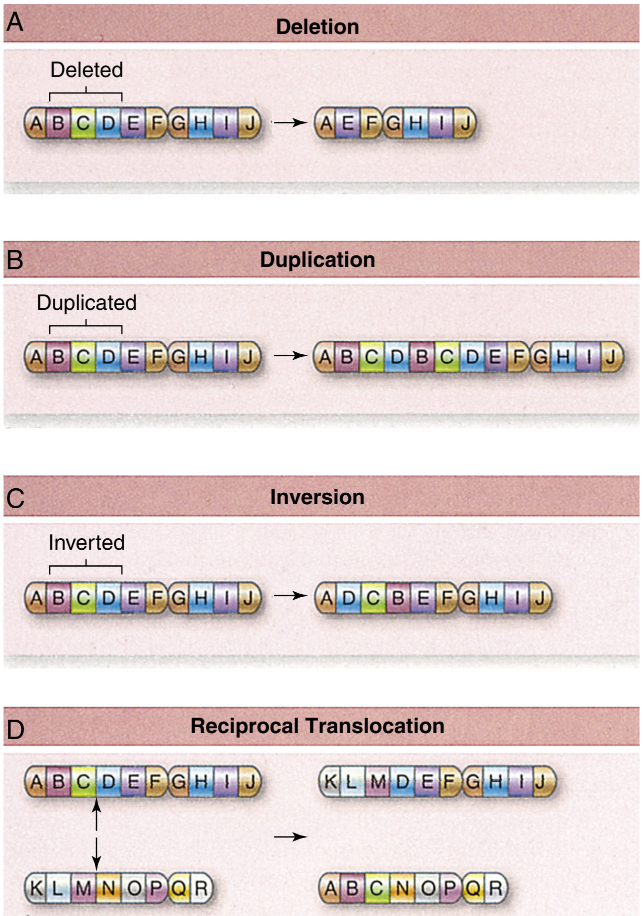

FIGURE 4-16 **Chromosomal Mutations.** Larger-scale changes in chromosomes are also possible. Material can be deleted **(A),** duplicated **(B),** and inverted **(C).** Translocations occur when one chromosome is broken and becomes part of another chromosome. This often occurs where both chromosomes are broken and exchange material, an event called a reciprocal translocation **(D).** (From Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

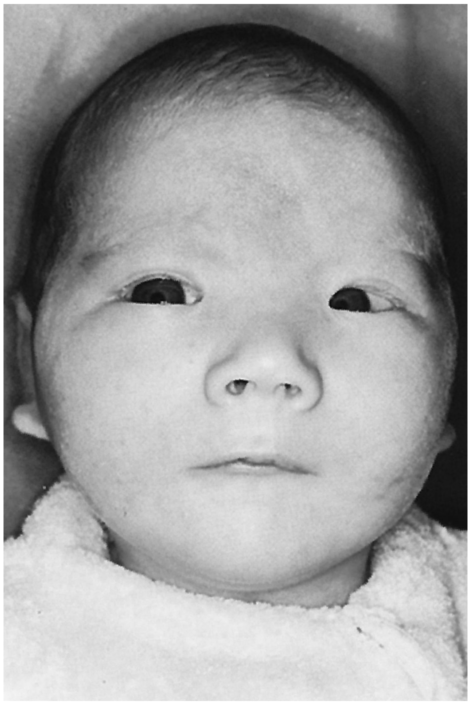

FIGURE 4-17 **Infant with Cri Du Chat Syndrome.** This syndrome is caused by deletion of part of the short arm of chromosome 5. (From Nussbaum RL, McInnes RR, Willard HF: *Thompson & Thompson genetics in medicine,* ed 7, Philadelphia, 2007, Saunders.)

head size), heart defects, and the typical facial appearance shown in Figure 4-17. The disease is caused by a deletion of part of the short arm of chromosome 5.

Duplications. **Duplications** of chromosome material are, like deletions, a form of chromosome aberration (see Figure 4-16, *B*). Because a deficiency of genetic material is more harmful than an excess, duplications usually have less serious consequences than deletions. For example, a deletion of a region of chromosome 5 causes cri du chat syndrome, but a duplication of the same region causes less severe disease.

Inversions. An **inversion** is the occurrence of two breaks on a chromosome, followed by the reinsertion of the missing fragment at its original site but in inverted order (see Figure 4-16, *C*). Thus a chromosome symbolized as ABCDEFG might become ABEDCFG after an inversion.

Unlike deletions and duplications, inversions result in no loss or gain of genetic material. They are thus said to be a "balanced" alteration of chromosome structure, and they often have no apparent physical effect. Genes are sometimes influenced by neighboring DNA sequences, however, and this **position effect,** a change in a gene's expression caused by its position, does sometimes result in disease in persons with inversions.

The serious problems caused by inversions usually occur in the offspring of individuals carrying the inversion. Because chromosomes must line up in perfect order during prophase I, a chromosome with an inversion must form a loop to align with its normal homolog. Crossing over within this loop can result in duplications or deletions in the chromosomes of daughter cells. Thus the offspring of individuals who carry inversions often have chromosome deletions or duplications.

Translocations. The interchanging of genetic material between nonhomologous chromosomes is called **translocation,** and the most clinically significant type of translocation is termed a **Robertsonian translocation.** In this translocation the long arms of two nonhomologous chromosomes fuse at the centromere, forming a single chromosome (Figure 4-18). Robertsonian translocations are confined to chromosomes 13, 14, 15, 21, and 22 because the short arms of these chromosomes are very small and contain no essential genetic material. When a Robertsonian translocation takes place, the short arms are usually lost during subsequent cell divisions. Because the carriers of Robertsonian translocations (about 1 in 500 individuals) lose no important genetic material, they are normal, although they have only 45 chromosomes in each cell. Their offspring, however, may have serious deletions or duplications (see Figure 4-18). For example, a common Robertsonian translocation involves the fusion of the long arms of chromosomes 21 and 14. An offspring who inherits a gamete carrying the fused chromosome receives an extra copy of the long arm of chromosome 21 and thus develops Down syndrome. Robertsonian translocations are responsible

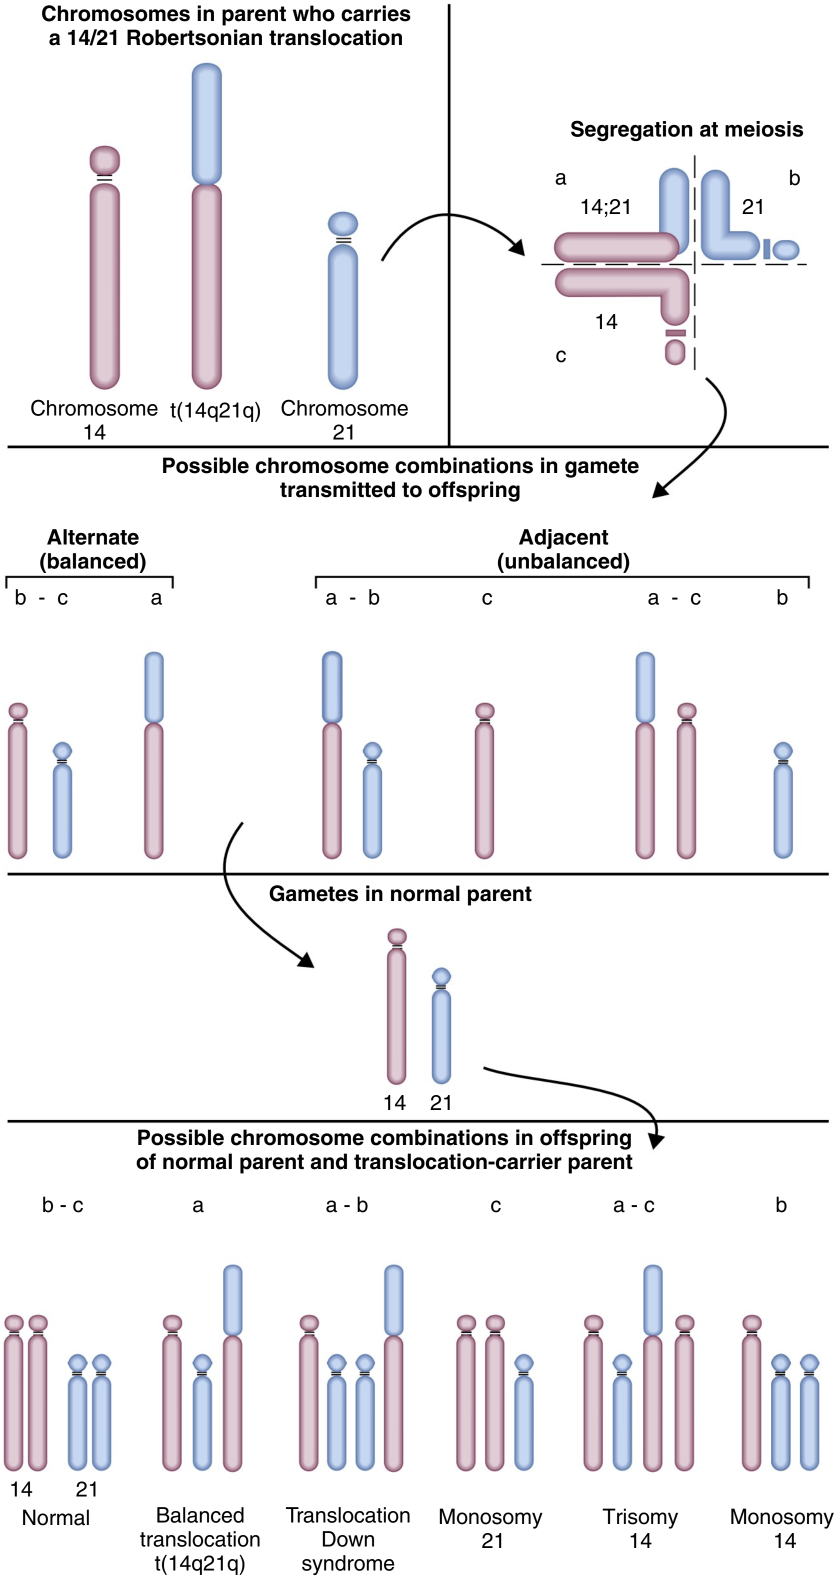

FIGURE 4-18 Possible Segregation Patterns for the Gametes Formed by a Carrier of a Robertsonian Translocation. Alternate segregation (quadrant a alone, or quadrant b with quadrant c) produces either a normal chromosome constitution or a translocation carrier with a normal phenotype. Adjacent segregation (quadrant a with b, quadrant c alone, quadrant a with c, or quadrant b alone) produces unbalanced gametes and results in conceptions with translocation Down syndrome, monosomy 21, trisomy 14, or monosomy 14, respectively. For example, monosomy 14 is produced when the parent who carries the translocation transmits a copy of chromosome 21 but does not transmit a copy of chromosome 14 (as in the lower right corner). (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

for approximately 3% to 5% of Down syndrome cases. Parents who carry a Robertsonian translocation involving chromosome 21 have an increased risk for producing multiple offspring with Down syndrome.

A **reciprocal translocation** occurs when breaks take place in two different chromosomes and the material is exchanged (see Figure 4-16, *D*). As with Robertsonian translocations, the carrier of a reciprocal translocation is usually normal because the individual has a normal complement of genetic material. However, the carrier's gametes can be normal, can carry the translocation, or can have duplications and deletions.

Fragile Sites. For reasons not yet fully understood, a number of areas on chromosomes develop microscopically observable breaks and gaps when the cells are cultured in a folate-deficient medium. Most of these **fragile sites** have no apparent relationship to disease. However, one fragile site, located on the long arm of the X chromosome, is associated with a disorder of considerable importance, both clinically and genetically. This disorder is known as *fragile X syndrome,* and it is associated with substantial cognitive impairment. With a relatively high population prevalence (affecting approximately 1 in 4000 males and 1 in 8000 females), fragile X syndrome is the second most common genetic cause of mental retardation (after Down syndrome).[9]

Fragile X syndrome is usually caused by an elevated number (more than about 200) of repeated DNA sequences in the first exon of the fragile X gene. These "repeats" consist of CGG sequences that are duplicated many times. Most individuals have fewer than 50 of these repeats, but those who have 50 to 200 are more likely to produce affected offspring because DNA replication becomes unstable.[9] An increase in the number of these repeated sequences in successive generations can lead to expression of fragile X syndrome. More than 20 other genetic diseases also are caused by this mechanism.[10,11]

ELEMENTS OF FORMAL GENETICS

The mechanisms by which an individual's set of paired chromosomes produces traits are the principles of genetic inheritance. Mendel's work with garden peas first defined these principles. Later geneticists have refined Mendel's work to explain patterns of inheritance for traits and diseases that appear in families.

Many traits can be attributed primarily to single genes and are often called *mendelian traits* (after Gregor Mendel). Each gene occupies a position along a chromosome known as a **locus.** The genes at a particular locus can take different forms (i.e., they can be composed of different nucleotide sequences) called **alleles.** For example, most people have a type of hemoglobin known as *hemoglobin A.* A few individuals have an alternative form of hemoglobin, termed *hemoglobin S,* which differs from hemoglobin A by a single amino acid substitution in the β-globin component of the molecule. The β-globin locus thus has two different alleles, one that encodes hemoglobin A and another that encodes hemoglobin S. A locus containing two or more alleles that each occur with an appreciable frequency in a population is said to be **polymorphic** or a **polymorphism.**

Because humans are diploid organisms, each chromosome is represented twice, with one member of the chromosome pair contributed by the father and one by the mother. At a given locus an individual has one gene whose origin is paternal and one whose origin is maternal. When the two genes are identical, the individual is **homozygous** at that locus. When the genes are not identical, the individual is **heterozygous** at the locus.

Phenotype and Genotype

The composition of genes at a given locus is known as the **genotype.** The outward appearance of an individual, which is the result of both genotype and environment, is the **phenotype** (see also Chapter 6, epigenetics). For example, an infant who is born with an inability to metabolize the amino acid phenylalanine has the single-gene disorder known as *phenylketonuria (PKU)* and thus has the PKU genotype. If the condition is left untreated, abnormal metabolites of phenylalanine will begin to accumulate in the infant's brain and irreversible mental retardation will occur. Mental retardation is thus one aspect of the PKU phenotype. By imposing dietary restrictions to limit the intake of food containing phenylalanine, however, retardation can be prevented. Although the child still has the PKU genotype, a modification of the environment (in this case the child's diet) produces an outwardly normal phenotype.

Dominance and Recessiveness

In many loci the effects of one allele mask those of another when the two are found together in a **heterozygote.** The allele whose effects are observable is said to be **dominant.** The allele whose effects are hidden is said to be **recessive** (from the Latin root for "hiding"). Traditionally, for loci having two alleles, the dominant allele is denoted by an uppercase letter and the recessive allele is denoted by a lowercase letter. When one allele is dominant over another, the heterozygote genotype *Aa* has the same phenotype as the dominant homozygote *AA.* For the recessive allele to be expressed, it must exist in the **homozygote** form, *aa.*

When the heterozygote is distinguishable from both homozygotes, the locus is said to exhibit **codominance.** For example, in the MN blood group, both alleles, *M* and *N,* of the heterozygote are detectable and therefore codominant. Another example is the ABO blood group, in which heterozygotes having the *A* and *B* alleles express both of them as A and B antigens on their red cells (forming blood group AB).

A **carrier** is an individual who has a disease-causing allele but is phenotypically normal. Most recessive disease-causing alleles occur in heterozygotes who carry one copy of the allele but do not express the disease. Because many recessive alleles are lethal in the homozygous state, they are eliminated from the population when they occur in homozygotes. By "hiding" in carriers, however, most recessive alleles survive to be passed on to the next generation.

TRANSMISSION OF GENETIC DISEASES

An important aspect of a genetic disease is the pattern in which it is inherited through the generations of a family, or its **mode of inheritance.** Once the mode of inheritance is known, much can be learned about the disease-causing gene itself, and reliable

genetic counseling can be given to members of families in which the disease is present.

Modes of inheritance were systematically studied by Mendel, who formulated two basic laws of inheritance. His **principle of segregation** states that homologous genes separate from one another during reproduction and that each reproductive cell carries only one of the homologous genes. Mendel's second law, the **principle of independent assortment,** states that the hereditary transmission of one gene has no effect on the transmission of another. Mendel discovered these laws in the mid-nineteenth century by performing breeding experiments with garden peas. He had no knowledge of chromosomes. Early in the twentieth century geneticists found that the behavior of chromosomes does essentially correspond to Mendel's laws, which now form the basis for the **chromosome theory of inheritance.**

The known single-gene diseases can be classified into four major modes of inheritance: autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive. The first two types involve genes known to occur on the 22 pairs of autosomes. The last two types occur on the X chromosome; only a few disease-causing genes, primarily affecting male fertility, are found on the Y chromosome. The number of diseases assigned to each category is growing rapidly. Current catalogs of single-gene traits, which include disease-producing and nonclinical traits (e.g., attached earlobes), list nearly 20,000 known autosomal traits and nearly 1200 X-linked traits.[1]

An important tool in the analysis of modes of inheritance is the **pedigree** chart. It summarizes family relationships and shows which members of a family are affected by a genetic disease (Figure 4-19). Generally, the pedigree begins with one individual in the family, the **proband,** also termed the **propositus** (male) or **proposita** (female). This individual is usually the first person in the family diagnosed or seen in a clinic.

Autosomal Dominant Inheritance

Characteristics of Pedigrees

Diseases caused by autosomal dominant genes are rare. The most common occur in fewer than 1 in 500 individuals, so it is uncommon for two individuals both affected by the same autosomal dominant disease to produce offspring together. Figure 4-20, *A,* illustrates this unusual pattern. More often, affected offspring are produced by the union of a normal parent with an affected heterozygous parent. The diagram (Punnett square) in Figure 4-20, *B,* illustrates this mating. The affected parent can pass either a disease gene or a normal gene to his or her children. Each event has a probability of 0.5; thus on average, half of the children will be heterozygous and will express the disease, and half will be normal.

Figure 4-21, *A,* is a typical pedigree showing the transmission of an autosomal dominant gene. The gene shown here causes achondroplasia (Figure 4-21, *B*). Several important characteristics of this pedigree support the conclusion that the trait is caused by an autosomal dominant gene:

1. The two sexes exhibit the trait in approximately equal proportions, and males and females are equally likely to transmit the trait to their offspring.
2. There is no skipping of generations. If an individual has achondroplasia, one parent must also have it. If neither parent has the trait, none of the children has it (with the exception of new mutations, as discussed later).
3. Affected heterozygous individuals transmit the trait to approximately half of their children, but because gamete transmission is subject to chance fluctuations, it is possible that all or none of the children of an affected parent may have the trait. When large numbers of matings of this type are studied, however, the proportion of affected children will closely approach one half.

Recurrence Risks

Parents at risk for producing children with a genetic disease nearly always ask the question, "What is the *chance* that our child will have this disease?" The probability that a family member

FIGURE 4-20 Punnett Square and Autosomal Dominant Traits. **A,** Punnett square for the mating of two individuals with an autosomal dominant gene. Here both parents are affected by the trait. **B,** Punnett square for the mating of a normal individual with a carrier for an autosomal dominant gene.

will have a genetic disease is termed the **recurrence risk.** When one parent is affected by an autosomal dominant disease (and is a heterozygote) and the other is normal, the recurrence risks for each child are one half.

An important principle is that each birth is an independent event, much like a coin toss. Thus, even though parents may already have had a child with the disease, their recurrence risk remains one half. If they have had several children, all affected (or all unaffected) by the disease, the law of independence dictates that the probability that their next child will have the disease is still one half. Parents' misunderstanding of this principle is a common problem encountered in genetic counseling.

If a child has been born with an autosomal dominant disease and there is no history of the disease in the family, the child is probably the product of a new mutation. The gene transmitted by one of the parents has thus undergone a mutation from a normal to a disease-causing allele. The genes at this locus in most of the parent's other germ cells would still be normal. In this situation the recurrence risk for the parent's subsequent offspring is not greater than that of the general population. The offspring of the affected child, however, will have a recurrence risk of one half. Because these diseases often reduce the potential for reproduction, a large proportion of the observed cases of many autosomal dominant diseases are the result of new mutations. For example, approximately seven eighths of all cases of achondroplasia are caused by new mutations.

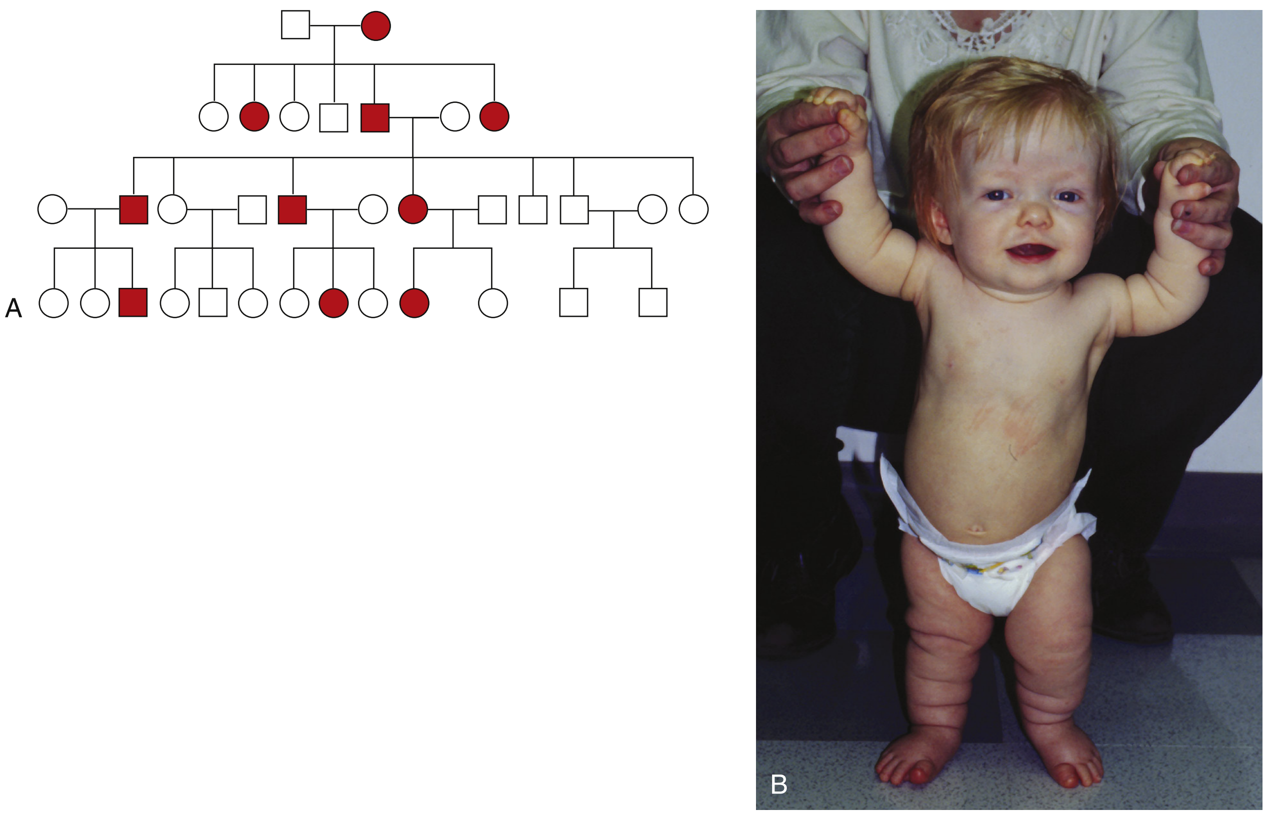

FIGURE 4-21 Achondroplasia. **A,** Pedigree showing the transmission of an autosomal dominant disease. **B,** Achondroplasia. This girl has short limbs relative to trunk length. She also has a prominent forehead, low nasal root, and redundant skin folds in the arms and legs. (**B** from Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

Occasionally, two or more offspring will present symptoms of an autosomal dominant disease when there is no family history of the disease. Because mutation is a rare event, it is unlikely that this disease would be a result of multiple mutations in the same family. The mechanism most likely to be responsible is termed **germline mosaicism.** During the embryonic development of one of the parents, a mutation occurred that affected all or part of the germline but few or none of the somatic cells of the embryo. Thus the parent carries the mutation in his or her germline but does not actually express the disease. As a result, the unaffected parent can transmit the mutation to multiple offspring. This phenomenon, although relatively rare, can have significant effects on recurrence risks.[12]

Penetrance and Expressivity

An important variation seen in some genetic diseases is incomplete penetrance. The **penetrance** of a trait is the percentage of individuals with a specific genotype who also exhibit the expected phenotype. Incomplete penetrance means that individuals who have a disease-causing allele may not exhibit the disease phenotype at all, even though the allele and the associated disease may be transmitted to the next generation. A pedigree illustrating the transmission of an autosomal dominant allele with incomplete penetrance is given in Figure 4-22. Retinoblastoma, the most common malignant eye tumor affecting children, typically exhibits incomplete penetrance. About 10% of the individuals who are **obligate carriers** of the allele (i.e., those who have an affected parent and affected children and therefore must themselves carry the allele) do not have the disease. The penetrance of the disease-causing genotype is then said to be 90%.

The gene responsible for retinoblastoma encodes a **tumor-suppressor gene:** the normal function of its protein product is to regulate the cell cycle so that cells do not divide in an uncontrollable manner. When a mutation alters the protein, its tumor-suppressing capacity is lost and a tumor can form[13,14] (see Chapters 12 and 20).

Huntington disease is another well-known autosomal dominant condition and its main features are progressive dementia and increasingly uncontrollable movements of the limbs (discussed further in Chapter 18). The latter is known as chorea (Greek *khoreia* = dance; the disease is sometimes called *Huntington chorea*).

One of the key features of this disease is that symptoms are not usually seen until age 40 years or later, a pattern known as **age-dependent penetrance.** Thus people who develop the disease often have had children before they are aware that they have the disease-causing allele. If the disease were present at birth, nearly all those affected would die before reaching reproductive age, and the occurrence of the allele in the population would be much lower. An individual whose parent has the disease has a 50% chance of developing it during middle age. He or she is thus confronted with a torturous question: "Should I have children, knowing that there is a 50-50 chance that I may have this disease gene and pass it to half my children?" Age-dependent penetrance characterizes a number of important genetic diseases, including familial breast cancer, hemochromatosis, and polycystic kidney disease.

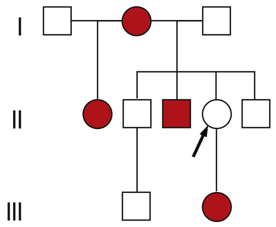

FIGURE 4-22 **Pedigree for Retinoblastoma Showing Incomplete Penetrance.** The female with marked arrow in line II must be heterozygous, but she does not express the trait.

Most genetic diseases exhibit variable expressivity. **Expressivity** is the extent of variation in phenotype associated with a particular genotype. If the expressivity of a disease is variable, the penetrance may be complete but the severity of the disease can vary greatly. A well-known example of variable expressivity in an autosomal dominant disease is type 1 neurofibromatosis, or von Recklinghausen disease. Like the retinoblastoma gene, the neurofibromatosis gene normally encodes a tumor suppressor.[15] The expression of this gene can vary from a few harmless café-au-lait spots ("coffee with milk," describing the light brown color) on the skin to malignant tumors, scoliosis, seizures, gliomas, hypertension, learning disabilities, and neuromas (Figure 4-23). A parent with mild expression of the disease—so mild that he or she is not aware of it—can transmit the gene to a child, who can then exhibit severe expression of the disease. Several factors can cause variation in expressivity. Genes at other loci can sometimes modify the expression of a disease-causing gene (these are termed *modifier genes*). Environmental factors also can influence the expression of a disease gene. Finally, different types of mutations at a locus can cause variation in severity. For example, a base substitution resulting in a single amino acid change usually produces a mild form of the clotting disorder hemophilia A. A base substitution resulting in a "stop" codon (and thus premature termination of translation) usually produces a more severe form of hemophilia A.

Autosomal Recessive Inheritance

Characteristics of Pedigrees

Like autosomal dominant diseases, those caused by autosomal recessive alleles are rare in populations, although the number of carriers for recessive diseases can be high. The most common lethal recessive disease in white children, cystic fibrosis, occurs in about 1 in 2500 births. Approximately 1 in 25 whites carries one copy of an allele that can cause cystic fibrosis (see Chapter 36). Because an individual must be homozygous for a recessive allele to express the disease, the carriers are phenotypically normal. Because most recessive alleles are maintained in normal carriers, they are able to survive in the population from one generation to the next. As with many autosomal dominant diseases, many autosomal recessive diseases are characterized by delayed age of onset, incomplete penetrance, and variable expressivity.

Figure 4-24 shows a pedigree for cystic fibrosis. The cystic fibrosis gene encodes a protein product that forms chloride

channels in the membranes of specialized epithelial cells.[16] Defective transport of chloride ions leads to a salt imbalance that results in secretions of abnormally thick, dehydrated mucus. Some of the digestive organs, particularly the pancreas, become obstructed, causing malnutrition, and the lungs become clogged with mucus, making them highly susceptible to bacterial infections (especially *Pseudomonas*). Death from lung disease or heart failure occurs on average by about 40 years of age. In the pedigree shown, the two affected individuals are the offspring of the marriage of two first cousins. Marriage between related individuals, termed **consanguinity** (from the Latin root meaning "with blood"), is often a factor in producing children with recessive diseases because related individuals are more likely to share the same recessive genes. Consanguinity is seen most often in rare recessive diseases because carriers of common recessive diseases (such as cystic fibrosis) have a fairly high probability of encountering one another just by chance.

Important criteria for discerning autosomal recessive inheritance include the following:

1. Males and females are affected in equal proportions.
2. Consanguinity is sometimes present.
3. The disease is seen in siblings but usually not in their parents.
4. On the average, one fourth of the offspring of carrier parents will be affected.

Recurrence Risks

In most cases of recessive disease, both parents of affected individuals are heterozygous carriers. On the average, one fourth of their offspring will be normal homozygotes, one half will be phenotypically normal carrier heterozygotes, and one fourth will be homozygotes with the disease (Figure 4-25). Thus the recurrence risk for the offspring of carrier parents is 25%. In any given family, chance fluctuations are likely, but a study of a large number of families would yield figures close to these proportions.

If two parents have a recessive disease, they each must be homozygous for the disease. Therefore, when two parents are affected by a recessive disease, all their children also must be affected. This observation helps to distinguish recessive from dominant inheritance, because two parents both affected by a dominant gene are nearly always both heterozygotes, and thus one fourth of their children will be unaffected.

Because carrier parents usually are unaware that they both carry the same recessive gene, they often produce an affected child before realization of their condition. **Carrier detection tests** can identify heterozygotes by measuring the reduced amount of a critical enzyme available. The critical enzyme is lacking in a homozygous recessive individual, but an essentially normal phenotype is seen when it is present in a reduced quantity in the carrier. Often carriers can be detected by direct examination of the disease locus for a mutation. Such testing is especially valuable for siblings of known carriers, who may themselves be carriers. Genetic testing is now available for more than 2000 diseases.

Consanguinity

Consanguinity and **inbreeding** are related concepts. *Consanguinity* refers to the mating of two related individuals, and the offspring of such matings are said to be *inbred.* Consanguinity is often an important characteristic of pedigrees for recessive diseases because relatives share a certain proportion of genes received from a common ancestor. The proportion of shared genes depends on the closeness of their biologic relationship. For example, siblings share one half of their DNA, on average, because of their descent from the same parents. With each decreasing degree of relationship, this proportion is reduced by one half. Uncles share one fourth of their DNA with nephews and nieces; first cousins share one eighth; first cousins once removed* share one sixteenth; second cousins share one thirty-second; and so on. With consanguineous matings, recessive disorders are significantly increased. Most empirical studies show that the proportion of offspring of marriages of first cousins who are affected by genetic diseases is approximately double that of the general population.[17] Marriages between first cousins are prohibited in most states of the United States. Marriages between closer relatives (except between double first cousins†) are prohibited throughout the United States.

X-Linked Inheritance

Not all genetic diseases are caused by genes located on the 22 autosomes. Some conditions are instead caused by genes located on the sex chromosomes, and that mode of inheritance is referred to as **sex-linked.** The Y chromosome contains only a few dozen genes, so most sex-linked traits are located on the X chromosome and are said to be X-linked. Only a few diseases are known to be inherited as X-linked dominant traits. Because these diseases are so seldom encountered, only the much more common X-linked recessive diseases are discussed here.

*First cousins once removed are the offspring of one's own first cousins.
†Double first cousins share both sets of grandparents; ordinarily, first cousins share just one set of grandparents.

Females receive two X chromosomes, one from the father and one from the mother, so they can be homozygous for a disease allele at a given locus, homozygous for the normal allele at the locus, or heterozygous. Males, having only one X chromosome, are said to be **hemizygous** for genes on this chromosome. A male who inherits a recessive disease gene on the X chromosome will be affected by the disease because the Y chromosome does not carry a normal allele to counteract the effects of the disease-causing allele. Males are more frequently affected by X-linked recessive diseases, with the difference becoming more pronounced as the disease becomes rarer.

X Inactivation

In the late 1950s Mary Lyon proposed that one X chromosome in the somatic cells of females is permanently inactivated, a process termed *X inactivation.*[18] This explains why most gene products coded by the X chromosome are present in equal amounts in males and females, even though males have only one X chromosome and females have two X chromosomes. This phenomenon is called **dosage compensation.** The inactivated X chromosomes are observable in many interphase cells as highly condensed chromatin bodies, termed **Barr bodies** (after Barr and Bertram, who discovered them in the late 1940s). Normal females have one Barr body in each somatic cell, whereas normal males have no Barr bodies.

The actual process of inactivation occurs very early in embryonic development—approximately 7 to 14 days after fertilization. In each somatic cell one of the two X chromosomes is inactivated. In some cells the X chromosome contributed by the father is inactivated; in others the maternal X chromosome is inactivated. Because the inactivation process is random, the maternal X chromosome is inactivated in approximately half the cells and the paternal X chromosome is inactivated in approximately half the cells. Once the X chromosome has been inactivated in a cell, all the descendants of that cell have the same chromosome inactivated. Thus inactivation is said to be *random* but *fixed.*

Some individuals do not have the normal number of X chromosomes in their somatic cells. For example, males with Klinefelter syndrome typically have two X chromosomes and one Y chromosome and they have one Barr body in each cell. Females whose cell nuclei have three X chromosomes have two Barr bodies in each cell, and females whose cell nuclei have four X chromosomes have three Barr bodies in each cell. Females with Turner syndrome have only one X chromosome and no Barr bodies. Thus the number of Barr bodies is always one less than the number of X chromosomes in the cell. All but one X chromosome are always inactivated.

People with abnormal numbers of X chromosomes, such as those with Turner syndrome or Klinefelter syndrome, are not physically normal. This situation presents a puzzle because they presumably have only one active X chromosome, the same as individuals with normal numbers of chromosomes. However, the distal portions of the short and long arms of the X chromosome, as well as several other regions on the chromosome, are not inactivated. Thus X inactivation is also known to be *incomplete.*

Although the mechanism underlying X inactivation is still incompletely understood, the gene responsible for initiating X inactivation, *XIST,* has been located.[19] This gene encodes an mRNA that coats one of the X chromosomes, which is then inactivated. Methylation of X chromosome DNA, a process in which DNA is inactivated when cytosine bases are enzymatically converted to 5-methylcytosine, occurs on the inactivated X chromosome. Inactive X chromosomes can be at least partially reactivated in vitro by administering 5-azacytidine, a demethylating agent.

Sex Determination

The process of sexual differentiation, in which the embryonic gonads become either testes or ovaries, begins during the sixth week of gestation. A key principle of sex determination in mammals is that one copy of the Y chromosome is sufficient to initiate the process of gonadal differentiation that produces a male fetus (Figure 4-26, *A*). The number of X chromosomes does not alter this process. For example, an individual with two X chromosomes and one Y chromosome in each cell is still phenotypically a male. Thus it is logical that the Y chromosome must contain a gene that begins the process of male gonadal development.

This gene, termed *SRY* (for "sex-determining region on the Y"), has been located on the short arm of the Y chromosome.[20,21] The *SRY* gene lies immediately proximal to the distal tip of the Y chromosome, known as the **pseudoautosomal** region (Figure 4-26, *B*). This portion of the Y chromosome is so named because it pairs with the distal tip of the short arm of the X chromosome during meiosis and exchanges genetic material with it (crossover), just as autosomes do. The DNA sequences of these regions on the X and Y chromosomes are highly similar. The remainder of the X and Y chromosomes, however, do not exchange material and are not similar in DNA sequence. An important piece of evidence that supports *SRY* as the male-determining gene is that female mouse embryos injected with this gene develop as phenotypic males.

Although the *SRY* gene is located on the Y chromosome, the other genes that contribute to male differentiation are located on other chromosomes. Thus *SRY* appears to act as a trigger that initiates the action of genes on other chromosomes (e.g., those that control Sertoli cell differentiation or secretion of müllerian-inhibiting substance). This concept is supported by the fact that the *SRY* gene is similar in sequence to other genes that are known to regulate the transcription of DNA (i.e., they turn other genes on and off).

Occasionally the crossover between X and Y occurs closer to the centromere than it should, placing the *SRY* gene on the X chromosome after crossover. This variation can result in offspring with an apparently normal XX karyotype but a male phenotype. Such XX males are seen in about 1 in 20,000 live births and closely resemble males with Klinefelter syndrome, although their stature is normal. Conversely, it is possible to inherit a Y chromosome that has lost the *SRY* gene (because of either a crossover error or a deletion of the gene). This situation produces an XY female. Such females have gonadal streaks rather than ovaries and have poorly developed secondary sex characteristics.

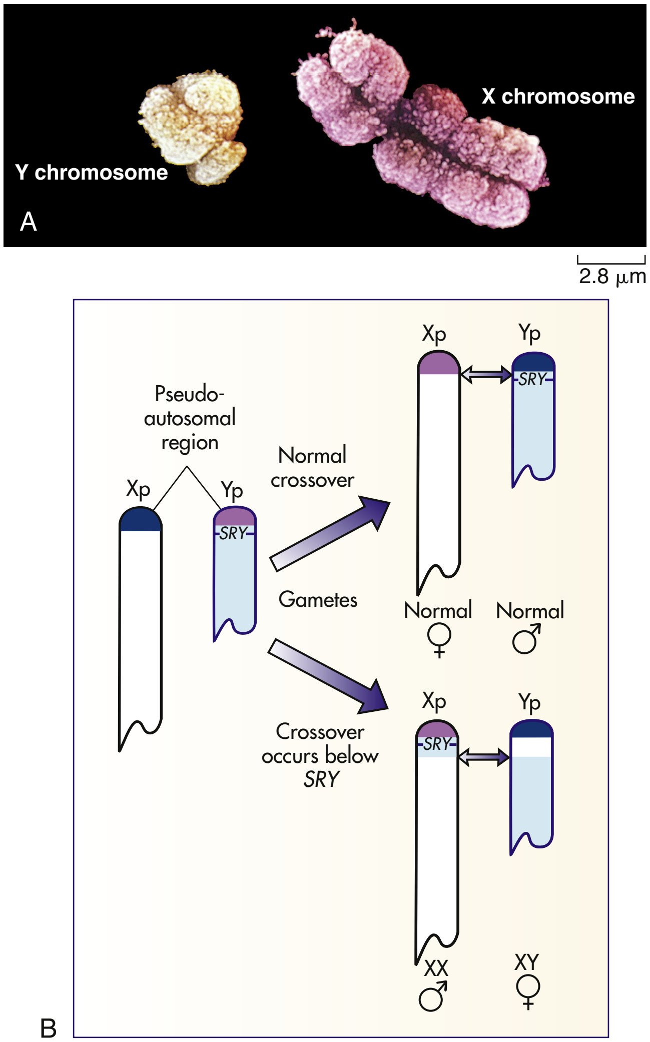

FIGURE 4-26 The Distal Short Arms of the X and Y Chromosomes Exchange Material During Meiosis in the Male. **A,** X and Y chromosomes. **B,** The region of the Y chromosome in which this crossover occurs is called the *pseudoautosomal region.* (Xp and Yp refer to the short arms of each chromosome.) The *SRY* gene, which triggers the process leading to male gonadal differentiation, is located just outside the pseudoautosomal region. Occasionally, the crossover occurs on the centromeric side of the *SRY* gene, causing it to lie on an X chromosome instead of a Y chromosome. An offspring receiving this X chromosome will be an XX male, and an offspring receiving the Y chromosome will be an XY female. (**A** from Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill. **B** from Jorde LB et al: *Medical genetics,* ed 3, St Louis, 2003, Mosby.)

Characteristics of Pedigrees

Pedigrees for X-linked recessive conditions show the following distinctive features:

1. The trait is seen much more often in males than in females because females must inherit two copies of the recessive allele (one from each parent) to express the disease, while males need only inherit one copy (from their mother) to express the disease.
2. Because a father can give a son only a Y chromosome, the trait is never transmitted from father to son.
3. The gene can be transmitted through a series of carrier females, causing the appearance of a "skipped generation."

4. The gene is passed from an affected father to all his daughters, who, as phenotypically normal carriers, transmit it to approximately half their sons, who are affected.

The most common and severe of all X-linked recessive disorders is Duchenne muscular dystrophy (DMD), which affects approximately 1 in 3500 males. As its name suggests, this disorder is characterized by progressive muscle degeneration. Affected individuals are usually unable to walk by 10 to 12 years of age. The disease affects the heart and respiratory muscles, and death caused by respiratory or cardiac failure usually occurs before 20 years. Until recently, the underlying pathologic origin of this disorder was a mystery. However, identification of the disease-causing gene has greatly increased our understanding of the disorder.[22] The *DMD* gene is the largest gene ever found in the human, spanning more than 2 million DNA bases. It encodes a previously undiscovered muscle protein, termed **dystrophin.** Extensive study of dystrophin indicates that it plays an essential role in maintaining the structural integrity of muscle cells: one end of the protein binds to actin filaments in the cytoplasm of the cell, and the other end binds to a group of membrane-spanning proteins known as the *dystrophin-associated glycoproteins.* When dystrophin is absent, as in individuals with DMD, the muscle cell cannot survive, and muscle deterioration ensues.

Most cases of Duchenne muscular dystrophy are caused by deletions of portions of the *DMD* gene. They generally involve frameshift deletions in which all the amino acids following the deletion are altered. It is interesting that an "in frame" deletion (in which a multiple of three bases is deleted, and the amino acids following the deletion are not altered) produces a milder form of muscular dystrophy, the Becker type. These two types of dystrophy are examples of a disease in which different types of mutations at the same locus produce variable expression of the disease.

Recurrence Risks

The most common mating type involving X-linked recessive genes is the combination of a carrier female and a normal male. On the average, the carrier mother will transmit the disease-causing allele to half her sons and half her daughters. As Figure 4-27, *A,* shows, half the daughters in such a mating will be carriers, whereas half will be normal. Half the sons will be normal, on the average, whereas half will have the disease.

The other common mating type is an affected father and a normal mother (see Figure 4-27, *B*). In this situation all the sons must be normal because the father can transmit only his Y chromosome to them. Because all the daughters must receive the father's X chromosome, they will all be heterozygous carriers. Because the sons *must* receive the Y chromosome and the daughters *must* receive the X with the disease gene, these are predictions and not probabilities. None of the children will express the disease.

The final mating pattern, less common than the other two, involves an affected father and a carrier mother (see Figure 4-27, *C*). With this pattern, on average, half the daughters will be heterozygous carriers and half will be homozygous for the disease allele and thus affected. Half the sons will be normal, and half will be affected. Some X-linked recessive diseases, such as DMD, are fatal or incapacitating before the affected individual reaches reproductive age, and therefore affected fathers are rare or nonexistent.

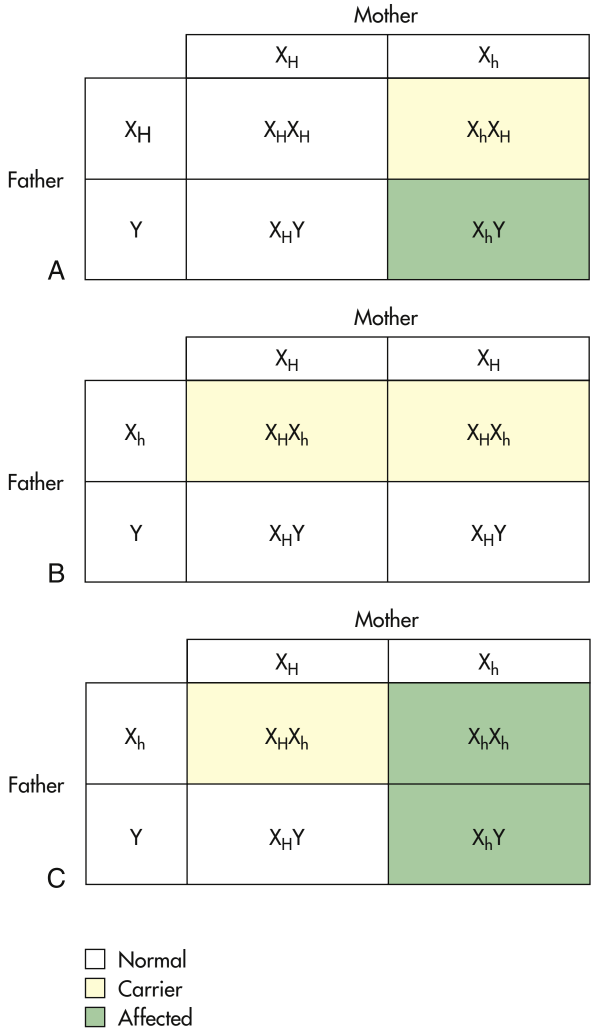

FIGURE 4-27 Punnett Square and X-linked Recessive Traits. **A,** Punnett square for the mating of a normal male (X_HY) and a female carrier of an X-linked recessive gene (X_HX_h). **B,** Punnett square for the mating of a normal female (X_HX_H) with a male affected by an X-linked recessive disease (X_hY). **C,** Punnett square for the mating of a female who carries an X-linked recessive gene (X_HX_h) with a male who is affected with the disease caused by the gene (X_hY).

Sex-Limited and Sex-Influenced Traits

Confusion sometimes exists regarding the difference between traits that are sex-linked and those that are sex-limited or sex-influenced. A **sex-limited trait** is one that can occur in only one of the sexes, often because of anatomic differences. Inherited uterine and testicular defects are two obvious examples.

A **sex-influenced trait** is one that occurs much more often in one sex than in the other. A good example of a sex-influenced trait is male-pattern baldness, which occurs in both males and females but is much more common in males. Another example is breast cancer, which is approximately 70 times more common in females than males.

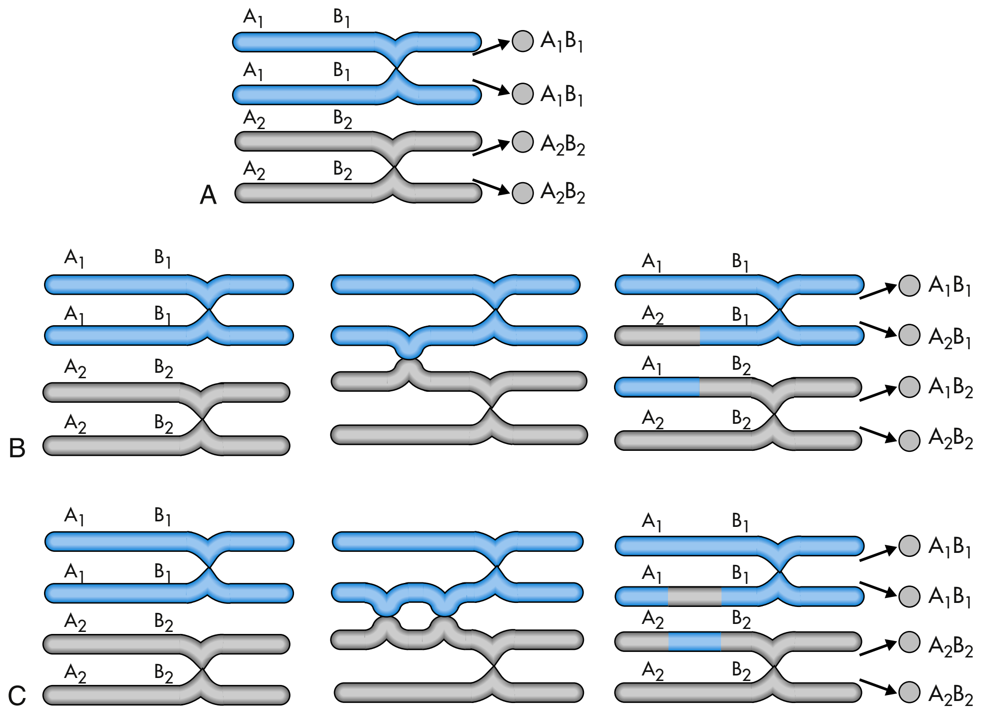

FIGURE 4-28 The Genetic Results of Crossing Over. **A,** No crossing over: A_1 and B_1 remain together after meiosis. **B,** Crossing over between A and B results in a recombination: A_1 and B_2 are inherited together on one chromosome, and A_2 and B_1 are inherited together on another chromosome. **C,** A double crossover between A and B results in no recombination of alleles.

Evaluation of Pedigrees

With complications such as incomplete penetrance, variable expressivity, delayed age of onset, and sex-influenced traits, it is not always possible simply to look at a disease pedigree and determine the mode of inheritance. A sophisticated statistical approach has evolved to deal with such complications. Incorporated into computer programs, these statistical techniques assess the probability of observing a certain pedigree if a particular mode of inheritance (e.g., autosomal dominant with incomplete penetrance) is in effect.

LINKAGE ANALYSIS AND GENE IDENTIFICATION

Locating the positions of genes on chromosomes has been one of the most important endeavors in human genetics. It is an important first step in identifying a disease-causing gene and can be used to predict the likelihood that certain individuals will develop a genetic disease.

Classic Pedigree Analysis

Mendel's second law, the principle of independent assortment, states that an individual's genes will be transmitted to the next generation independently of one another. This law is only partly true, however, because genes located close together on the same chromosome *do* tend to be transmitted together to the offspring. Thus Mendel's principle of independent assortment holds true for most pairs of genes but not those that occupy the same region of a chromosome. Such loci demonstrate **linkage** and are said to be linked.

During the first meiotic stage, the arms of homologous chromosome pairs intertwine and sometimes exchange portions of their DNA (Figure 4-28) in a process known as **crossing over.** During crossing over, new combinations of alleles can be formed. For example, two loci on a chromosome have alleles *A* and *a* and alleles *B* and *b*. Alleles *A* and *B* are located together on one chromosome arm, and alleles *a* and *b* are located on the other arm. The genotype of this individual is denoted as *AB/ab*.

As Figure 4-28, *A*, shows, the allele pairs *AB* and *ab* would be transmitted together when no crossing over occurs. However, when crossing over does occur (see Figure 4-28, *B*), all four possible pairs of alleles can be transmitted to the offspring: *AB, aB, Ab,* and *ab*. The process of forming such new arrangements of alleles is called **recombination.** Crossing over does not necessarily lead to recombination, however, because double crossing over between two loci can result in no actual recombination of the alleles at the loci (see Figure 4-28, *C*).

The rate of crossing over can be used to infer the distance between two loci on a chromosome because the probability of crossovers occurring between two loci increases as the loci become more distant. For example, if an individual with genotype *AB/ab* produces recombinant offspring gametes (composition of *Ab* and *aB)* 2% of the time, it is said that the two loci are two map units apart. One **map unit** equals a 1% recombination rate between two loci. When loci on the same chromosome are 50 or more map units apart, they are considered unlinked because their recombination frequency is just as great as it would be if they were on different chromosomes (where the probability of being transmitted together must equal one half). Recombination frequencies provide a good estimate of actual

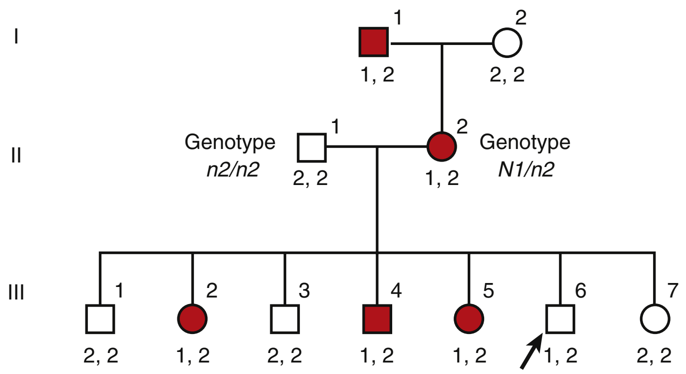

FIGURE 4-29 **Linkage between Neurofibromatosis Type 1 and a Marker Polymorphism in Three Generations of a Family.** Numbers below symbols indicate marker polymorphism alleles. Individual III-6 shows recombination *(arrow).*

physical distance between loci: on average, each map unit is equal to approximately 1 million DNA base pairs.

Pedigrees can be used to determine recombination rates between loci. Figure 4-29 shows a pedigree in which neurofibromatosis type 1 (NF1), an autosomal dominant disease discussed previously, is being transmitted in a family. The NF1 alleles are labeled *N* (the dominant disease-causing allele) and *n* (the normal allele). The individuals in this pedigree have been typed for a **marker polymorphism,** a small DNA sequence whose chromosome location is known and can be typed in the laboratory. The alleles of the marker polymorphism are labeled 1 and 2. Examination of generations I and II shows that the NF1 locus must be on the same chromosome as marker allele 1 because the mother, whose marker genotype was 2,2, was unaffected with the disease. The daughter's genotype would then be *N1/n2,* in which *N* indicates the disease allele and *n* indicates the normal allele. The daughter's husband (individual II-1) must have the genotype *n2/2n2.* If the marker locus and NF1 are linked, the children of this union who are affected with NF12 should have marker allele 1; those who are unaffected should have the marker genotype 2,2 (i.e., they inherited a copy of the normal chromosome from their affected mother). In six of seven cases we find this to be true. In one case a recombination occurred (individual III-6), indicating a recombination rate of 1 in 7, or 14%. The two loci are therefore 14 map units apart. In practice, a much larger sample of families would be used to ensure against statistical artifacts.

Once a close linkage has been established between a disease locus and a **marker polymorphism** and once the alleles of the two loci that are inherited together within a family have been determined, reliable predictions of whether a member of a family will develop the disease can be made. If, for example, the recombination rate between a disease locus and a marker polymorphism is less than 1%, family members can simply have the marker locus assayed to determine, with 99% or greater certainty, whether each member carries the disease-causing allele.

For most genetic diseases, it is now possible to test directly for the disease-causing mutation, often by sequencing the DNA in family members. In some cases, however, the actual disease-causing mutation cannot be identified, but linked marker loci can be assayed providing an indirect genetic test. These genetic tests are now used routinely to confirm diagnosis of a genetic disease, to identify carriers of recessive diseases, and to presymptomatically identify individuals who are at risk for inheriting a disease with delayed age of onset, such as autosomal dominant breast or colon cancer, Huntington disease, and many others. In some cases, testing can help provide preventive treatment, such as prophylactic oophorectomy in women who have inherited a dominant allele that can cause breast or ovarian cancer.

Assigning Loci to Specific Chromosomes

With completion of the human DNA sequence (see following), computer analysis of the published sequence has become an effective and popular approach for identifying genes. Computerized databases of known DNA sequences play an important role in gene identification. When studying a specific region of DNA to find a gene, it is common to search for similarity between DNA sequences from the region and DNA sequences in the database. The sequences in the database may derive from genes with known function or tissue-specific expression patterns. Suppose, for example, that we have used linkage analysis to identify a region containing a gene that causes a developmental disorder such as a limb malformation. As we evaluate DNA sequences in the region, we would look for similarity between a DNA sequence from this region and a plausible sequence from the database (e.g., sequence from a gene that encodes a protein involved in bone development, such as a fibroblast growth factor). Because genes that encode similar protein products usually have similar DNA sequences, a match between the sequence from our region and a sequence in the database could be a vital clue that this particular DNA sequence is actually part of the gene that causes the limb malformation.

As the cost of sequencing whole human genomes has declined, it is now common to search for a disease-causing mutation in an individual or a family by evaluating their entire DNA sequence. Their sequences are compared with those of unaffected individuals, and statistical methods are used to determine which, if any, of their DNA variants cause disease. Linkage results, as discussed previously, can help to define a specific chromosome region that contains a disease-causing variant in a family. Currently, the genetic causes of about 3000 mendelian conditions have been determined, enabling genetic testing, more accurate diagnosis, and in some cases more effective treatment of disease.

SUMMARY REVIEW

DNA, RNA, and Proteins: Heredity at the Molecular Level

1. Genes, the basic units of inheritance, are composed of DNA and are located on the chromosomes.
2. The most important constituent of DNA is the four types of nitrogenous bases, labeled A, C, G, and T. The physical structure of DNA is a double helix.
3. The DNA bases code for amino acids, which in turn make up proteins. The amino acids are specified by triplet codons of nitrogenous bases.
4. DNA replication is based on complementary base pairing, in which a single strand of DNA serves as the template for attracting bases that form a new strand of DNA.
5. DNA polymerase is the primary enzyme involved in replication. It adds bases to the new DNA strand and performs "proofreading" functions.
6. A mutation is an inherited alteration of genetic material (i.e., DNA).
7. Substances that cause mutations are called mutagens.
8. The mutation rate in humans varies from locus to locus and ranges from 10^{-4} to 10^{-7} per gene per generation.
9. Transcription and translation, the two basic processes in which proteins are specified by DNA, both involve RNA. RNA is chemically similar to DNA, but it is single stranded and has uracil rather than thymine as one of its four nitrogenous bases.
10. Transcription is the process by which DNA specifies a sequence of mRNA.
11. Much of the RNA sequence is spliced from the mRNA before the mRNA leaves the nucleus. The excised sequences are called introns, and those that remain to code for proteins are called exons.
12. Transcription factors bind to DNA sequences called transcription factor binding sites near genes to regulate the timing of transcription, as well as the specific tissues in which genes are actively transcribed.
13. Translation is the process by which RNA directs the synthesis of polypeptides. This process takes place in the ribosomes.
14. During translation, mRNA interacts with tRNA, a molecule that has an attachment site for a specific amino acid.

Chromosomes

1. Human cells consist of diploid somatic cells (body cells) and haploid gametes (sperm and egg cells).
2. Humans have 23 pairs of chromosomes: 22 of these pairs are autosomes. The remaining pair consists of the sex chromosomes. Females have two homologous X chromosomes as their sex chromosomes; males have an X and a Y chromosome.
3. A karyotype is an ordered display of chromosomes arranged according to length and the location of the centromere.
4. Various types of stains can be used to make chromosome bands more visible.
5. About 1 in 150 live births has a major diagnosable chromosome abnormality. Chromosome abnormalities are the leading known cause of mental retardation and miscarriage.
6. Polyploidy is a condition in which a euploid cell has some multiple of the normal number of chromosomes. Humans have been observed to have triploidy (three copies of each chromosome) and tetraploidy (four copies of each chromosome); both conditions are lethal.
7. Somatic cells that do not have a multiple of 23 chromosomes are aneuploid. Aneuploidy is usually the result of nondisjunction.
8. Trisomy is a type of aneuploidy in which one chromosome is present in three copies in somatic cells. A partial trisomy is one in which only part of a chromosome is present in three copies.
9. Monosomy is a type of aneuploidy in which one chromosome is present in only one copy in somatic cells.
10. In general, monosomies cause more severe physical defects than do trisomies, illustrating the principle that the loss of chromosome material has more severe consequences than the duplication of chromosome material.
11. Down syndrome, a trisomy of chromosome 21, is the most well-known disease caused by a chromosome aberration. It affects 1 in 800 live births and is much more likely to occur in the offspring of women older than 35 years of age.
12. Most aneuploidies of the sex chromosomes have less severe consequences than those of the autosomes.
13. The most commonly observed sex chromosome aneuploidies are the 47,XXX karyotype, 45,X karyotype (Turner syndrome); 47,XXY karyotype (Klinefelter syndrome); and 47,XYY karyotype.
14. Abnormalities of chromosome structure include deletions, duplications, inversions, and translocations.

Elements of Formal Genetics

1. Mendelian traits are caused by single genes, each of which occupies a position, or locus, on a chromosome.
2. Alleles are different forms of genes located at the same locus on the chromosome.
3. At any given locus in a somatic cell, an individual has two genes, one from each parent. An individual may be homozygous or heterozygous for a locus.
4. An individual's genotype is his or her genetic makeup, and the phenotype reflects the interaction of genotype and environment.
5. At a heterozygous locus, a dominant gene's effects mask those of a recessive gene. The recessive gene is expressed only when it is present in two copies.

Transmission of Genetic Diseases

1. Genetic diseases caused by single genes usually follow autosomal dominant, autosomal recessive, or X-linked recessive modes of inheritance.
2. Pedigree charts are an important tool in the analysis of modes of inheritance.
3. Recurrence risks specify the probability that future offspring will inherit a genetic disease. For single-gene diseases, recurrence risks remain the same for each offspring, regardless of the number of affected or unaffected offspring.

SUMMARY REVIEW—cont'd

4. The recurrence risk for autosomal dominant diseases is usually 50%.
5. Germline mosaicism can alter recurrence risks for genetic diseases because unaffected parents can produce multiple affected offspring. This situation occurs because the germline of one parent is affected by a mutation but the parent's somatic cells are unaffected.
6. Skipped generations are not seen in classic autosomal dominant pedigrees.
7. Males and females are equally likely to exhibit autosomal dominant diseases and to pass them on to their offspring.
8. A gene that is not always expressed phenotypically is said to have incomplete penetrance.
9. Penetrance may be age-dependent, as in Huntington disease and familial breast cancer.
10. Variable expressivity is a characteristic of many genetic diseases.
11. Most commonly, parents of children with autosomal recessive diseases are both heterozygous carriers of the disease gene. In this case, the recurrence risk for autosomal recessive diseases is 25%.
12. Males and females are equally likely to be affected by autosomal recessive diseases.
13. Consanguinity is sometimes present in families with autosomal recessive diseases, and it becomes more prevalent with rarer recessive diseases.
14. Carrier detection tests for an increasing number of autosomal recessive diseases are available.
15. The frequency of genetic diseases approximately doubles in the offspring of first-cousin matings.
16. In each normal female somatic cell, one of the two X chromosomes is inactivated early in embryogenesis.
17. X inactivation is random, fixed, and incomplete (i.e., only part of the chromosome is actually inactivated). It may involve methylation.
18. Gender is determined embryonically by the presence of the *SRY* gene on the Y chromosome. Embryos that have a Y chromosome (and thus the *SRY* gene) become males, whereas those lacking the Y chromosome become females. When the Y chromosome lacks the *SRY* gene, an XY female can be produced. Similarly, an X chromosome that contains the *SRY* gene can produce an XX male.
19. X-linked genes are those that are located on the X chromosome. Nearly all known X-linked diseases are caused by X-linked recessive genes.
20. Males are hemizygous for genes on the X chromosome.
21. X-linked recessive diseases are seen much more often in males than in females because males need only one copy of the gene to express the disease.
22. Fathers cannot pass X-linked genes to their sons.
23. Skipped generations are often seen in X-linked recessive disease pedigrees because the gene can be transmitted through carrier females.
24. Recurrence risks for X-linked recessive diseases depend on the carrier and affected status of the mother and father.
25. A sex-limited trait is one that occurs in only one of the sexes.
26. A sex-influenced trait is one that occurs more often in one sex than in the other.

Linkage Analysis and Gene Identification

1. During meiosis I, crossing over occurs and can cause recombinations of alleles located on the same chromosome.
2. The frequency of recombinations can be used to infer the map distance between loci on the same chromosome.
3. A marker locus, when closely linked to a disease-gene locus, can be used to predict whether an individual will develop a genetic disease.
4. The complete human genome sequence will facilitate gene identification, diagnosis, and disease treatment.

CHAPTER OUTLINE

Chapter 4 focuses on diseases that are caused by single genes or by abnormalities of single chromosomes. Much progress has been made in identifying specific mutations that cause these diseases, leading to better risk estimates and, in some cases, more effective treatment of the disease. However, these conditions form only a small portion of the total burden of human genetic disease. Most congenital malformations are not caused by single genes or chromosome defects. Many common adult diseases, such as cancer, heart disease, and diabetes, have genetic components, but again they are usually not caused by single genes or by chromosomal abnormalities.[1] These diseases, whose treatment collectively occupies the attention of most healthcare practitioners, are the result of a complex interplay of multiple genetic and environmental* factors.

*In human genetics, it is common practice to use the term “environment” to designate all nongeneric factors, such as diet and lifestyle.

FACTORS INFLUENCING INCIDENCE OF DISEASE IN POPULATIONS

Concepts of Incidence and Prevalence

How common is a given disease, such as diabetes, in a population? Well-established measures are used to answer this question.[2] The **incidence rate** is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population. The denominator is often expressed as *person-years.* The incidence rate can be contrasted with the **prevalence rate,** which is the proportion of the population affected by a disease at a specific point in time. Prevalence is thus determined by both the incidence rate and the length of the survival period in affected individuals. For example, the prevalence rate of acquired immunodeficiency syndrome (AIDS) is larger than the yearly incidence rate because most people with AIDS survive for at least several years after diagnosis.

Many diseases vary in prevalence from one population to another. Cystic fibrosis is relatively common among Europeans, occurring about once in every 2500 births. In contrast, it is quite rare in Asians, occurring only once in every 90,000 births. Similarly, sickle cell disease affects approximately 1 in 600 American blacks, but it is seen much less frequently in whites. Both of these diseases are single-gene disorders, and they vary among populations because disease-causing mutations are more or less common in different populations. (This is in turn the result of differences in the evolutionary history of these populations.) Nongenetic (environmental) factors have little influence on the current prevalence of these diseases.

The picture often becomes more complex with the common diseases of adulthood. For example, colon cancer was until recently relatively rare in Japan, but it is the second most common cancer in the United States. Stomach cancer, on the other hand, is common in Japan but relatively rare in the United States. These statistics, in themselves, cannot distinguish environmental from genetic influences in the two populations. However, because large numbers of Japanese emigrated first to Hawaii and then to the U.S. mainland, we can observe what happens to the rates of stomach and colon cancer among the migrants. It is important that the Japanese émigrés maintained a genetic identity, marrying largely among themselves. Among first-generation Japanese in Hawaii, the frequency of colon cancer rose several-fold—not yet as high as in the U.S. mainland but higher than that in Japan. Among second-generation Japanese on the U.S. mainland, colon cancer rates rose to 5%, equal to the U.S. average. At the same time, stomach cancer has become relatively rare among Japanese-Americans.

These observations strongly indicate an important role for environmental factors in the etiology of cancers of the colon and stomach. In each case, diet is a likely culprit—a high-fat, low-fiber diet in the United States is thought to increase the risk of colon cancer, whereas techniques used to preserve and season the fish commonly eaten in Japan are thought to increase the risk of stomach cancer. It is interesting that the incidence of colon cancer in Japan has increased dramatically during the past several decades as the Japanese population has adopted a more "Western" diet. These results do not, however, rule out the potential contribution of genetic factors in common cancers. Genes also play a role in the etiology of colon and other cancers.

Analysis of Risk Factors

The comparison just discussed is one example of the analysis of risk factors (in this case, diet) and their influence on the prevalence of disease in populations. A common measure of the effect of a specific risk factor is the **relative risk.** This quantity is expressed as a ratio:

$$\frac{\text{Increased rate of the disease among individuals exposed to a risk factor}}{\text{Incidence rate of the disease among individuals } \textit{not} \text{ exposed to a risk factor}}$$

A classic example of a relative risk analysis was carried out in a sample of more than 40,000 British physicians to determine the relationship between cigarette smoking and lung cancer. This study compared the incidence of death from lung cancer in physicians who smoked with those who did not. The incidence of death from lung cancer was 1.66 (per 1000 person-years) in heavy smokers (more than 25 cigarettes daily), but it was only 0.07 in the nonsmokers. The ratio of these two incidence rates is 1.66/0.07, which yields a relative risk of 23.7 deaths. Thus, it is concluded that the risk of dying from lung cancer increased by about 24-fold in heavy smokers compared with nonsmokers. Many other studies have obtained similar risk figures.

Although cigarette smoking clearly increases one's risk of developing lung cancer (as well as heart disease, as we will see later), it is equally clear that *most* smokers do not develop lung cancer. Other lifestyle factors are likely to contribute to one's risk of developing this disease (e.g., exposure to cancer-causing substances in the air, such as asbestos fibers). In addition, differences in genetic background may be involved. Smokers who have variants in genes, such as *CYP1A1* and *GSTM1,* that are involved in the metabolism of components of tobacco smoke are at significantly increased risk of developing lung cancer.

Many factors can influence the risk of acquiring a common disease such as cancer, diabetes, or high blood pressure. These include age, gender, diet, amount of exercise, and family history of the disease. Usually, complex interactions occur among these genetic and nongenetic factors. The effects of each factor can be quantified in terms of relative risks. The following discussion demonstrates how genetic and environmental factors contribute to the risk of developing common diseases.

PRINCIPLES OF MULTIFACTORIAL INHERITANCE

Basic Model

Traits in which variation is thought to be caused by the combined effects of multiple genes are **polygenic** ("many genes"). When environmental factors are also believed to cause variation in the trait, which is usually the case, the term **multifactorial trait** is used.[3] Many **quantitative traits** (those, such as blood pressure, that are measured on a continuous numeric scale) are multifactorial. Because they are caused by the additive effects of many genetic and environmental factors, these traits tend to follow a normal, or bell-shaped, distribution in populations.

An example illustrates this concept. To begin with the simplest case, suppose (unrealistically) that height is determined by a single gene with two alleles, *A* and *a*. Allele *A* tends to make people tall, whereas allele *a* tends to make them short. If there is no dominance at this locus, then the three possible genotypes *(AA, Aa, aa)* will produce three phenotypes: tall, intermediate, and short, respectively. Assume that the gene frequencies of *A* and *a* are each 0.50. If we look at a population of individuals, we will observe the height distribution depicted in Figure 5-1, *A*.

Now suppose, a bit more realistically, that height is determined by two loci instead of one. The second locus also has two alleles, *B* (tall) and *b* (short), and they affect height in exactly the same way as alleles *A* and *a*. There are now nine possible genotypes in our population: *aabb, aaBb, aaBB, Aabb, AaBb, AaBB, AAbb, AABb,* and *AABB.* An individual may have zero, one,

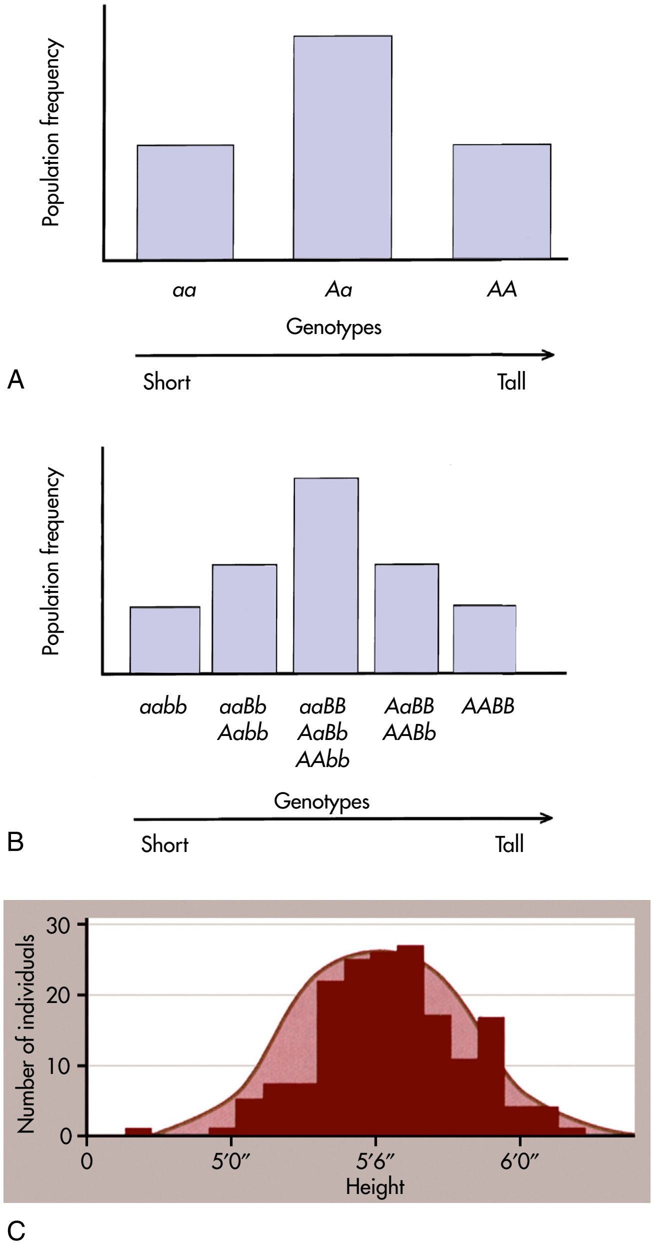

FIGURE 5-1 Distribution of Height. **A,** Distribution of height in a population, assuming that height is controlled by a single locus with genotypes *AA, Aa,* and *aa.* **B,** Distribution of height, assuming that height is controlled by two loci. Five distinct genotypes are shown instead of three, and the distribution begins to look more like the normal distribution. **C,** Height is portrayed, realistically, as a trait with a continuous statistical distribution. Because many genes contribute to height and tend to segregate independently of one another, the cumulative contribution of different combinations of alleles to height forms a continuous distribution of possible heights, in which the extremes are much rarer than the intermediate values. Variation also can be due to environmental factors such as nutrition. (**A** and **B** adapted from Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby; **C** from Raven PH et al: *Biology,* ed 8, New York, 2008, McGraw-Hill.)

two, three, or four "tall" alleles, so now five distinct phenotypes are possible (see Figure 5-1, *B*). Although the height distribution in our fictional population is still not normal compared with an actual population, it approaches a normal distribution more closely than in the single-gene case just described.

From extension of this example, *many* genes and environmental factors influence height, each having a small effect. Then many phenotypes are possible, each differing slightly from the others, and the height distribution of the population approaches the bell-shaped curve shown in Figure 5-1, *C*.

It should be emphasized that the individual genes underlying a multifactorial trait such as height follow the mendelian principles of segregation and independent assortment, just like any other gene. The only difference is that many of them *act together* to influence the trait. More than 100 genes have now been shown to be associated with variation in human height.

Blood pressure is another example of a multifactorial trait. A correlation exists between parents' blood pressures (systolic and diastolic) and those of their children. The evidence is good that this correlation is partially caused by genes, but blood pressure is also influenced by environmental factors, such as diet, exercise, and stress. Two goals of genetic research are the identification and measurement of the relative roles of genes and environment in the causation of multifactorial diseases.

Threshold Model

A number of diseases do not follow the bell-shaped distribution. Instead, they appear to be either present or absent in individuals, yet they do not follow the inheritance patterns expected of single-gene diseases. A commonly used explanation for such diseases is that there is an underlying **liability distribution** for the disease in a population (Figure 5-2). Those individuals who are on the "low" end of the distribution have little chance of developing the disease in question (i.e., they have few of the alleles or environmental factors that would cause the disease). Individuals who are closer to the "high" end of the distribution have more of the disease-causing genes and environmental factors and are more likely to develop the disease. For diseases that are either present or absent, it is thought that a **threshold of liability** must be crossed before the disease is expressed. Below the threshold, an individual appears normal; above it, he or she is affected by the disease.

A disease that is thought to correspond to this threshold model is *pyloric stenosis,* a disorder that presents shortly after birth and is caused by a narrowing or obstruction of the pylorus, the area between the stomach and intestine. Chronic vomiting, constipation, weight loss, and imbalance of electrolyte levels result from the condition, but it sometimes resolves spontaneously or can be corrected by surgery. The prevalence of pyloric stenosis is about 3 per 1000 live births in whites. It is much more common in males than females, affecting 1 of 200 males and 1 of 1000 females. It is thought that this difference in prevalence reflects two thresholds in the liability distribution—a lower one in males and a higher one in females (see Figure 5-2). A lower male threshold implies that fewer disease-causing factors are required to generate the disorder in males.

The liability threshold concept may explain the pattern of recurrence risks for pyloric stenosis seen in Table 5-1. Note that males, having a lower threshold, always have a higher risk than females. However, the sibling risk also depends on the gender of the proband (i.e., the individual from which the pedigree begins). It is higher when the proband is female than when the

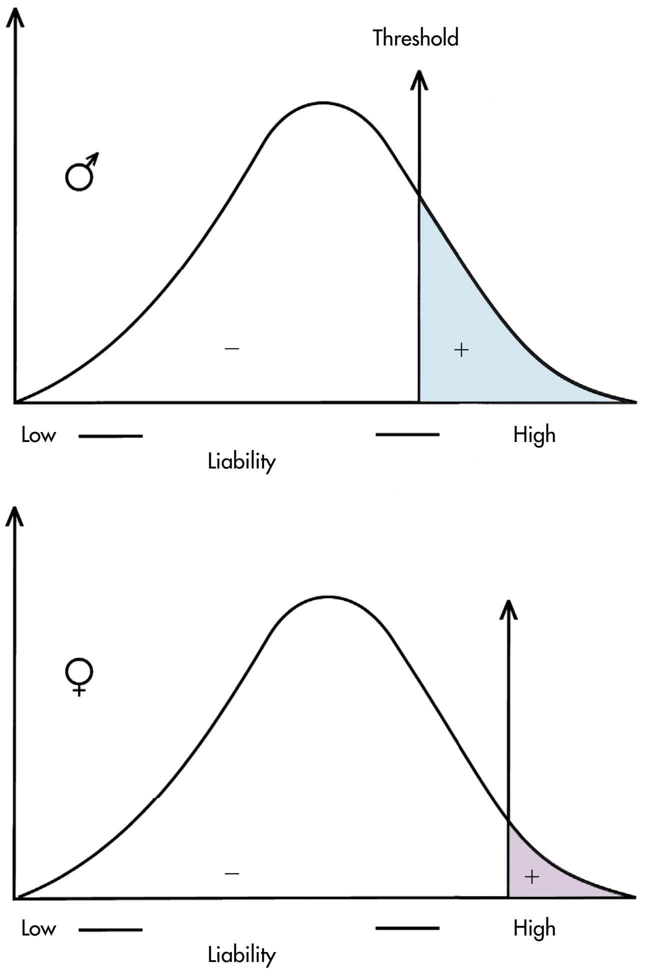

FIGURE 5-2 **A Liability Distribution in a Population for a Multifactorial Disease.** To be affected with the disease, an individual must exceed the threshold on the liability distribution. This figure shows two thresholds, a lower one for males and a higher one for females (as in pyloric stenosis; see text). (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

proband is male. This reflects the concept that females, having a higher liability threshold, must be exposed to more disease-causing factors than males to develop the disease. Thus a family with an affected female must have more genetic and environmental risk factors, producing a higher recurrence risk for pyloric stenosis in future offspring. It would be expected that the highest risk category would be *male* relatives of *female* probands; Table 5-1 shows that this is the case.

A similar pattern has been observed in a study of *autism,* a behavioral disorder in which the male/female ratio is approximately 4:1. As expected for a multifactorial disorder, the recurrence risks for siblings of male probands (3.5%) is substantially lower than that of siblings of female probands (7%). When the sex ratio for a disease is reversed (i.e., more affected females than males), one would expect a higher recurrence risk when the proband is male.

A number of other congenital malformations are thought to correspond to this model. They include isolated *cleft lip and/or cleft palate (CL/P), neural tube defects (anencephaly, spina bifida), clubfoot (talipes),* and some forms of congenital heart

Note that the risks differ somewhat between the two populations.

disease. In this context, isolated means that this is the only observed disease feature (i.e., the feature is not part of a larger constellation of findings, as in CL/P secondary to trisomy 13). In addition, many common adult diseases, such as *hypertension, coronary heart disease, stroke, diabetes mellitus* (types 1 and 2), and some cancers, are caused by complex genetic and environmental factors and can thus be considered multifactorial diseases.

Recurrence Risks and Transmission Patterns

Whereas recurrence risks can be given with confidence for single-gene diseases (e.g., 50% for typical autosomal dominant diseases, 25% for autosomal recessive diseases), the situation is more complicated for multifactorial diseases. This is because the number of genes contributing to the disease is usually not known, the precise allelic constitution of the parents is not known, and the extent of environmental effects can vary substantially. For most multifactorial diseases, **empirical risks** (i.e., risks based on direct observation of data) have been derived. To estimate empirical risks, a large series of families is examined in which one child has developed the disease (the proband). Then the siblings of each proband are surveyed to calculate the percentage of siblings who also have developed the disease. For example, in the United States about 3% of siblings of individuals with neural tube defects also have neural tube defects (Box 5-1). Thus the recurrence risk for parents who have had one child with a neural tube defect is 3% in the United States. For conditions such as CL/P that are not lethal or severely debilitating, recurrence risks also can be estimated for the offspring of affected parents. Empirical recurrence risks are, of course, specific for each multifactorial disease.

In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change substantially from one population to another because gene frequencies as well as environmental factors can differ among populations (note the differences between the London and Belfast populations in Table 5-1).

It is sometimes difficult to distinguish polygenic or multifactorial diseases from single-gene diseases that have reduced penetrance or variable expression. Large data sets and good epidemiologic data are necessary to make the distinction. Several criteria are commonly used to define multifactorial inheritance.

BOX 5-1 NEURAL TUBE DEFECTS

Neural tube defects (NTDs), which include *anencephaly, spina bifida,* and *encephalocele* (as well as several other less common forms), are one of the most important classes of birth defects, and they are seen in 0.5 to 2 of 1000 pregnancies.[4] The prevalence of NTDs among different populations varies considerably, with an especially high rate among some northern Chinese populations (as high as 6 or more per 1000 births). The prevalence of NTDs has been decreasing in many parts of the United States and Europe during the past three decades, partly because of dietary changes.

Normally the neural tube closes at about the fourth week of gestation. A defect in closure, or a subsequent reopening of the neural tube, results in a neural tube defect. Spina bifida (Figure 5-3, *A*) is the most commonly observed NTD and consists of a protrusion of spinal tissue through the vertebral column (the tissue usually includes meninges, spinal cord, and nerve roots). About 75% of individuals with spina bifida have secondary hydrocephalus, which sometimes in turn produces mental retardation. Paralysis or muscle weakness, lack of sphincter control, and clubfeet are often observed. A study conducted in British Columbia showed that survival rates for people with spina bifida have improved dramatically over the past several decades. Less than 30% of people born between 1952 and 1969 survived to 10 years of age, whereas 65% of those born between 1970 and 1986 survived to this age. Anencephaly (see Figure 5-3, *B*) is characterized by partial or complete absence of the cranial vault and calvarium and partial or complete absence of the cerebral hemispheres. At least two thirds of newborns with anencephaly are stillborn; term deliveries do not survive more than a few hours or days.

NTDs are thought to arise from a combination of genetic and environmental factors. In most populations surveyed thus far, empirical recurrence risks for siblings of affected people range from 2% to 5%. Consistent with a multifactorial model, the recurrence risk increases with additional affected siblings. Studies conducted in Great Britain showed that the sibling recurrence risk was approximately 5% when one sibling was affected and 10% when two were affected. A Hungarian study showed that the overall prevalence of NTDs was 1 in 300 births and that the sibling recurrence risks were 3%, 12%, and 25% after one, two, and three affected offspring, respectively. Recurrence risks tend to be slightly lower in populations with lower NTD prevalence rates, as predicted by the multifactorial model. Recurrence risk data support the idea that the major forms of NTDs are caused by similar factors. An anencephalic conception increases the recurrence risk for subsequent spina bifida conceptions, and vice versa.

NTDs can usually be diagnosed prenatally, sometimes by ultrasound and usually by an elevation in α-fetoprotein (AFP) level in the maternal serum or amniotic fluid (see Chapter 20). A spina bifida lesion can be either open or closed (i.e., covered with a layer of skin). Fetuses with open spina bifida are more likely to be detected by AFP assays.

A major epidemiologic finding is that mothers who supplement their diet with folic acid at the time of conception are less likely to produce children with NTDs. This result has been replicated in several different populations and thus appears to be well confirmed. It has been estimated that as many as 50% to 70% of NTDs can be avoided simply by dietary folic acid supplementation.[5] (Traditional prenatal vitamin supplements have little effect because administration does not usually begin until well after the time that the neural tube closes.) It is now recommended that all women of reproductive age supplement their diet with 0.4 mg of folic acid each day; many foods in the United States are supplemented with folic acid. Consequently, average folate levels in U.S. females have doubled and the incidence of neural tube defects has declined by 30% to 50% in the past decade.

Because mothers would be likely to ingest similar amounts of folic acid from one pregnancy to the next, folic acid deficiency could well account for at least part of the elevated sibling recurrence risk for NTDs. This is an important example of a *nongenetic* factor that contributes to familial clustering of a disease.

First, *the recurrence risk becomes higher if more than one family member is affected.* For example, the sibling recurrence risk for a *ventricular septal defect* (VSD, a type of congenital heart defect) is 3% if one sibling has been affected by a VSD but increases to approximately 10% if two siblings have been diagnosed with VSDs.[6] In contrast, the recurrence risk for single-gene diseases remains the same regardless of the number of affected siblings. It should be emphasized that this increase does not mean that the family's risk has actually *changed.* Rather, it means that there is more information about the family's true risk; because they have had two affected children, they are probably located higher on the liability distribution than a family with only one affected child. In other words, they have more risk factors (genetic or environmental) and are more likely to produce an affected child.

Second, *if the expression of the disease in the proband is more severe, the recurrence risk is higher.* This is again consistent with the liability model because a more severe expression indicates that the affected individual is at the extreme tail end of the liability distribution (see Figure 5-2). His or her relatives are thus at a higher risk for inheriting disease genes. For example, the occurrence of a bilateral (both sides) CL/P confers a higher recurrence risk on family members than does the occurrence of a unilateral (one side) cleft.

Third, *the recurrence risk is higher if the proband is of the less commonly affected gender* (see the preceding discussion of pyloric stenosis). This is because an affected individual of the less susceptible gender is usually at a more extreme position on the liability distribution.

Fourth, *the recurrence risk for the disease usually decreases rapidly in more remotely related relatives* (Table 5-2). Whereas the recurrence risk for single-gene diseases decreases by 50% with each degree of relationship (e.g., an autosomal dominant disease has a 50% recurrence risk for siblings, 25% for uncle-nephew relationships, 12.5% for first cousins), it decreases much more quickly for multifactorial diseases. This reflects the fact that many genes and environmental factors must combine to produce a trait. All the necessary risk factors are unlikely to be present in less closely related family members.

Finally, *if the prevalence of the disease in a population is f, the risk for offspring and siblings of probands is approximately* $\sqrt{f}$. This does not hold true for single-gene traits because their recurrence risks are independent of population prevalence. It is not an absolute rule for multifactorial traits either, but many such diseases tend to conform to this prediction. Examination of the risks given in Table 5-2 shows that the first three diseases follow the prediction fairly well. However, the observed sibling risk for the fourth disease, infantile autism, is substantially higher than that predicted by $\sqrt{f}$.

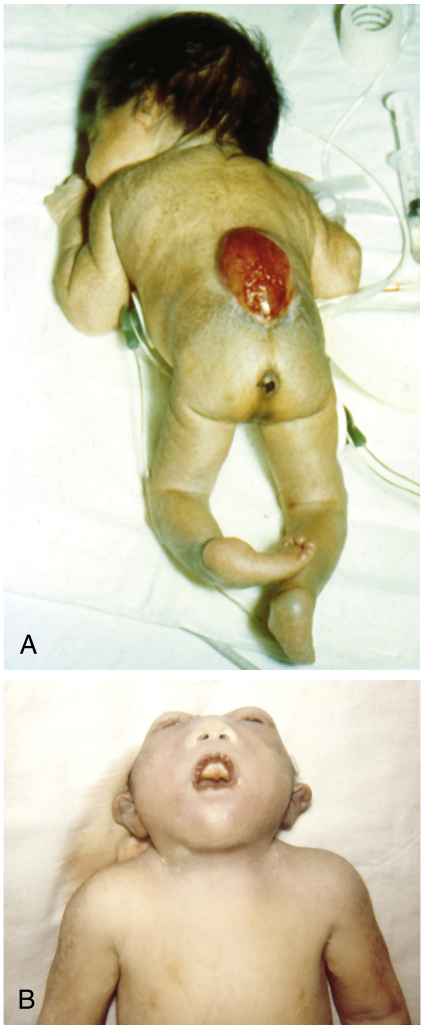

FIGURE 5-3 Spina Bifida and Anencephaly. **A,** Spina bifida in a newborn. **B,** Anencephaly, showing the absence of the cranial vault. (From Jones KL: *Smith's recognizable patterns of human malformation,* ed 6, Philadelphia, Saunders, 2006, p. 705.)

NATURE AND NURTURE: DISENTANGLING THE EFFECTS OF GENES AND ENVIRONMENT

Family members share genes and a common environment. Family resemblance in traits such as blood pressure reflects both genes (nature) and environment (nurture). For centuries people have debated the relative importance of these two types of factors. It is a mistake, of course, to view them as mutually exclusive. Few traits are influenced only by genes or only by environmental factors. Most are influenced by both. It is useful to try to determine the *relative* influence of genetic and environmental factors (Figure 5-4). This can lead to a better understanding of disease etiology. It can also help in planning public health strategies. A disease in which the genetic influence is relatively small, such as lung cancer, may be prevented most effectively through emphasis on lifestyle changes (avoidance of tobacco). When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification.

FIGURE 5-4 Continuum of Genetic Diseases. Some diseases (e.g., cystic fibrosis) are strongly determined by genes, whereas others (e.g., infectious diseases) are strongly determined by environmental factors. (Adapted from Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

TABLE 5-2 RECURRENCE RISKS (%) FOR FIRST-, SECOND-, AND THIRD-DEGREE RELATIVES

	RISK			
DEGREE	FIRST DEGREE	SECOND DEGREE	THIRD DEGREE	GENERAL POPULATION
Cleft lip/palate	4	0.7	0.3	0.1
Clubfoot	2.5	0.5	0.2	0.1
Congenital hip dislocation	5	0.6	0.4	0.2

Here, two research strategies are reviewed that often are used to estimate the relative influence of genes and environment: twin studies and adoption studies.

Twin Studies

Twins occur with a frequency of about 1 in 100 births in white populations. They are a bit more common in blacks and a bit less common among Asians. **Monozygotic (MZ, identical) twins** originate when, for unknown reasons, the developing embryo divides to form two separate but identical embryos. Because they are genetically identical, MZ twins are an example of natural clones. **Dizygotic (DZ, fraternal) twins** are the result of a double ovulation followed by the fertilization of each egg by a different sperm. Thus dizygotic twins are genetically no more similar than siblings. Because two different sperm cells are required to fertilize the two eggs, it is possible for each DZ twin to have a different father. Whereas MZ twinning rates are constant across populations, DZ twinning rates vary somewhat. DZ twinning increases with maternal age until about 40 years, after which it declines.

Because MZ twins are genetically identical, any differences between them should be caused only by environmental effects.[7] MZ twins should thus resemble one another very closely for traits that are strongly influenced by genes. DZ twins provide a convenient comparison because their environmental differences should be similar to those of MZ twins, but their genetic differences are as great as those between siblings. Twin studies thus usually consist of comparisons between MZ and DZ twins.[8] If both members of a twin pair share a trait (e.g., a cleft lip), it is said to be a **concordant trait.** If they do not share the trait, it is a **discordant trait.** For a trait determined totally by genes, MZ twins should always be concordant, whereas DZ twins should

be concordant less often, because they, like siblings, share only 50% of their genes. Concordance rates may differ between opposite-sex DZ twin pairs and same-sex DZ pairs for some traits, such as those that have different frequencies in males and females. For such traits, only same-sex DZ twin pairs should be used when comparing MZ and DZ concordance rates, because MZ twins are necessarily of the same sex.

Table 5-3 gives concordance rates for a number of traits. Note that the concordance rates for contagious diseases such as measles are quite similar in MZ and DZ twins. This is expected because a contagious disease is unlikely to be influenced markedly by genes. On the other hand, the concordance rates are quite dissimilar for *schizophrenia* and *bipolar affective disorder*, suggesting a sizable genetic component for these diseases. The MZ correlations for dermatoglyphics (fingerprints), which are determined almost entirely by genes, are close to 1.0.

At one time, twins were thought to provide a perfect "natural laboratory" in which to determine the relative influences of genetics and environment, but several difficulties arose. One of the most important is the assumption that the environments of MZ and DZ twins are equally similar. As one would expect, MZ twins are often treated more similarly than DZ twins. A greater similarity in environment can make MZ twins more concordant for a trait, inflating the apparent influence of genes. In addition, MZ twins may be more likely to seek the same type of environment, further reinforcing environmental similarity. On the other hand, it has been suggested that MZ twins tend to develop personality differences in an attempt to assert their individuality.

Adoption Studies

Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait. Children born to parents who have a disease but are then subsequently adopted by parents lacking the disease can be studied to find out whether these children develop the disease. In some cases such children develop the disease more often than a comparative control population (i.e., adopted children who were born to parents who do *not* have the disease). This provides some evidence that genes may be involved in the causation of the disease, because the adopted children do not share an environment with their affected natural parents. For example, about 8% to 10% of adopted children of a schizophrenic parent develop *schizophrenia*, whereas only 1% of adopted children of normal parents develop schizophrenia.

As with twin studies, several precautions must be exercised in interpreting the results of adoption studies. First, prenatal environmental influences could have long-lasting effects on an adopted child. Second, children are sometimes adopted after they are several years old, ensuring that some environmental influence would have been imparted by the natural parents. Finally, adoption agencies sometimes try to match the adoptive parents with the natural parents in terms of background, socioeconomic status, and so on. All of these factors could exaggerate the apparent influence of biologic inheritance.

These reservations, as well as those summarized for twin studies, underscore the need for caution in basing conclusions on twin and adoption studies. These approaches do not provide definitive measures of the role of genes in multifactorial disease nor can they identify specific genes responsible for disease. Instead, they serve a useful purpose in providing a preliminary indication of the extent to which a multifactorial disease may be caused by genetic factors. Sophisticated molecular techniques are being used to identify the specific genes that underlie predisposition to multifactorial diseases.

TABLE 5-3 CONCORDANCE RATES IN MZ AND DZ TWINS FOR SELECTED TRAITS AND DISEASES*

	CONCORDANCE RATE		
TRAIT OR DISEASE	MZ TWINS	DZ TWINS	HERITABILITY
Affective disorder (bipolar)	0.79	0.24	>1*
Affective disorder (unipolar)	0.54	0.19	0.7
Alcoholism	>0.6	<0.3	0.6
Autism	0.92	0	>1
Blood pressure (diastolic)†	0.58	0.27	0.62
Blood pressure (systolic)†	0.55	0.25	0.6
Body fat percentage†	0.73	0.22	>1
Body mass index†	0.95	0.53	0.84
Cleft lip/palate	0.38	0.08	0.6
Clubfoot	0.32	0.03	0.58
Dermatoglyphics (finger ridge count)†	0.95	0.49	0.92
Diabetes mellitus	0.45-0.96	0.03-0.37	>1
Diabetes mellitus (type 1)	0.55	—	—
Diabetes mellitus (type 2)	0.9	—	—
Epilepsy (idiopathic)	0.69	0.14	>1
Height†	0.94	0.44	1
Intelligence quotient (IQ)†	0.76	0.51	0.5
Measles	0.95	0.87	0.16
Multiple sclerosis	0.28	0.03	0.5
Myocardial infarction (males)	0.39	0.26	0.26
Myocardial infarction (females)	0.44	0.14	0.6
Schizophrenia	0.47	0.12	0.7
Spina bifida	0.72	0.33	0.78

*NOTE: Heritability, which is defined as the proportion of the variation in a trait that is due to genetic factors, can be measured as $2(C_{MZ} - C_{DZ})$, where C_{MZ} and C_{DZ} are the concordance rates for MZ twins and DZ twins, respectively. These figures were compiled from a large variety of sources and represent primarily European and U.S. populations.
†Several heritability estimates exceed 1. Because it is impossible for >100% of the variance of a trait to be genetically determined, these values indicate that other factors, such as shared environmental factors, must be operating.
‡Because these are quantitative traits, correlation coefficients are given rather than concordance rates.
DZ, Dizygotic; *MZ,* monozygotic.

BOX 5-2 α_1-ANTITRYPSIN DEFICIENCY: THE INTERACTION OF GENES AND ENVIRONMENT-LIFESTYLE

α_1-Antitrypsin (α_1-AT) deficiency is one of the most common autosomal recessive disorders among whites, affecting approximately 1 in 2500 members of this ethnic group. α_1-AT, synthesized primarily in the liver, is a serine protease inhibitor. It does bind trypsin, as its name suggests. However, α_1-AT binds much more strongly to neutrophil elastase, a protease that is produced by neutrophils (a type of leukocyte) in response to infections and irritants. It carries out its binding and inhibitory role primarily in the lower respiratory tract, where it prevents elastase from digesting the alveolar septi of the lung.

Individuals with less than 10% to 15% of the normal level of α_1-AT activity will experience significant lung damage and typically develop emphysema during their 30s, 40s, or 50s. In addition, at least 10% develop liver cirrhosis as a result of the accumulation of variant α_1-AT molecules in the liver; α_1-AT deficiency accounts for nearly 20% of all nonalcoholic liver cirrhosis cases in the United States. An important feature of this disease is that cigarette smokers with α_1-AT deficiency develop emphysema much earlier than do nonsmokers. This is because cigarette smoke irritates lung tissue, increasing secretion of neutrophil elastase. At the same time it inactivates α_1-AT, so there is also less inhibition of elastase. One study showed that the median age of survival of nonsmokers with α_1-AT deficiency was 62 years, whereas it was only 40 years for smokers with this disease. Because the combination of cigarette smoking (an environmental factor) and the α_1-AT mutation (a genetic factor) produces more severe disease than either factor alone, it is an example of a gene-environment interaction.

This discussion should make clear that most common diseases are not the result of either genetics *or* environment. Instead, genetic and nongenetic factors usually interact to influence one's likelihood of developing a common disease. In some cases a genetic predisposition may interact with an environmental factor to increase the risk of disease acquisition to a much higher level than would either factor acting alone. A good example of a **gene-environment interaction** is given by α_1-antitrypsin deficiency, a genetic condition that causes pulmonary emphysema and is greatly exacerbated by cigarette smoking (Box 5-2).

GENETICS OF COMMON DISEASES

Some common multifactorial disorders, the congenital malformations, are by definition present at birth. Others, including heart disease, cancer, diabetes, and most psychiatric disorders, are seen primarily in adolescents and adults. Because these disorders are complex, unraveling their genetics is a daunting task. Nonetheless, significant progress is being made.

Congenital Malformations

Congenital diseases are present at birth. Approximately 2% of newborns present with a congenital malformation; most of these are multifactorial in etiology. Table 5-4 lists some more common congenital malformations. In general, sibling recurrence risks for most of these disorders range from 1% to 5%.

Some congenital malformations, such as CL/P and pyloric stenosis, are relatively easy to repair and thus are not considered to be serious problems. Others, such as the neural tube defects, usually have more severe consequences. Although some cases of congenital malformations occur in the absence of any other problems, it is quite common for them to be associated with other disorders. For example, hydrocephaly and clubfoot are often seen secondary to spina bifida, CL/P is often seen in babies with trisomy 13, and congenital heart defects are seen in children with many other disorders, including Down syndrome.

TABLE 5-4 PREVALENCE RATES OF COMMON CONGENITAL MALFORMATIONS IN WHITES

DISORDER	PREVALENCE PER 1000 BIRTHS (APPROXIMATE)
Cleft lip/palate	1
Clubfoot	1
Congenital heart defects	4-8
Hydrocephaly	0.5-2.5
Isolated cleft palate	0.4
Neural tube defects	1-3
Pyloric stenosis	3

Environmental factors also cause some congenital malformations. An example is thalidomide, a sedative used during pregnancy in the early 1960s. When ingested during early pregnancy this drug often caused **phocomelia** (severely shortened limbs) in babies. Maternal exposure to retinoic acid, which is used to treat acne, can cause congenital defects of the heart, ear, and central nervous system. Maternal rubella infection can cause congenital heart defects.

Multifactorial Disorders in the Adult Population

Until quite recently, very little was known about specific genes responsible for common adult diseases. With the more powerful laboratory and analytic techniques now available, this situation is changing. This section reviews recent progress in understanding the genetics of the major common adult diseases. Table 5-5 gives approximate prevalence figures for these disorders in the United States.

Coronary Heart Disease

It is well-known that coronary heart disease (CHD) is the leading killer of Americans, accounting for approximately 25% of all deaths in the United States. It is caused by *atherosclerosis* (narrowing as a result of the formation of lipid-laden lesions) of the coronary arteries. This narrowing impedes blood flow to the heart and can eventually result in a *myocardial infarction* (destruction of heart tissue caused by an inadequate supply of oxygen). When atherosclerosis occurs in arteries supplying blood to the brain, a *stroke* can result. Many risk factors for heart disease have been identified, including obesity, cigarette smoking, hypertension, elevated cholesterol level, and positive family history (usually defined as having one affected first-degree relative). Many studies have examined the role of family history in CHD, and they show that an individual with a positive family history is two to seven times more likely to have heart disease than is an individual with no family history (this would be the relative risk of heart disease as a result of a positive

TABLE 5-5 PREVALENCE OF COMMON ADULT DISEASES IN THE UNITED STATES

DISEASE	NUMBER AFFECTED (APPROXIMATE)
Alcoholism	14 million
Alzheimer disease	4 million
Arthritis	43 million
Asthma	17 million
Cancer	8 million
Cardiovascular disease (all forms)	
Coronary artery disease	13 million
Congestive heart failure	5 million
Congenital defects	1 million
Hypertension	50 million
Stroke	5 million
Depression and bipolar disorder	17 million
Diabetes (type 1)	1 million
Diabetes (type 2)	15 million
Epilepsy	2.5 million
Multiple sclerosis	350,000
Obesity*	60 million
Parkinson disease	500,000
Psoriasis	3-5 million
Schizophrenia	2 million

Data from National Center for Chronic Disease Prevention and Health Promotion; American Heart Association (2002 Heart and Stroke Statistical Update); National Institute on Alcohol Abuse and Alcoholism; Office of the U.S. Surgeon General; American Academy of Allergy, Asthma and Immunology; Cown WM, Kandel ER: *JAMA* 285:594–600, 2001; Flegal et al: *JAMA* 288:1723–1727, 2002.
*Body mass index >30.

family history). Generally, these studies also show that the risk increases if (1) there are more affected relatives; (2) the affected relative or relatives are female (the less commonly affected sex) rather than male; and (3) the age of onset in the affected relative is early (before 55 years). For example, one study showed that men between the ages of 20 and 39 years had a relative risk of 3 for CHD if they had one affected first-degree relative. The relative risk increased to 13 if two first-degree relatives were affected with CHD before 55 years of age.[11]

What part do genes play in the familial clustering of heart disease? Because of the key role of lipids in atherosclerosis, many studies are focusing on the genetic determination of various lipoproteins.[12] An important advance in this area has been the isolation and cloning of the gene for the low-density lipoprotein (LDL)–receptor defects that cause *familial hypercholesterolemia* (Box 5-3). Many other genes involved in lipid variation, coagulation, and hypertension have been identified, including several genes encoding apolipoproteins (the protein components of lipoproteins) (Table 5-6).[13] Functional analysis of these genes is leading to an increased understanding, and eventually more effective treatment, of CHD.

Environmental factors, many of which are easily modified, are also important causes of CHD. Abundant epidemiologic evidence shows that cigarette smoking and obesity increase the risk of CHD, whereas exercise and a diet low in saturated fats decrease the risk. Indeed, the approximate 50% decline in CHD prevalence in the United States during the past 40 years is usually attributed to a decrease in the proportion of adults who smoke cigarettes, a decreased consumption of saturated fats, and an increased emphasis on exercise and a generally healthier lifestyle.

Hypertension

Systemic hypertension, which has a worldwide prevalence of approximately 25% to 30%, is a key risk factor for heart disease, stroke, and kidney disease. Studies of blood pressure correlations within families indicate that about 20% to 40% of the variation in both systolic and diastolic blood pressure is caused by genetic factors. The fact that this figure is substantially less than 100% indicates that environmental factors also must be important causes of blood pressure variation. The most important environmental risk factors for hypertension are increased sodium intake, decreased physical activity, psychosocial stress, and obesity (but, as discussed later, the latter factor is itself influenced by both genes and environment).

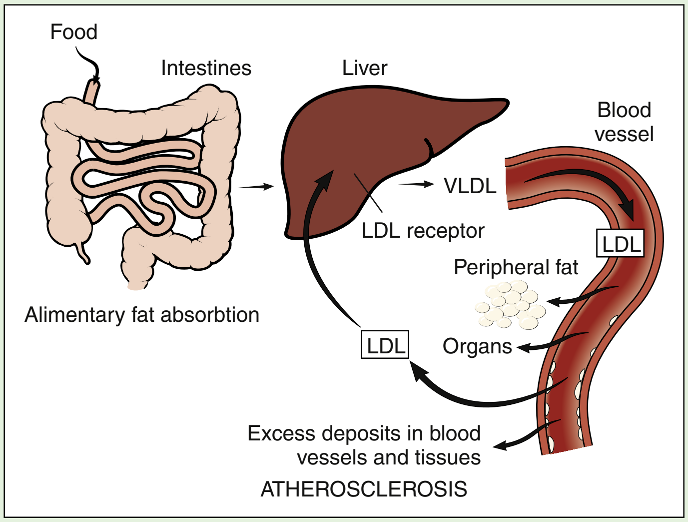
Blood pressure regulation is a highly complex process that is influenced by many physiologic systems, including various aspects of kidney function, cellular ion transport, and heart function.[14] Because of this complexity, much research is now focused on specific components that may influence blood pressure variation, such as the renin-angiotensin system (involved in sodium reabsorption and vasoconstriction), vasodilators such as nitric oxide and the kallikrein-kinin system, and ion-transport systems such as adducin and sodium-lithium countertransport (Figure 5-7). These individual factors are more likely to be under the control of smaller numbers of genes than is blood pressure itself, simplifying the task of identifying these genes and their role in blood pressure regulation. For example, linkage and association studies have implicated several genes involved in the renin-angiotensin system (e.g., the genes that encode angiotensinogen, angiotensin-converting enzyme, type 1 and angiotensin II type 1 receptor) in the causation of hypertension.

Cancer

Cancer is the second leading cause of death in the United States. It is well established that many major types of cancer (e.g., breast, colon, prostate, ovarian) cluster strongly in families. This is caused by both shared genes and shared environmental factors. Although numerous cancer genes are being isolated,[15] environmental factors also play an important role in causing cancer. In particular, tobacco use is estimated to account for one third of all cancer cases in the United States, making it the most important known cause of cancer.[16]

Breast Cancer. Breast cancer is the most common cancer among women, affecting approximately 12% of American women who live to 85 years or more. Formerly the leading cause of cancer death among women, it has been surpassed by lung cancer. Breast cancer aggregates strongly in families. If a woman has one affected first-degree relative, her risk of developing breast cancer doubles. This risk increases if the age of onset in

BOX 5-3 FAMILIAL HYPERCHOLESTEROLEMIA



Autosomal dominant familial hypercholesterolemia (FH) is an important cause of heart disease, accounting for approximately 5% of myocardial infarctions in individuals less than 60 years of age.[9] FH is one of the most common autosomal dominant disorders: in most populations surveyed to date, about 1 in 500 people is a heterozygote. Plasma cholesterol levels are approximately twice as high as normal (i.e., about 300 to 400 mg/dl), resulting in substantially accelerated atherosclerosis and distinctive cholesterol deposits in skin and tendons (*xanthomas* [see Figure 5-5]). Data compiled from five studies showed that approximately 75% of men with FH developed coronary disease and 50% had a fatal myocardial infarction by 60 years. The corresponding percentages for women were lower (45% and 15%) because women generally develop heart disease at a later age than men.

Consistent with Hardy-Weinberg predictions, about 1 in 1 million births is homozygous for the FH gene. Homozygotes are much more severely affected, with cholesterol levels ranging from 600 to 1200 mg/dl. Most experience myocardial infarctions before 20 years of age, and a myocardial infarction at 18 months of age has been reported. If untreated, most FH homozygotes die before 30 years of age.

All cells require cholesterol as a component of their plasma membrane. They can either synthesize their own cholesterol or, preferably, obtain it from the extracellular environment, where it is carried primarily by low-density lipoprotein (LDL). In a process known as *endocytosis,* LDL-bound cholesterol is taken into the cell via LDL receptors on the cell's surface (see Figure 5-6). FH is most commonly caused by a reduction in the number of functional LDL receptors on cell surfaces. Lacking the normal number of LDL receptors, cellular cholesterol uptake is reduced and circulating cholesterol levels increase.

Much of what we know about endocytosis has been learned through the study of LDL receptors. The process of endocytosis and the processing of LDL in the cell are described in detail in Figure 5-6 (endocytosis is discussed in Chapter 1). These processes result in a fine-tuned regulation of cholesterol levels within cells, and they influence the level of circulating cholesterol as well.

The identification of the LDL receptor gene in 1984 was critical in understanding exactly how LDL receptor defects cause FH. More than 1000 different mutations, including missense and nonsense substitutions as well as insertions and deletions, have been identified in the LDL receptor gene. These can be grouped into five broad classes according to their effects on the activity of the receptor.[10] Class 1 mutations result in no detectable protein product. Thus heterozygotes would produce only half the normal number of LDL receptors. Class 2 mutations in the LDL receptor gene result in production of the LDL receptor, but it is altered such that it cannot leave the endoplasmic reticulum. It is eventually degraded. Class 3 mutations produce an LDL receptor that is capable of migrating to the cell surface but incapable of normal binding to LDL. Class 4 mutations, which are comparatively rare, produce receptors that are normal except that they do not migrate specifically to coated pits and thus cannot carry LDL into the cell. The final group of mutations, class 5, produces an LDL receptor that cannot dissociate from the LDL particle after entry into the cell. The receptor cannot return to the cell surface and is degraded. Each class of mutations reduces the number of effective LDL receptors, resulting in decreased LDL uptake and hence elevated levels of circulating cholesterol. The number of effective receptors is reduced by about half in FH heterozygotes, and homozygotes have virtually no functional LDL receptors.

Understanding the defects that lead to FH has helped to develop effective therapies for the disorder. Dietary reduction of cholesterol (primarily through the reduced intake of saturated fats) has only modest effects on cholesterol levels in FH heterozygotes. Because cholesterol is reabsorbed into the gut and then recycled through the liver (where most cholesterol synthesis takes place), serum cholesterol levels can be reduced by the administration of bile acid–absorbing resins, such as cholestyramine. The absorbed cholesterol is then excreted. It is interesting that reduced recirculation from the gut causes the liver cells to form additional LDL receptors, lowering circulating cholesterol levels. However, the decrease in the concentration of intracellular cholesterol also stimulates cholesterol synthesis by liver cells, so the overall reduction in plasma LDL level is only about 15% to 20%. This treatment is much more effective when combined with agents that reduce cholesterol synthesis by inhibiting 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase (the "statin" class of drugs). Decreased synthesis leads to further production of LDL receptors. When these therapies are used in combination, serum cholesterol levels in FH heterozygotes can be reduced to approximately normal levels.

The picture is less encouraging for FH homozygotes. The therapies just discussed can enhance cholesterol elimination and reduce its synthesis, but they are largely ineffective because homozygotes have few or no LDL receptors. Liver transplants, which provide hepatocytes that have normal LDL receptors, have been successful in some cases, but this option is often limited by a lack of donors. Plasma exchange, carried out every 1 to 2 weeks, in combination with drug therapy, can reduce cholesterol levels by about 50%. However, this therapy is difficult to continue for long periods. Somatic cell gene therapy, in which hepatocytes carrying normal LDL receptor genes are introduced into the portal circulation, is now being tested. It may eventually prove to be an effective treatment for FH homozygotes.

The FH story illustrates how medical research has made important contributions both to our understanding of basic cell biology and to advances in clinical therapy. The process of receptor-mediated endocytosis, elucidated largely by research on the LDL receptor defects, is of fundamental significance for cellular processes throughout the body. Equally important is that this research, by clarifying how cholesterol synthesis and uptake can be modified, has led to significant improvements in therapy for this important cause of heart disease.

FIGURE 5-5 **Xanthoma.** Fatty deposits, referred to as xanthomas as seen here on the knuckles, are often noted in individuals with familial hypercholesterolemia. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

the affected relative is early and if the cancer is bilateral (tumors in both breasts).

An autosomal dominant form of breast cancer accounts for approximately 5% of breast cancer cases in the United States. Genes responsible for this form of breast cancer have been mapped to chromosomes 17 *(BRCA1)* and 13 *(BRCA2)*. It is possible to test each of these genes for inherited cancer-causing mutations.[17] Women who inherit a mutation in *BRCA1* or *BRCA2* experience a 50% to 80% lifetime risk of developing breast cancer. *BRCA1* mutations also increase the risk of ovarian cancer among women (20% to 50% lifetime risk), and they confer a modestly increased risk of prostate and colon cancers. *BRCA2* mutations also confer an increased risk of ovarian cancer (10% to 20% lifetime prevalence). Approximately 6% of males who inherit a *BRCA2* mutation will develop breast cancer; this represents a 100-fold increase over the risk in the general male population. The evaluation of the *BRCA1* and *BRCA2* gene products, which are both involved in deoxyribonucleic acid (DNA) repair, is yielding valuable evidence on the etiology of breast cancer in general.

Although *BRCA1* and *BRCA2* mutations are the most common known causes of inherited breast cancer, this disease also can be caused by inherited mutations in several other tumor-suppressor genes (e.g., the *CHK2* and *TP53* genes). Germline mutations in a tumor-suppressor gene called *PTEN* are responsible for Cowden disease, which is characterized by multiple benign tumors and an increased susceptibility to breast cancer.

Colorectal Cancer. Colorectal cancer is second only to lung cancer in the number of cases occurring annually in the United States, with approximately 143,000 new cases (and 52,000 deaths) estimated in 2012.[18] Approximately 1 in 20 Americans will develop colorectal cancer. Like breast cancer, it clusters in families (in fact, familial clustering of this form of cancer was reported in the medical literature as early as 1881). The risk of colorectal cancer in people with one affected first-degree relative is two to three times higher than that in the general population.

This familial aggregation is caused in part by subsets of colorectal cancer cases that are inherited as single-gene traits. *Familial adenomatous polyposis* occurs in approximately 1 in 8000 whites. The gene responsible for this disorder, *APC,* encodes a tumor suppressor.[19] Importantly, somatic mutations of *APC* are found in at least 85% of all colon tumors. Thus although inherited *APC* mutations play a vital role in relatively rare familial adenomatous polyposis, somatic mutations are involved in the great majority of all common colon cancers.

Hereditary nonpolyposis colorectal cancer, which may account for as many as 5% of colorectal cancer cases, is caused by mutations in any of six genes.[20] Identification has shown that all of these genes are involved in the vital process of DNA repair. When this function is compromised, cancer-causing mutations can persist in cells, leading eventually to growth of a tumor.

Other colorectal cancer cases are likely to be caused by a complex interaction of multiple genes. In addition, environmental factors, such as a high-fat, low-fiber diet, are thought to increase the risk of colorectal cancer.

Other Cancers. The genetic basis of various other cancers, including retinoblastoma, has been discussed. Although each of these cancers is relatively rare, study of the causative genes has provided many important insights into the nature of carcinogenesis in general. This will lead to more effective treatment and prevention of all cancers.

Diabetes Mellitus

Like the other disorders discussed in this chapter, the etiology of diabetes mellitus is complex and not fully understood. Nevertheless, progress is being made in understanding the genetic basis of this disorder, which is a leading cause of blindness, heart disease, and kidney failure.[21,22] An important advance has been the recognition that diabetes is actually a heterogeneous group of disorders, all characterized by elevated blood glucose level. The focus here is on the two major types of diabetes: type 1 (insulin-dependent diabetes mellitus [IDDM]) and type 2 (non–insulin-dependent diabetes mellitus [NIDDM]).

Type 1 Diabetes. Type 1 diabetes, which is characterized by T-cell infiltration of the pancreas and destruction of the insulin-producing beta cells, usually (though not always) presents before age 40. Individuals with type 1 diabetes must receive exogenous insulin to survive. In addition to T-cell infiltration of the pancreas, autoantibodies are formed against pancreatic cells; the latter can be observed long before clinical symptoms occur. These findings, along with a strong association between type 1 diabetes and the presence of several human leukocyte antigen (HLA) class II alleles, indicate that this is an autoimmune disease.

Siblings of individuals with type 1 diabetes face a substantial elevation in risk: approximately 6%, as opposed to a risk of about 0.3% to 0.5% in the general population. The recurrence risk is also elevated when there is a diabetic parent, although this risk varies with the sex of the affected parent. The risk for offspring of diabetic mothers is only 1% to 3%, whereas it is 4% to 6% for the offspring of diabetic fathers (because type 1 diabetes affects males and females in roughly equal proportions in the general population, this risk difference is inconsistent

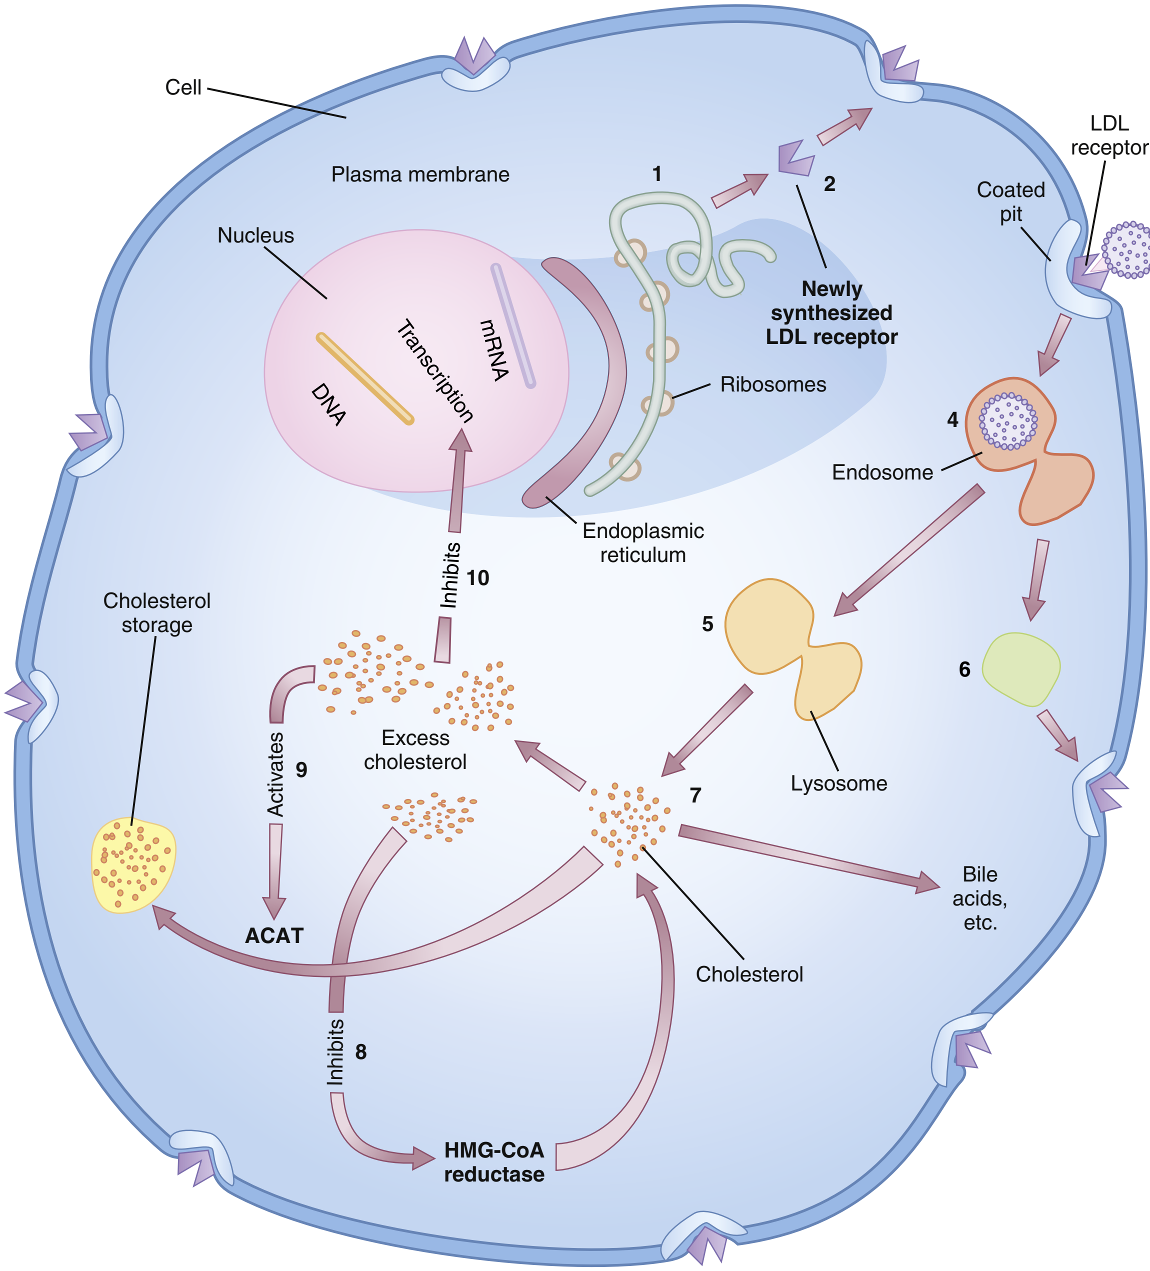

FIGURE 5-6 **Process of Receptor-Mediated Endocytosis.** Numbers in parentheses correspond to numbers shown in the figure. **(1)** The low-density lipoprotein (LDL) receptors, which are glycoproteins, are synthesized in the endoplasmic reticulum of the cell. **(2)** From here, they pass through the Golgi apparatus to the cell surface, where part of the receptor protrudes outside the cell. **(3)** The circulating LDL particle is bound by the LDL receptor and localized in cell surface depressions called *coated pits* (so named because they are coated with a protein called clathrin). **(4)** The coated pit invaginates, bringing the LDL particle inside the cell. **(5)** Once inside the cell, the LDL particle is separated from the receptor, taken into a lysosome, and broken down into its constituents by lysosomal enzymes. **(6)** The LDL receptor is recirculated to the cell surface to bind another LDL particle (each LDL receptor goes through this cycle approximately once every 10 minutes even if it is not occupied by an LDL particle). **(7)** Free cholesterol is released from the lysosome for incorporation into cell membranes or metabolism into bile acids or steroids. Excess cholesterol can be stored in the cell as a cholesterol ester or removed from the cell by associating with high-density lipoprotein (HDL). **(8)** As cholesterol levels in the cell rise, cellular cholesterol synthesis is reduced by inhibition of the rate-limiting enzyme HMG-CoA (3-hydroxy-3-methylglutaryl coenzyme A) reductase. **(9)** Rising cholesterol levels also increase the activity of acyl coenzyme A (acyl CoA): cholesterol acyltransferase (ACAT), an enzyme that modifies cholesterol for storage as cholesterol esters. **(10)** In addition, the number of LDL receptors is decreased by lowering the transcription rate of the LDL receptor gene itself. This decreases cholesterol uptake. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

TABLE 5-6 LIPOPROTEIN GENES KNOWN TO CONTRIBUTE TO CORONARY ARTERY DISEASE RISK

GENE	CHROMOSOME LOCATION	FUNCTION OF PROTEIN PRODUCT
Apolipoprotein A-I	11q	HDL component; LCAT cofactor
Apolipoprotein A-IV	11q	Component of chylomicrons and HDL; may influence HDL metabolism
Apolipoprotein C-III	11q	Allelic variation associated with hypertriglyceridemia
Apolipoprotein B	2p	Ligand for LDL receptor; involved in formation of VLDL, LDL, IDL, and chylomicrons
Apolipoprotein D	2p	HDL component
Apolipoprotein C-I	19q	LCAT activation
Apolipoprotein C-II	19q	Lipoprotein lipase activation
Apolipoprotein E	19q	Ligand for LDL receptor
Apolipoprotein A-II	1p	HDL component
LDL receptor	19p	Uptake of circulating LDL particles
Lipoprotein (a)	6q	Cholesterol transport
Lipoprotein lipase	8p	Hydrolysis of lipoprotein lipids
Hepatic triglyceride lipase	15q	Hydrolysis of lipoprotein lipids
LCAT	16q	Cholesterol esterification
Cholesterol ester transfer protein	16q	Facilitates transfer of cholesterol esters and phospholipids between lipoproteins

HDL, High-density lipoprotein; *IDL,* intermediate-density lipoprotein; *LCAT,* lecithin cholesterol acyltransferase; *LDL,* low-density lipoprotein; *VLDL,* very-low-density lipoprotein.

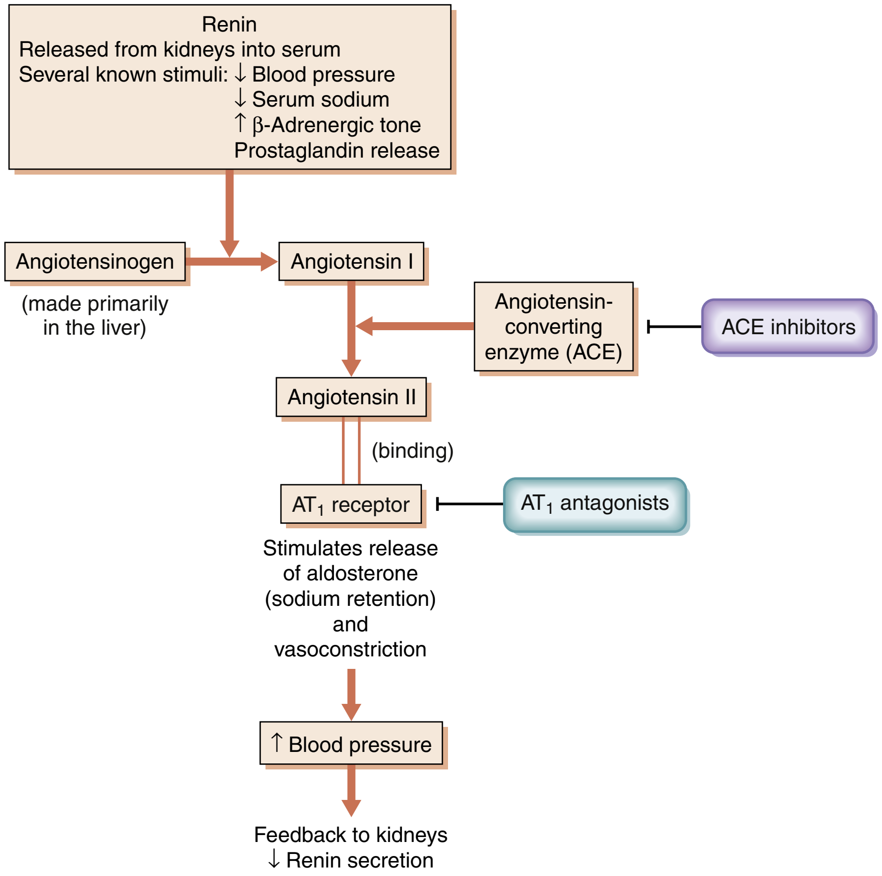

FIGURE 5-7 **Renin-Angiotensin-Aldosterone System.** (Modified from King RA, Rotter JI, Motulsky AG (eds): The genetic basis of common diseases, New York, Oxford University Press, 1992. In Jorde LB et al: *Medical genetics,* ed 4, St. Louis, 2010, Mosby.)

with the sex-specific threshold model for multifactorial traits). Twin studies show that the empirical risks for identical twins of people with type 1 diabetes range from 30% to 50%. In contrast, the concordance rates for dizygotic twins are 5% to 10%. The fact that type 1 diabetes is not 100% concordant among identical twins indicates that genetic factors are not solely responsible for the disorder. There is good evidence that specific viral infections contribute to the causation of type 1 diabetes in at least some individuals, possibly by activating an autoimmune response.

The association of specific HLA class II alleles (see Chapter 22) and type 1 diabetes has been studied extensively, and it is estimated that the HLA system accounts for about 40% of the familial clustering of type 1 diabetes. Approximately 95% of whites with type 1 diabetes have the HLA DR3 and/or DR4 alleles, whereas only about 50% of the general white population has either of these alleles. If an affected proband and a sibling are heterozygous for the DR3 and DR4 alleles, the sibling's risk of developing type 1 diabetes is nearly 20% (i.e., about 40 times higher than the risk in the general population). In addition, the presence of aspartic acid at position 57 of the DQ chain is strongly associated with resistance to type 1 diabetes. In fact, those who do not have this amino acid at position 57 (and instead are homozygous for a different amino acid) are 100 times more likely to develop type 1 diabetes. The aspartic acid substitution alters the shape of the HLA class II molecule and thus its ability to bind and present peptides to T cells. Altered T-cell recognition may help protect individuals with the aspartic acid substitution from an autoimmune episode.

The insulin gene, which is located on the short arm of chromosome 11, is another logical candidate for type 1 diabetes susceptibility. Polymorphisms within and near this gene have been tested for association with type 1 diabetes. It is estimated that inherited genetic variation in the insulin region accounts for approximately 10% of the familial clustering of type 1 diabetes.

Within the past several years, additional genes have been shown to be associated with susceptibility to type 1 diabetes. The most significant of these are cytotoxic lymphocyte associated-4 *(CTLA4),* which encodes a protein involved in the regulation of T-cell proliferation, and *PTPN22,* which encodes a lymphoid-specific tyrosine phosphatase that negatively regulates T-cell activation. It is interesting that variation in the latter gene has been associated with several other autoimmune diseases, including systemic lupus erythematosus (SLE), rheumatoid arthritis, and autoimmune thyroid disease.

Type 2 Diabetes. Type 2 diabetes accounts for more than 90% of all diabetes cases and affects 10% to 20% of the adult populations of many developed countries. A number of features distinguish it from type 1 diabetes. There is nearly always some endogenous insulin production in people with type 2 diabetes, and the disease can often be treated successfully with dietary modification and/or oral drugs. People with type 2 diabetes suffer from insulin resistance (i.e., their cells have difficulty in using insulin). This disease typically occurs among people older than age 40 and, in contrast to type 1 diabetes, is seen more commonly among the obese. The incidence of type 2 diabetes is rising dramatically among adolescents and young adults in developed countries, however, and is strongly correlated with an increased incidence of obesity. Neither HLA associations nor autoantibodies are seen commonly in this form of diabetes. Monozygotic twin concordance rates are substantially higher than those seen in type 1 diabetes, often exceeding 90% (because of age dependence, the concordance rate increases if older subjects are studied). The empirical recurrence risks for first-degree relatives of type 2 diabetes cases are higher than those for type 1, generally ranging from 15% to 40%. The differences between type 1 and type 2 diabetes are summarized in Table 5-7.

TABLE 5-7 COMPARISON OF MAJOR FEATURES OF TYPES 1 AND 2 DIABETES

FEATURE	TYPE 1 DIABETES	TYPE 2 DIABETES
Age of onset	Usually <40 yr	Usually >40 yr (except maturity-onset diabetes of the young [MODY])
Insulin production	None	Partial
Insulin resistance	No	Yes
Autoimmunity	Yes	No
Obesity	Not common	Common
Monozygotic (MZ) twin concordance	0.55	0.90
Sibling recurrence risk	1-6%	10-15%

Hundreds of studies have been undertaken to identify genes that may contribute to type 2 diabetes susceptibility. The most significant gene identified thus far is *TCF7L2,* which encodes a transcription factor involved in the secretion of insulin. A variant of *TCF7L2* is associated with a 50% increased risk of developing type 2 diabetes. A significant association has also been observed between type 2 diabetes and a common allele of the gene that encodes peroxisome proliferator–activated receptor-gamma (PPAR-γ), a transcription factor that is involved in adipocyte differentiation and glucose metabolism. Although this allele confers only a 25% increase in the risk of developing type 2 diabetes, it is found in more than 75% of individuals of European descent and thus helps to account for a significant proportion of type 2 diabetes cases. Variation in *KCNJ11,* which encodes a potassium channel necessary for glucose-stimulated insulin secretion, confers an additional 20% increase in type 2 diabetes susceptibility. The associations between diabetes susceptibility and each of these genes have been widely replicated in multiple populations.

The two most important risk factors for type 2 diabetes are positive family history and obesity; the latter increases insulin resistance. The disease tends to rise in prevalence when populations adopt a diet and exercise pattern typical of U.S. and European populations. Increases have been seen, for example, among Japanese immigrants to the United States and among some native populations of the South Pacific, Australia, and the Americas. Several studies, conducted on male and female subjects, have shown that regular exercise can substantially lower

one's risk of developing type 2 diabetes, even among individuals with a family history of the disease. This is partly because exercise reduces obesity. However, even in the absence of weight loss, exercise increases insulin sensitivity and improves glucose tolerance.

Because of the dramatic increase in obesity in the United States and other developed countries, the prevalence of type 2 diabetes is also rising rapidly, and the average age of onset is decreasing. A small proportion of type 2 diabetes cases occurs early in life, typically before 25 years of age, and typically exhibits autosomal dominant inheritance (unlike most type 2 diabetes cases). This subset is termed *maturity-onset diabetes of the young* (MODY). Studies of MODY pedigrees have shown that about half of cases of the disease are caused by mutations in the glucokinase gene. Glucokinase converts glucose to glucose-6-phosphate in the pancreas. In addition to the glucokinase gene, five other genes, all of which are involved in pancreatic development or regulation of insulin levels, have now been shown to be causes of MODY.

Obesity

Obesity is most commonly defined as a body mass index (BMI) greater than 30.* Using this criterion, approximately one third of American adults are obese, and an additional one third are overweight (BMI greater than 25 but less than 30). The proportion of obese adults and children continues to increase rapidly. Although obesity itself is not a "disease," it is an important risk factor for several common diseases, including heart disease, stroke, hypertension, and type 2 diabetes.

As one might expect, there is a strong correlation between obesity in parents and their children. This could easily be ascribed to common environmental effects: parents and children usually share similar dietary and exercise habits. However, there is good evidence for genetic components as well. Four adoption studies each showed that the body weights of adopted individuals correlated significantly with their natural parents' body weights but not with those of their adoptive parents. Twin studies also provide evidence for a genetic effect on body weight, with most studies yielding heritability estimates between 0.60 and 0.80.

Research, aided substantially by mouse models, has shown that several genes each play a role in human obesity. Important among these are the genes that encode leptin (Greek, "thin") and its receptor. The leptin hormone is secreted by adipocytes (fat storage cells) and binds to receptors in the hypothalamus, the site of the body's appetite control center. Cloning of the human leptin gene and its receptor led to optimistic predictions that leptin could be a key to weight loss in humans (without the perceived unpleasantness of dieting and exercise). Although mutations in the human leptin gene and its receptor have been identified in a few humans with severe obesity (BMI >40), they both appear to be extremely rare. Clinical trials using recombinant leptin have demonstrated moderate weight loss in a subset of obese individuals. In addition, leptin participates in important interactions with other components of appetite control, such as neuropeptide Y and α-melanocyte-stimulating hormone and its receptor, the melanocortin-4 receptor (MC4R). Mutations in the gene that encodes MC4R have been found in 3% to 5% of severely obese individuals. Recently, homozygosity for a DNA variant in the *FTO* gene (which is seen in 16% of whites) has been associated with 40% and 70% increases in the risks of overweight and obesity, respectively. Identification of these human genes is leading to a better understanding of natural weight control in the human, and it could eventually lead to effective treatments for some cases of obesity.

Alzheimer Disease

Alzheimer disease (AD), which is responsible for 60% to 70% of cases of progressive cognitive impairment among older adults, affects approximately 5% to 10% of the population older than 65 years of age and 40% of the population older than 85 years of age. Because of the aging of the population, the number of Americans with AD is predicted to increase substantially during the coming decade. AD is characterized by progressive dementia and memory loss and by the formation of amyloid plaques and neurofibrillary tangles in the brain, particularly in the cerebral cortex and hippocampus. The plaques and tangles lead to progressive neuronal loss, and death usually occurs within 7 to 10 years after the first appearance of symptoms.

The risk of developing AD doubles in individuals who have an affected first-degree relative. Although most cases do not appear to be caused by single loci, approximately 10% follow an autosomal dominant mode of transmission. About 3% to 5% of AD cases occur before age 65 and are considered early onset; these are much more likely to be inherited in autosomal dominant fashion.[23]

AD is a genetically heterogeneous disorder. Approximately half of early-onset cases can be attributed to mutations in any of three genes, all of which affect amyloid-β deposition.[24] Two of the genes, presenilin 1 *(PS1)* and presenilin 2 *(PS2)*, are very similar to one another, and their protein products are involved in cleavage of the amyloid-β precursor protein (APP). When APP is not cleaved normally, a long form of it accumulates excessively and is deposited in the brain. This is thought to be a primary cause of AD. Mutations in *PS1* typically result in especially early onset of AD, with the first occurrence of symptoms in the fifth decade of life.

A small number of cases of early-onset AD are caused by mutations of the gene that encodes APP itself, which is located on chromosome 21. These mutations disrupt normal cleavage sites in APP, again leading to the accumulation of the longer protein product. It is interesting that this gene is present in three copies in trisomy 21 individuals, in which the extra gene copy leads to amyloid deposition and the occurrence of AD in those with Down syndrome (see Chapter 4).

An important risk factor for the more common late-onset form of AD is allelic variation in the apolipoprotein E *(APOE)* locus, which has three major alleles: *ε2, ε3,* and *ε4.* Studies conducted in diverse populations have shown that persons who

*BMI is defined as W/H^2, in which W is weight in kilograms and H is height in meters.

have one copy of the ε4 allele are at least 2 to 5 times more likely to develop AD, whereas those with two copies of this allele are at least 5 to 10 times more likely to develop AD. The risk varies somewhat by population, with higher ε4-associated risks in Europeans and Japanese and relatively lower risks in Hispanics and blacks. Despite the strong association between ε4 and AD, approximately half of individuals who develop late-onset AD do not have a copy of the ε4 allele, and many who are homozygous for ε4 remain free of AD even at advanced age. The apolipoprotein E protein product is not involved in cleavage of APP but instead appears to be associated with clearance of amyloid from the brain.

Alcoholism

At some point, alcoholism is diagnosed in approximately 10% of adult males and 3% to 5% of adult females in the United States. The national cost of alcoholism, in terms of lost productivity and direct medical costs, is approximately $200 billion per year. More than 100 studies have shown that this disease clusters in families.[25] The risk of developing alcoholism among individuals with one affected parent is three to five times higher than for those with unaffected parents.

Most twin studies have yielded concordance rates for DZ twins less than 30% and concordance rates for MZ twins in excess of 60%. Adoption studies have shown that the offspring of an alcoholic parent, even when raised by nonalcoholic parents, have a fourfold increased risk of developing the disorder. To control for possible prenatal effects in an alcoholic mother, some studies have included only the offspring of alcoholic fathers. The results have remained the same. One study showed that the offspring of nonalcoholic parents, when reared by alcoholics, did *not* have an increased risk of developing alcoholism. These data argue that there may be genes that predispose some people to alcoholism.

It has long been known that an individual's physiologic response to alcohol can be influenced by variation in the key enzymes responsible for alcohol metabolism: alcohol dehydrogenases (ADHs), which convert ethanol to acetaldehyde; and aldehyde dehydrogenases (ALDHs), which convert acetaldehyde to acetate. In particular, an allele of the *ALDH2* gene *(ALDH2*2)* results in excessive accumulation of acetaldehyde and thus in facial flushing, nausea, palpitations, and lightheadedness. Because of these unpleasant effects, individuals who have the *ALDH2*2* allele are much less likely to become alcoholics. This "protective" allele is common in some Asian populations but is rare in other populations.

A number of other genes are associated with susceptibility to alcohol addiction, including genes that encode components of gamma-aminobutyric acid (GABA) receptors. This finding is biologically plausible, because the GABA neurotransmitter system inhibits excitatory signals in neurons, exerting a calming effect. Alcohol has been shown to increase GABA release, and allelic variation in GABA receptor genes may modulate this effect.

It should be underscored that genes may increase one's *susceptibility* to alcoholism. Obviously this is a disease that requires an environmental component, regardless of genetic constitution.

TABLE 5-8 RECURRENCE RISKS FOR RELATIVES OF SCHIZOPHRENIC PROBANDS

RELATIONSHIP TO PROBAND	RECURRENCE RISK (%)
Monozygotic twin	44.3
Dizygotic twin	12.1
Offspring	9.4
Sibling	7.3
Niece/nephew	2.7
Grandchild	2.8
First cousin	1.6
Spouse	1

Figures are based on multiple studies of Western European populations.

Psychiatric Disorders

The major psychiatric diseases, schizophrenia and affective disorder, have been the subjects of numerous genetic studies.[26] Twin, adoption, and family studies have shown that both disorders aggregate in families.

Schizophrenia. *Schizophrenia* is a severe emotional disorder characterized by delusions, hallucinations, retreat from reality, and bizarre, withdrawn, or inappropriate behavior. (Contrary to popular belief, schizophrenia is not a "split personality" disorder.) The lifetime recurrence risk for schizophrenia among the offspring of one affected parent is approximately 8% to 10%, which is about 10 times higher than the risk in the general population.[27] As one might expect, the empirical risks increase when more relatives are affected. For example, an individual with an affected sibling and an affected parent has a risk of about 17%, and an individual with two affected parents has a risk of 46%. The risks decrease when the affected family member is a second- or third-degree relative. Details are given in Table 5-8. On inspection of Table 5-8, it may seem puzzling that the proportion of schizophrenic probands who have a schizophrenic parent is only about 5%, which is substantially lower than the risk for other first-degree relatives (e.g., siblings, affected parents and their offspring). This can be explained by the fact that people with schizophrenia are less likely to marry and produce children than are other individuals. Thus substantial selection against schizophrenia occurs in the population.

Twin and adoption studies also indicate that genetic factors are likely to be involved in schizophrenia. Data pooled from five different twin studies show a 47% concordance rate for MZ twins, compared with a concordance rate of only 12% for DZ twins. When the offspring of a schizophrenic parent are adopted by normal parents, their risk of developing the disease is about 10%, which is approximately the same as the risk when raised by a schizophrenic biologic parent. Recent studies have identified promising associations between schizophrenia and several

brain-expressed genes whose products interact with glutamate receptors. These include dysbindin (*DTNBP1;* chromosome 6p), neuregulin 1 (*NRG1;* chromosome 8p), and D-amino acid oxidase activator (*G30;* chromosome 13q). Another susceptibility gene is *DISC1* (Disrupted-in-Schizophrenia-1), which was originally identified by its consistent translocation in affected members of a large schizophrenia pedigree. Each of these associations has been replicated in multiple populations. However, the precise mechanisms through which mutations in these genes contribute to schizophrenia susceptibility are not yet known.

Bipolar Disorder. *Bipolar disorder,* also known as *manic-depressive disorder,* is a form of psychosis with extreme mood swings and emotional instability. The incidence of the disorder in the general population is approximately 0.5%, but it rises to 5% to 10% among those with an affected first-degree relative. A study using the Danish twin registry yielded concordance rates of 79% and 24% for MZ and DZ twins, respectively.[28] The corresponding concordance rates for unipolar disorder (major depression) were 54% and 19%. In general, it appears that bipolar disorder is more strongly influenced by genetic factors than is unipolar disorder.

As with schizophrenia, many large-scale studies have been undertaken to identify genes associated with susceptibility to bipolar disorder. Some of these loci were identified because their products are involved in neurotransmitter systems that are targets of drugs used to treat the disease (e.g., the serotonin, dopamine, and noradrenaline systems). Examples of these genes include those that encode monoamine oxidase A (MAOA), the serotonin transporter (5HTT), and catechol-*O*-methyltransferase (COMT), a gene that has also been associated with schizophrenia susceptibility. In addition, the *NRG1* and *DISC1* genes, which were discussed previously because of their association with schizophrenia, have been shown in some studies to be associated with susceptibility to bipolar disorder.

Comments on Psychiatric Disorders. Large-scale linkage studies involving hundreds of polymorphisms throughout the genome have been carried out for both schizophrenia and bipolar affective disorder. Most of these studies have produced negative results, although a few recent large-scale studies have yielded promising findings. A number of candidate genes have been tested for linkage or association with both diseases. Most of these candidates were chosen on the basis of the known involvement of certain neurotransmitters, receptors, or neurotransmitter-related enzymes in each disease (e.g., schizophrenia can be treated by drugs that block dopamine receptors, and bipolar affective disorder is sometimes treated with lithium). None of the candidate genes tested thus far, including those for sodium-lithium countertransport, various components of the dopaminergic system, and several neurotransmitter-related enzymes (e.g., monoamine oxidase, dopamine-β-hydroxylase, tyrosine hydroxylase), have been shown unequivocally to be linked or associated with either disease.

These results reflect some of the difficulties encountered in conducting genetic studies of psychiatric disorders. These disorders are undoubtedly heterogeneous, reflecting the influence of numerous genetic and environmental factors. Also, definition of the phenotype is not always straightforward and it may change through time, significantly complicating genetic analysis.

Other Complex Disorders

The disorders discussed in this chapter represent some of the most common multifactorial disorders and those for which significant progress has been made in identifying genes. Many other multifactorial disorders are being studied as well, and in some cases specific susceptibility genes have been identified. These include, for example, Parkinson disease, hearing loss, multiple sclerosis, amyotrophic lateral sclerosis, epilepsy, asthma, inflammatory bowel disease, and some forms of blindness.

Some General Principles and Conclusions

Some general principles can be deduced from the results obtained thus far on the genetics of complex disorders. First, the more strongly inherited forms of complex disorders generally have an earlier age of onset (e.g., breast cancer, AD, heart disease). Often these represent subsets of cases in which there is single-gene inheritance. Second, when laterality is a component, the bilateral forms are more likely to cluster strongly in families (e.g., breast cancer, CL/P). Third, although the sex-specific threshold model fits some of the complex disorders (e.g., pyloric stenosis, CL/P, autism, heart disease), it fails to fit others (e.g., type 1 diabetes).

A tendency exists, particularly among the lay public, to assume that the presence of a genetic component means that the course of a disease cannot be altered. *This is incorrect.* Most of the diseases discussed in this chapter have both genetic and environmental components. Thus lifestyle modification (e.g., diet, exercise, stress reduction) often can reduce risk significantly. Such modification may be especially important for individuals with a family history of a disease because they are likely to develop the disease earlier in life. Those with a family history of heart disease, for example, can often add many years of productive living with relatively minor lifestyle alterations. By targeting those who can benefit most from intervention, genetics helps to serve the goal of preventive medicine.

In addition, it should be stressed that the identification of a specific genetic lesion can lead to more effective prevention and treatment of the disease. Identification of mutations that cause autosomal dominant breast cancer may enable early screening and prevention of metastasis. Pinpointing a gene responsible for a neurotransmitter defect in a behavioral disorder such as schizophrenia could lead to the development of more effective drug treatments. In some cases, such as those with familial hypercholesterolemia, gene therapy may prove to be useful in treating the disease. It is important for healthcare practitioners to help individuals understand these facts.

Although the genetics of common disorders is complex and often confusing, the community health effect of these diseases, together with the evidence for hereditary factors in their etiology, demands that genetic studies be pursued. Substantial progress is already being made. The next decade will undoubtedly witness many further advances in the understanding and treatment of these disorders.

SUMMARY REVIEW

Factors Influencing Incidence of Disease in Populations

1. The incidence rate is the number of new cases of a disease reported during a specific period (typically 1 year) divided by the number of individuals in the population.
2. The prevalence rate is the proportion of the population affected by a disease at a specific point in time. This rate, and the incidence rate, can be used to compare population variations in disease frequency.
3. Relative risk is a common measure of the effect of a specific risk factor. It is expressed as a ratio of the incidence rate of the disease among individuals exposed to a risk factor divided by the incidence of the disease among individuals *not* exposed to a risk factor.
4. Many factors can influence the risk of acquiring a common disease, such as cancer, diabetes, or hypertension. The factors can include age, gender, diet, exercise, and family history of the disease.

Principles of Multifactorial Inheritance

1. Traits in which variation is thought to be caused by the combined effects of multiple genes are polygenic.
2. The term *multifactorial* is used when environmental factors also are believed to cause variation in the trait.
3. Many quantitative traits (e.g., blood pressure) are multifactorial.
4. Because traits are caused by the additive effects of many genetic and environmental factors, they tend to follow a normal or bell-shaped distribution in populations.
5. Those diseases, however, that do not follow a bell-shaped distribution appear to be either present or absent in individuals. They do not follow the inheritance patterns of single-gene disease. Instead, such diseases may follow an underlying liability distribution. It is thought that a threshold of liability must be crossed before the disease is expressed.
6. Examples of diseases that correspond to the liability model include pyloric stenosis, neural tube defects, CL/P, and some forms of congenital heart disease.
7. Many of the common adult diseases, such as hypertension, coronary heart disease, stroke, diabetes mellitus (types 1 and 2), and some cancers, are caused by complex genetic and environmental factors and are thus multifactorial diseases.
8. For most multifactorial diseases, empirical risks (risks based on direct observation of data) have been derived.
9. In contrast to most single-gene diseases, recurrence risks for multifactorial diseases can change significantly from one population to another because gene frequencies, as well as environmental factors, can differ among populations.
10. Several criteria are used to define multifactorial inheritance: (a) the recurrence risk becomes higher if more than one family member is affected; (b) if the expression of the disease in a proband is more severe, the recurrence risk is higher; (c) the recurrence risk is higher if the proband is of the less commonly affected sex; (d) the recurrence risk for the disease usually decreases rapidly in more remotely related relatives; and (e) if the prevalence of the disease in a population is *f*, the risk for offspring and siblings of probands is approximately $\sqrt{f}$.

Nature and Nurture: Disentangling the Effects of Genes and Environment

1. Family members share genes and a common environment; therefore, resemblance in traits, such as high blood pressure, reflects both genetic and environmental factors (nature and nurture, respectively).
2. Few traits are influenced *only* by genes or *only* by environment. Most are influenced by both.
3. When a disease has a relatively larger genetic component, as in breast cancer, examination of family history should be emphasized in addition to lifestyle modification.
4. Two research strategies often are used to estimate the relative influence of genes and environment-lifestyle: twin studies and adoption studies.
5. Monozygotic twins originate when the developing embryo divides to form two separate but identical embryos.
6. Dizygotic twins are the result of a double ovulation followed by the fertilization of each egg by a different sperm.
7. If both members of a twin pair share a trait, they are said to be *concordant.* If they do not share the same trait, they are *discordant.*
8. Studies of adopted children also are used to estimate the genetic contribution to a multifactorial trait.
9. A genetic predisposition may interact with an environmental-lifestyle factor to increase the risk of disease; this is called a *gene-environment interaction.*

Genetics of Common Diseases

1. Congenital diseases are those present at birth. Most of these diseases are multifactorial in etiology.
2. Multifactorial diseases in adults include coronary heart disease, hypertension, breast cancer, colon cancer, diabetes mellitus, obesity, AD, alcoholism, schizophrenia, and bipolar affective disorder.
3. It is incorrect to assume that the presence of a genetic component means that the course of a disease cannot be altered—most diseases have *both* genetic and environmental aspects.

- Review Questions and Answers

CHAPTER OUTLINE

The traditional focus of human genetics has been on the ways in which alterations of DNA sequences can lead to disease (Chapter 4). In some cases, diseases and other phenotypic variation are caused by mechanisms *other* than changes in the DNA sequences—termed epigenetics ("upon genetics").[1] **Epigenetics** is the study of heritable changes in gene expression or phenotype caused by mechanisms other than changes in DNA sequences. Epigenetic modifications can cause individuals with the same DNA sequences (such as identical twins) to have different disease profiles. There are three major types of epigenetic modifications (Figure 6-1):

1. **DNA methylation:** The attachment of a methyl group to a cytosine base is followed by a guanine base (a "CpG dinucleotide") (Figures 6-1 and 6-2).[2] DNA methylation causes a gene to become transcriptionally inactive or silent.[3] When the DNA sequence in the promoter region of a gene becomes heavily methylated, the DNA is less likely to be transcribed into mRNA. Methylation along with histone hypoacetylation (the acetyl group consists of a methyl group single-bonded to a carbonyl) and condensation of chromatin together inhibit the binding of transcription-binding factors (see Chapter 4) that regulate transcription. In other words, the gene becomes transcriptionally inactive. Aberrant methylation can lead to silencing of tumor-suppressor genes in the development of cancer (see Chapter 12 and Figure 6-1). DNA methylation is a key component of X-inactivation, the transcriptional silencing of genes on the X chromosome, discussed in Chapter 4. As with X-inactivation, epigenetic modifications are maintained in successive mitotic cell divisions, but most are erased from the genome when new gametes (sperm or egg cells) are formed.
2. **Histone modification** (e.g., histone acetylation and deacetylation, alterations in chromatin): Chromatin compaction and organization help to regulate gene expression, determining and maintaining cell identity. Chromatin structure must

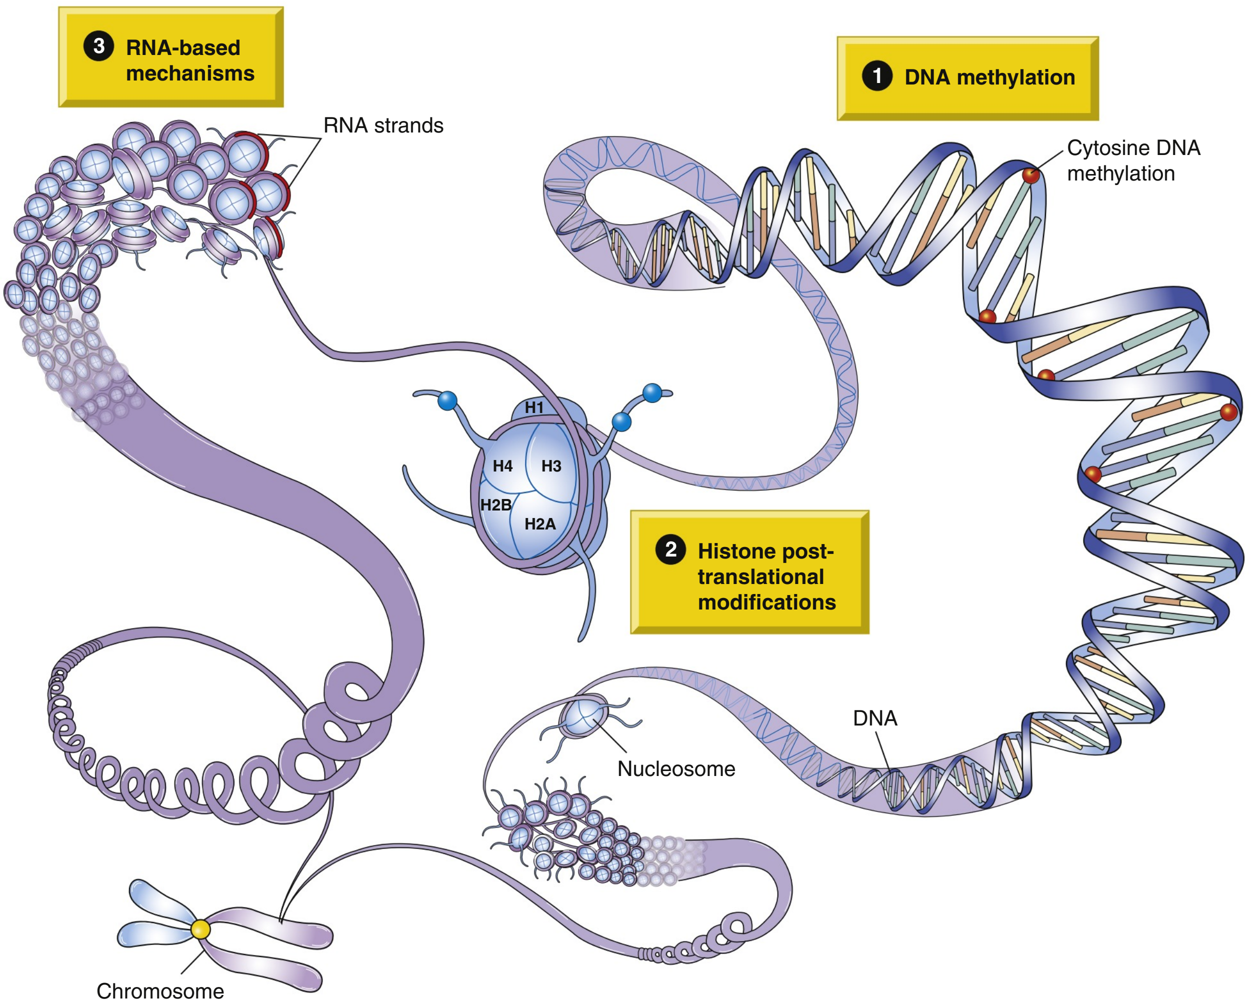

FIGURE 6-1 **Three Major Types of Epigenetic Processes.** Investigators are studying the following epigenetic mechanisms: **(1)** DNA methylation, **(2)** histone modifications, and **(3)** RNA based-mechanisms. See text for discussion.

be controlled in self-renewing and differentiated cells in cell renewal systems. For example, there are differences in chromatin structure in stem cells and terminally differentiated cells.[4]

3. **Micro-ribonucleic acids (miRNAs or miRs):** These RNAs are encoded by short DNA sequences (approximately 22 nucleotides) located in introns of genes or transcribed from noncoding DNA located between genes. Gene expression networks can be regulated by changes in miRNAs and other noncoding RNAs. **Noncoding RNAs (ncRNAs)** have been shown to regulate gene expression by novel mechanisms such as RNA interference, gene cosuppression, gene silencing, imprinting (see p. 187), and DNA demethylation. It is becoming clear that these novel RNAs perform critical functions during development and cell differentiation. MicroRNAs regulate diverse signaling pathways, and those that stimulate cancer development and progression are called **oncomirs.** For example, miRNAs have been linked to carcinogenesis because they can act as either oncogenes or tumor-suppressor genes (see Chapter 12).

EPIGENETICS AND DEVELOPMENT

Early in embryonic development, all cells of the embryo have the potential to become any type of cell in the fetus or adult. These **embryonic stem cells** are said to be pluripotent. A key event in early embryogenesis is the differential epigenetic modification (including extensive methylation) of specific DNA nucleotide sequences in these cells. This modification helps to determine the fate of each cell (i.e., the type of cell it becomes, such as a myocyte, neuron, or fibroblast) by helping to ensure that specific genes are expressed only in the cells and tissue types in which their gene products are needed (e.g., factor VIII expression primarily in hepatocytes, or dopamine receptor expression in neurons). Thus, even though nearly all cells have the same DNA sequence, the transcriptional activity of most genes varies substantially and depends on cell and tissue type. A small percentage of genes, termed **housekeeping genes,** are necessary for the function and maintenance of all cells. These genes escape the methylation process and remain transcriptionally active in all cells.

Much remains to be learned about factors that cause epigenetic modifications. Findings so far indicate that specific

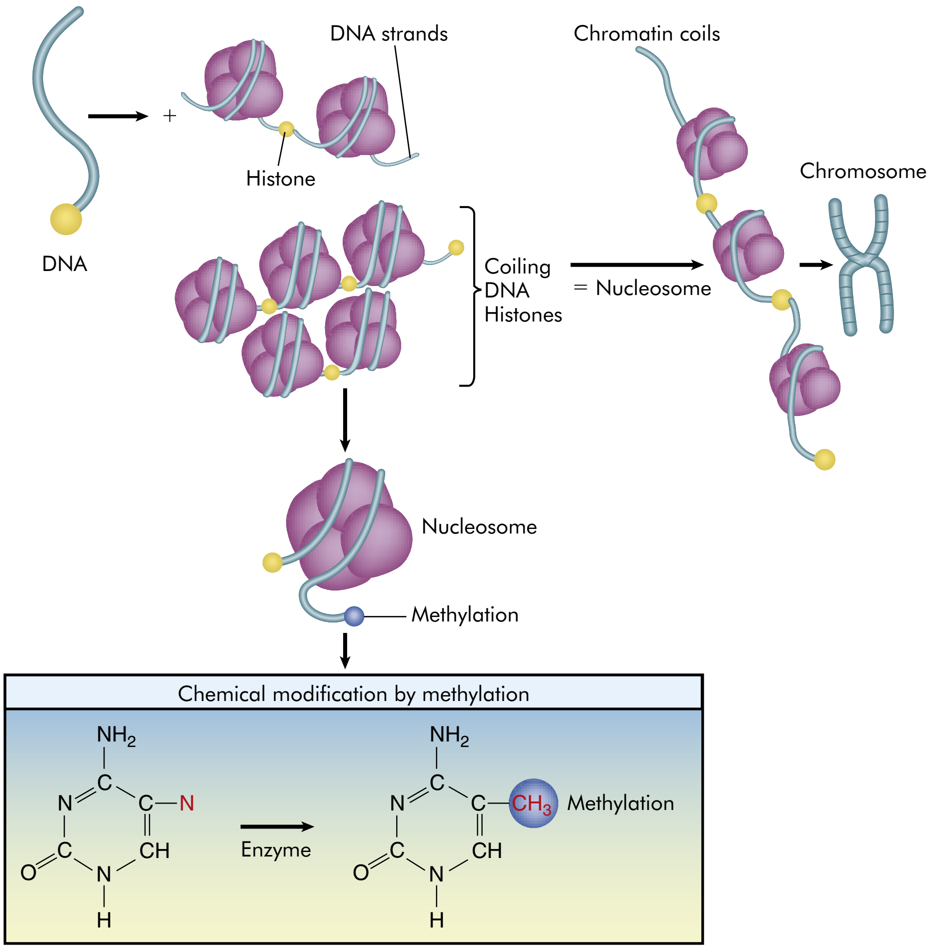

FIGURE 6-2 **Epigenetic Modifications.** Because DNA is a long molecule, it needs packaging to fit in the tiny nucleus. Packaging involves *coiling* of the DNA in a "left-handed" spiral around spools, made of four pairs of proteins individually known as histones and collectively as the histone octamer. The entire spool is called a nucleosome (also see Figure 1-2). Nucleosomes are organized into chromatin, the repeating building blocks of a chromosome. Histone modifications are correlated with methylation, are reversible, and occur at multiple sites. Methylation occurs at the 5 position of cytosine and provides a "footprint" or signature as a unique epigenetic alteration *(red)*. When genes are expressed, chromatin is open or active; however, when chromatin is condensed because of methylation and histone modification, genes are inactivated.

environmental or nongenetic factors, such as diet and exposure to certain chemicals, can drive such modifications. For example, alcohol has been shown to affect methylation patterns in animal models,[5] so the harmful effects of fetal alcohol exposure may be mediated through epigenetic mechanisms. Maternal dietary deficiency during pregnancy may cause epigenetic modifications of fetal genes, leading to an increased risk of obesity and diabetes in the offspring later in life.[6] In some animal models, the insulin-like growth factor 2 gene *(IGF2)* is a target of these epigenetic modifications. Although the observed changes in methylation status of CpG sequences in these genes are typically small, it is possible that they affect phenotypic development. The hereditary transmission of epigenetic changes to successive generations has been termed **epigenetic transgenerational inheritance.** If demonstrated to occur in humans, transgenerational inheritance could have important implications for disease and disease prevention.

Twin Studies Provide Insights on Epigenetic Modification

A powerful means to test for epigenetic effects is to compare methylation and other signatures of epigenetic modification in identical (monozygotic) twin pairs, whose DNA sequences are essentially the same. As twins age, they demonstrate increasing differences in methylation patterns of the DNA sequences of their somatic cells; these changes are reflected in increasing numbers of phenotypic differences.[7] Twins with significant lifestyle differences (e.g., smoking vs. nonsmoking) accumulated larger numbers of differences in their methylation patterns. The twins, despite having identical DNA sequences, become more and more different as a result of epigenetic changes, which in turn affect the expression of genes. These results, along with findings generated in animal studies, suggest that changes in epigenetic patterns may be an important part of the aging process.[8]

EPIGENETICS AND CANCER

DNA Methylation and Cancer

The best evidence for epigenetic effects on disease risk comes from studies of human cancer (Figure 6-3).[9,10] Tumor cells typically exhibit hypomethylation (decreased methylation), which can increase the activity of oncogenes (see Chapter 12). Hypomethylation increases as tumors progress from benign neoplasms to malignancy. In addition, the promoter regions of tumor-suppressor genes are often hypermethylated, which decreases their rate of transcription and their ability to inhibit tumor formation. Hypermethylation of the promoter region of the *RB1* gene is often seen in retinoblastoma,[11] and hypermethylation of the *BRCA1* gene is seen in some cases of inherited breast cancer.[12] Similarly, von Hippel-Lindau disease, in which renal cell carcinomas frequently occur, can be caused by hypermethylation of the *VHL* promoter region.

A major cause of one form of inherited colon cancer (hereditary nonpolyposis colorectal cancer [HNPCC]) is the methylation of the promoter region of a gene, *MLH1,* whose protein product repairs damaged DNA. When *MLH1* becomes inactive, damaged DNA accumulates, eventually resulting in colon tumors[13,14] (see Figure 41-28).

miRNAs and Cancer

Hypermethylation also is seen in miRNA genes, which encode small (22 base pair) RNA molecules that bind to the ends of mRNAs, degrading them and preventing their translation. More than 1000 miRNA sequences have been identified in humans, and hypermethylation of specific subgroups of miRNAs is associated with tumorigenesis. When miRNA genes are methylated, their mRNA targets are over-expressed, and this over-expression has been associated with metastasis.[9]

Strategies for Treating Epigenetic Disease

Unlike DNA sequence mutations, which cannot be directly altered, epigenetic modifications can be reversed. For example, 5-azacytidine, a demethylating agent, has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome. Another class of drugs, histone deacetylase (HDAC) inhibitors, counteracts the removal of acetyl groups from histone proteins, which can silence the activity of tumor-suppressor genes. HDAC inhibitors have been used in the treatment of T-cell lymphomas. A major challenge in developing drugs that modify epigenetic alterations is to target only the genes responsible for a specific cancer.

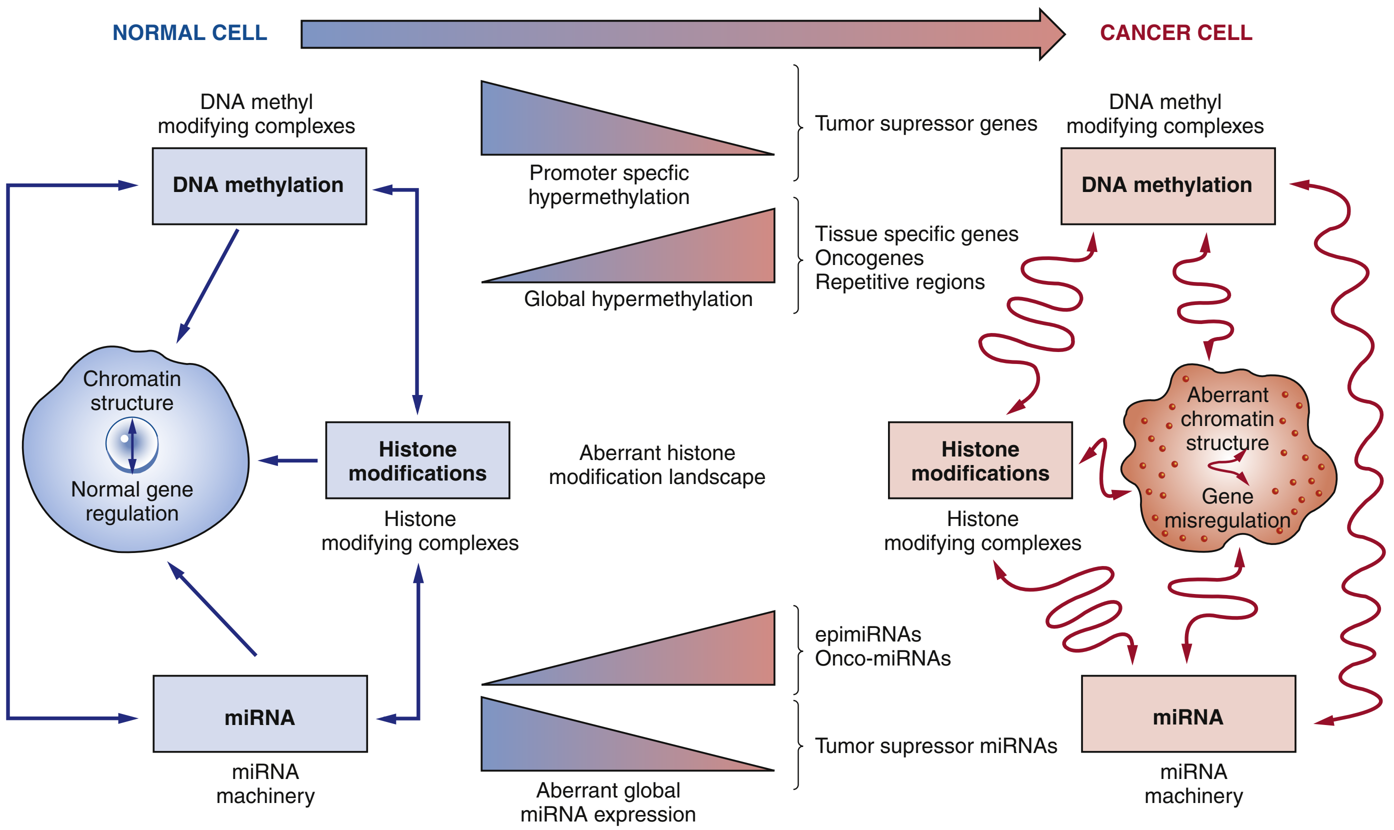

FIGURE 6-3 **Global Epigenomic Alterations and Cancer.** Oncogenesis involves accumulated genetic alterations combined with the epigenetic changes: DNA methylation, histone modifications, and miRNAs. In cancer cells, tumor-suppressor genes become hypermethylated and with histone modifications cause abnormal gene silencing. The gene silencing of tumor-suppressor genes results in tumor progression. Global hypomethylation leads to chromosomal instability and fragility. Additionally, these modifications create abnormal mRNA and miRNA expression, which leads to activation of oncogenes and silencing of tumor-suppressor genes. (Adapted from Sandoval J, Esteller M: *Curr Opin Genet Dev* 22:50–55, 2012.)

GENOMIC IMPRINTING

Gregor Mendel's nineteenth century experiments with garden peas indicated that the phenotype is typically the same whether a given allele is inherited from the mother or the father. It is now clear that this principle, which has long been part of the central dogma of genetics, does not always hold. For some human genes, the gene is transcriptionally active on only one copy of a chromosome (e.g., the copy inherited from the father). On the other copy of the chromosome (in this example, the one inherited from the mother), the gene is transcriptionally inactive. This process of gene silencing, in which genes are predictably silenced depending on which parent transmits them, is known as *imprinting,* and the transcriptionally silenced genes are then said to be "imprinted." Approximately 100 human genes are thought to be imprinted. Imprinted genes are usually heavily methylated (in contrast to the nonimprinted copy of the allele, which is typically not methylated). Next we describe some important human diseases that can be caused by abnormal imprinting patterns.

Prader-Willi and Angelman Syndromes

A well-known disease example of imprinting is associated with a deletion of about 4 million base pairs (Mb) of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests **Prader-Willi syndrome,** whose features include short stature, hypotonia, small hands and feet, obesity, mild to moderate mental retardation, and hypogonadism (Figure 6-4, *A*).[15] The same 4-Mb deletion, when inherited from the mother, causes **Angelman syndrome,** which is characterized by severe mental retardation, seizures, and an ataxic gait (Figure 6-4, *B*).[16] These diseases are each seen in about 1 of every 15,000 live births, and chromosome deletions are responsible for about 70% of cases of both diseases. The deletions that cause Prader-Willi and Angelman syndromes are indistinguishable at the DNA sequence level and affect the same group of genes.

For several decades, it was unclear how the same deletion could produce such disparate results in different persons. Further analysis showed that the 4-Mb deletion (the *critical region*) contains several genes that are normally transcribed only on the copy of chromosome 15 that is inherited from the father.[17] These genes are transcriptionally inactive (imprinted) on the copy of chromosome 15 inherited from the mother. Similarly, other genes in the critical region are transcriptionally active only on the chromosome copy inherited from the mother and are inactive on the chromosome inherited from the father. Thus, several genes in this region are normally active on only one chromosome copy (Figure 6-5). If the single active copy of one of these genes is lost because of a chromosome deletion, then no gene product is produced at all, resulting in disease.

Molecular analysis has revealed much about genes in this critical region of chromosome 15.[17,18] The gene responsible for Angelman syndrome encodes a ligase involved in protein

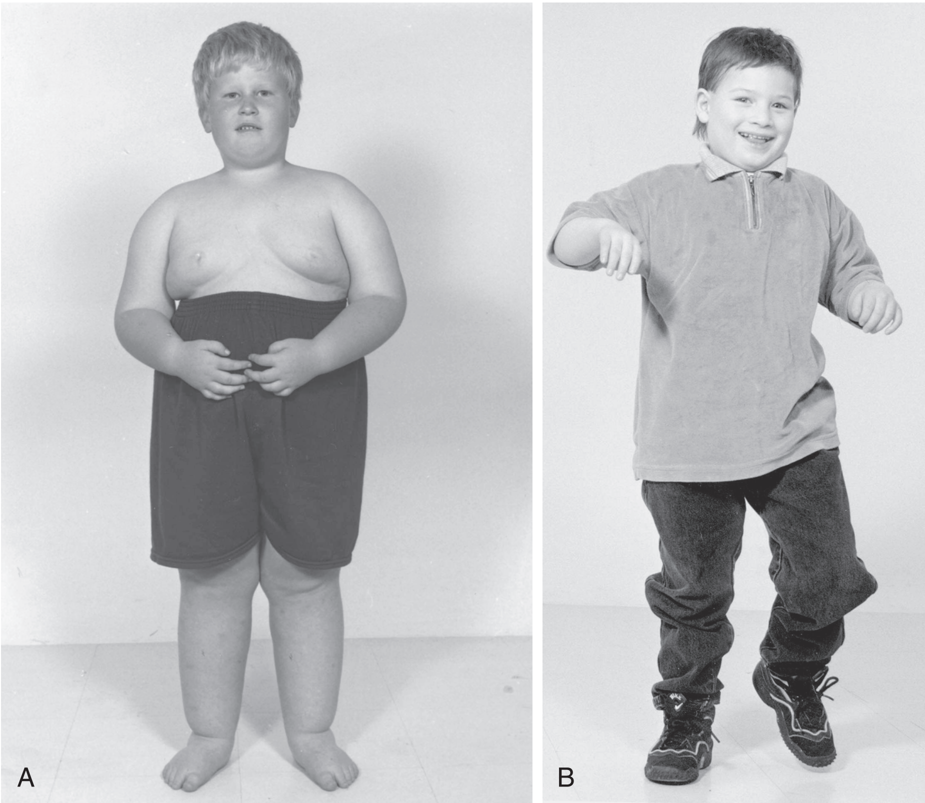

FIGURE 6-4 Prader-Willi and Angelman Syndromes. **A,** A child with Prader-Willi syndrome (truncal obesity, small hands and feet, inverted V-shaped upper lip). **B,** A child with Angelman syndrome (characteristic posture, ataxic gait, bouts of uncontrolled laughter). (From Jorde LB, Carey JC, Bamshad MJ: *Medical genetics*, ed 4, Philadelphia, 2010, Mosby.)

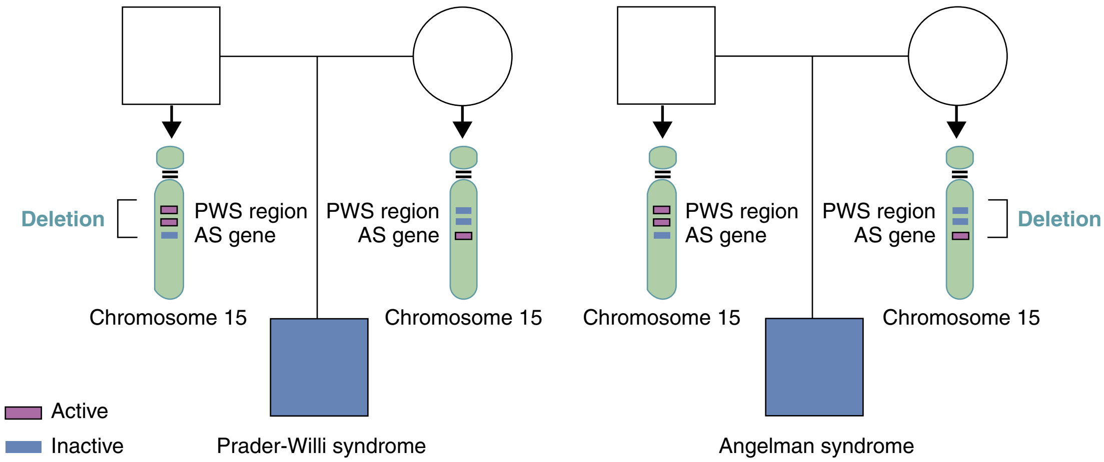

FIGURE 6-5 Prader-Willi Syndrome and Angelman Syndrome Pedigrees. These pedigrees illustrate the inheritance patterns of Prader-Willi syndrome, which can be caused by a 4-Mb deletion of chromosome 15q when inherited from the father. In contrast, Angelman syndrome can be caused by the same deletion but only when it is inherited from the mother. The reason for this difference is that different genes in this region are normally imprinted (inactivated) in the copies of 15q transmitted by the mother and the father. (From Jorde LB, Carey JC, Bamshad MJ: *Medical genetics*, ed 4, Philadelphia, 2010, Mosby.)

degradation during brain development (consistent with the mental retardation and ataxia observed in this disorder). In brain tissue, this gene is active only on the chromosome copy inherited from the mother. Consequently, a maternally transmitted deletion removes the single active copy of this gene. Several genes in the critical region are associated with Prader-Willi syndrome, and they are transcribed only on the chromosome transmitted by the father. A paternally transmitted deletion removes the only active copies of these genes, producing the features of Prader-Willi syndrome.

Beckwith-Wiedemann Syndrome

Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer. **Beckwith-Wiedemann syndrome** is usually identifiable at birth because of large size for gestational age, neonatal hypoglycemia, a large tongue, creases on the earlobe, and omphalocele.[19] Children with Beckwith-Wiedemann syndrome have an increased risk of developing Wilms tumor or hepatoblastoma. Both of these tumors can be treated effectively if they are detected early, so screening at regular intervals is an important part of management. Some children with Beckwith-Wiedemann syndrome also develop asymmetric overgrowth of a limb or one side of the face or trunk (hemihyperplasia).

As with Angelman syndrome, a minority of Beckwith-Wiedemann syndrome cases (about 20% to 30%) are caused by the inheritance of two copies of a chromosome from the father and no copy of the chromosome from the mother (uniparental disomy, in this case affecting chromosome 11). Several genes on the short arm of chromosome 11 are imprinted on either the paternally or the maternally transmitted chromosome. These genes are found in two separate, differentially methylated regions (DMRs). In DMR1, the gene that encodes insulin-like growth factor 2 *(IGF2)* is inactive on the maternally transmitted chromosome but active on the paternally transmitted chromosome. Thus, a normal individual has only one active copy of *IGF2*. When two copies of the paternal chromosome are inherited (i.e., paternal uniparental disomy) or there is loss of imprinting on the maternal copy of *IGF2,* an active *IGF2* gene is present in double dose. This produces increased levels of insulin-like growth factor 2 during fetal development, contributing to the overgrowth features of Beckwith-Wiedemann syndrome. (Note that, in contrast to Prader-Willi and Angelman syndromes, which are produced by a missing gene product, Beckwith-Wiedemann syndrome is caused, in part, by overexpression of a gene product.)

Russell-Silver Syndrome

Russell-Silver syndrome is characterized by growth retardation, proportionate short stature, leg length discrepancy, and a small, triangular-shaped face. About one third of Russell-Silver syndrome cases are caused by imprinting abnormalities of chromosome 11p15.5 that lead to down-regulation of *IGF2* and therefore diminished growth. Another 10% of cases of Russell-Silver syndrome are caused by maternal uniparental disomy. Thus, while up-regulation, or extra copies, of active *IGF2* causes overgrowth in Beckwith-Wiedemann syndrome, down-regulation of *IGF2* causes the diminished growth seen in Russell-Silver syndrome.

FUTURE DIRECTIONS

Robust experimental observations are clarifying the roles of epigenetic states in determining cell fates and disease phenotypes. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed in other chapters) will likely elucidate possibilities for reversing the epigenetic abnormalities and preventing their establishment in utero.

SUMMARY REVIEW

Epigenetics and Development

1. Epigenetics bridges DNA information and function by modifying gene expression without any alteration in DNA sequence. These often heritable chemical modifications of DNA sequence are collectively termed epigenetics.
2. Investigators are studying three major types of epigenetic processes: (a) DNA methylation, which results from attachment of a methyl group to a cytosine base that is followed by a guanine base (a "CpG dinucleotide"); (b) histone modification, which includes histone acetylation and alterations in chromatin; and (c) micro-ribonucleic acids (miRNAs or miRs), short nucleotides derived from introns of protein coding genes or transcribed as independent genes from regions of the genome whose functions, if any, remain poorly understood. MiRNAs regulate diverse signaling pathways.
3. DNA methylation is, at present, the best-studied epigenetic process. When a gene becomes heavily methylated the DNA is less likely to be transcribed into mRNA.
4. Methylation, along with histone hypoacetylation and condensation of chromatin, inhibits the binding of proteins that promote transcription, such that the gene becomes transcriptionally inactive.
5. Environmental factors, such as diet and exposure to certain chemicals, may cause epigenetic modifications.
6. The heritable transmission to future generations of epigenetic modifications is called transgenerational inheritance.
7. As twins age, they demonstrate increasing differences in methylation patterns of their DNA sequences, causing increasing numbers of phenotypic differences.
8. In studies of twins with significant lifestyle differences (e.g., smoking vs. nonsmoking) large numbers of differences in their methylation patterns are observed to accrue over time.

Epigenetics and Cancer

1. The best evidence for epigenetic effects on disease risk comes from studies of human cancer.
2. Methylation densities decline as tumors progress, which can increase the activity of oncogenes, causing tumors to progress from benign neoplasms to malignancy. Additionally, the promoter regions of tumor-suppressor genes are often hypermethylated. These elevated methylation levels decrease their rate of transcription at these critical genes, thus reducing the ability to inhibit tumor formation.
3. Hypermethylation also is seen in miRNA genes and is associated with tumorigenesis.
4. Unlike DNA sequence mutations, epigenetic modifications can be reversed through pharmaceutical intervention. For example, 5-azacytidine, a demethylating agent, has been used as a therapeutic drug in the treatment of leukemia and myelodysplastic syndrome.

Genomic Imprinting

1. Gregor Mendel's experiments with garden peas demonstrated that the phenotype is the same whether a given allele is inherited from the mother or the father. This principle, which has long been part of the central dogma of genetics, does not always hold. For some human genes, a given gene is transcriptionally active on only one copy of a chromosome (e.g., the copy inherited from the father). On the other copy of the chromosome (the one inherited from the mother), the gene is transcriptionally inactive. This process of gene silencing, in which genes are silenced depending on which parent transmits them, is known as *imprinting,* and the transcriptionally silenced genes are said to be "imprinted."
2. When an allele is imprinted, it typically has heavy methylation. By contrast, the nonimprinted allele is typically not methylated.
3. A well-known disease example of imprinting is associated with a deletion of about 4 million base pairs (Mb) of the long arm of chromosome 15. When this deletion is inherited from the father, the child manifests Prader-Willi syndrome.
4. The same 4-Mb deletion, when inherited from the mother, causes Angelman syndrome.
5. Another well-known example of imprinting is Beckwith-Wiedemann syndrome, an overgrowth condition accompanied by an increased predisposition to cancer.
6. Although up-regulation, or extra copies, of active *IGF2* causes overgrowth in Beckwith-Wiedemann syndrome, down-regulation of *IGF2* causes the diminished growth seen in Russell-Silver syndrome.

Future Directions

1. Robust experimental observations are defining the roles of epigenetic states in shaping cell fates.
2. The well-documented involvement of epigenetic abnormalities in carcinogenesis and the mounting evidence for these epigenetic changes in other common diseases (discussed throughout the text) will likely elucidate new therapies with the possibilities of reversing the epigenetic abnormalities.

CHAPTER OUTLINE

People are exposed daily to an environment containing a large variety of toxic substances and potentially infectious and disease-causing microorganisms. Without an efficient system of protection most individuals would succumb to these hazards early in life. That system consists of multiple complementary and interdependent layers. An outer layer of specialized epithelium, including the skin and mucosal surfaces, is relatively resistant to most environmental hazards and resists infection with disease-causing microorganisms.[1] If the epithelial barrier is damaged, a highly efficient local and systemic response (**inflammation**) is mobilized to limit the extent of damage, protect against infection, and initiate repair of the damaged tissue. The natural epithelial barrier and inflammation confer innate resistance and protection, commonly referred to as **innate, native,** or **natural immunity.** Inflammation associated with infection usually initiates an adaptive process that results in a long-term and very effective immunity to the infecting microorganism, referred to as **adaptive, acquired,** or **specific immunity.** Adaptive immunity is relatively slow to develop but has memory and more rapidly targets and eradicates a second infection with a particular disease-causing microorganism.

The information presented in this chapter introduces the components and processes of innate immunity and sets the stage for Chapter 8, which discusses adaptive immunity. Although inflammation and adaptive immunity provide protection, either genetic or acquired aberrations in these processes

can lead to disease. Diminution of innate or adaptive immunity may lead to critically decreased resistance to infection. Excessive inflammation or adaptive immunity may lead to damage to normal tissue or organs. Both may result in severe and potentially fatal disease, examples of which are discussed in Chapter 9. Many microorganisms that cause disease have developed methods of bypassing our protective systems. These are discussed in Chapter 10. Each chapter is designed to render an overview and is not intended to be all-inclusive. Protective mechanisms consist of a very large number of soluble factors and cells and would require many more pages to discuss in adequate detail. Different classes or groups of molecules and cells will be discussed, but only a few examples will be described in detail. Some components directly participate in the protective response, whereas others are designed to limit the extent of the response.

HUMAN DEFENSE MECHANISMS

Innate immunity includes two lines of defense: natural barriers and inflammation (Table 7-1). **Natural barriers** are physical, mechanical, and biochemical barriers at the body's surfaces and are in place at birth to prevent damage by substances in the environment and thwart infection by pathogenic microorganisms. If the surface barriers are breached, the second line of defense, the **inflammatory response,** is activated to protect the body from further injury, prevent infection of the injured tissue, and promote healing. The inflammatory response is a rapid activation of biochemical and cellular processes that is relatively nonspecific, with similar responses being initiated against a wide variety of causes of tissue damage.

FIRST LINE OF DEFENSE: PHYSICAL, MECHANICAL, AND BIOCHEMICAL BARRIERS

Physical and Mechanical Barriers

The physical barriers that protect against damage and infection are composed of tightly associated epithelial cells including those of the skin and of the membranous sheets lining the gastrointestinal, genitourinary, and respiratory tracts (Figure 7-1). The mucosal epithelial cells are highly interconnected junctions that prohibit the passage of microorganisms into the underlying tissue.[2] The normal turnover of the cells in these sites as well as mechanisms for "washing" the surfaces may mechanically remove many infectious microorganisms and prevent their residence on the epithelial surfaces. For instance, the routine sloughing off and replacement of dead skin cells also removes adherent bacteria. Mechanical cleansing of the surfaces includes vomiting and urination. Goblet cells of the upper respiratory tract produce mucus that coats the epithelial surface and traps microorganisms that are removed by hairlike cilia that mechanically move the mucus upward to be expelled by coughing or sneezing. Additionally, the low temperature on the skin generally inhibits microorganisms, most of which prefer temperatures near 37° C for more efficient growth.

Biochemical Barriers

Epithelial surfaces also provide biochemical barriers by synthesizing and secreting substances meant to trap or destroy microorganisms. Mucus, perspiration (or sweat), saliva, tears, and earwax are all examples of biochemical secretions that can trap and kill potential disease-causing microorganisms. Sebaceous

TABLE 7-1 OVERVIEW OF HUMAN DEFENSES

	INNATE IMMUNITY		
CHARACTERISTICS	BARRIERS	INFLAMMATORY RESPONSE	ADAPTIVE (ACQUIRED) IMMUNITY
Level of defense	First line of defense against infection and tissue injury	Second line of defense; occurs as a response to tissue injury or infection	Third line of defense; initiated when innate immune system signals the cells of adaptive immunity
Timing of defense	Constant	Immediate response	Delay between primary exposure to antigen and maximum response; immediate against secondary exposure to antigen
Specificity	Broadly specific	Broadly specific	Response is very specific toward "antigen"
Cells	Epithelial cells	Mast cells, granulocytes (neutrophils, eosinophils, basophils), monocytes/macrophages, natural killer (NK) cells, platelets, endothelial cells	T lymphocytes, B lymphocytes, macrophages, dendritic cells
Memory	No memory involved	No memory involved	Specific immunologic memory by T and B lymphocytes
Peptides	Defensins, cathelicidins, collectins, lactoferrin, bacterial toxins	Complement, clotting factors, kinins	Antibodies, complement
Protection	Protection includes anatomic barriers (i.e., skin and mucous membranes), cells and secretory molecules or cytokines (e.g., lysozymes, low pH of stomach and urine), and ciliary activity	Protection includes vascular responses, cellular components (e.g., mast cells, neutrophils, macrophages), secretory molecules or cytokines, and activation of plasma protein systems	Protection includes activated T and B lymphocytes, cytokines, and antibodies

glands in the skin secrete antibacterial and antifungal fatty acids and lactic acid. Perspiration, tears, and saliva contain an enzyme (lysozyme) that attacks the cell walls of gram-positive bacteria. These glandular secretions result in an acidic skin surface (pH 3 to 5), which is an inhospitable environment for most bacteria.

Epithelial-Derived Chemicals

The epithelial surfaces of the body secrete a complex array of proteins that destroy potential pathogens. Epithelial cells secrete small-molecular-weight **antimicrobial peptides.**[3] These are generally positively charged polypeptides of approximately 15 to 95 amino acids and can be divided into two classes—cathelicidins and defensins—based on their 3-dimensional structures. Both classes are in very high local concentrations and are toxic to several bacteria, fungi, and viruses. **Cathelicidins** have a linear α-helical shape, and only one is currently known to function in humans. In contrast, about 50 different defensins have been identified thus far. All are triple-stranded β-sheet structures. **Defensin** molecules contain 3 intrachain disulfide bonds and can be further subdivided into α (at least 6 identified in humans) and β types (at least 10 identified, but perhaps up to 40 different molecules), depending on how the cysteine residues are connected during formation of the disulfide linkages.[4] The α-defensins often require activation by proteolytic enzymes, whereas the β-defensins are synthesized in active forms. Bacteria have cholesterol-free cell membranes, which may allow cathelicidins to insert into and disrupt their membranes. Given the similarity in their chemical charges, defensins may kill bacteria in the same way. These same chemicals also may contribute to other means of protection because they are also produced by monocytes, macrophages, and neutrophils, which are components of the inflammatory response. Cathelicidin is stored in neutrophils, mast cells, and a variety of epithelial cells. The α-defensins are particularly rich in the granules of neutrophils and may contribute to the killing of bacteria by those cells. They are also found in Paneth cells lining the small intestine, where they protect against a variety of disease-causing microorganisms. The β-defensins are found in a variety of epithelial cells lining the respiratory, urinary, and intestinal tracts, as well as in the skin. In addition to antibacterial properties, β-defensins may also help protect epithelial surfaces from human immunodeficiency virus (HIV) infection. Both classes of antimicrobial peptides also can activate cells of innate and adaptive immunity.

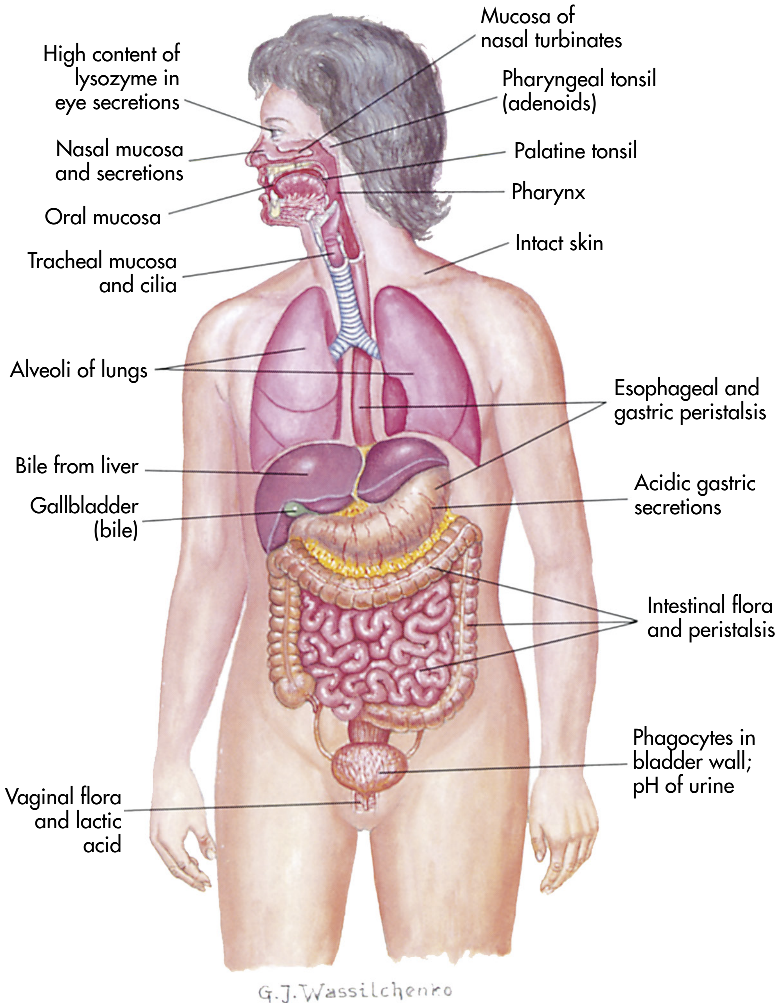

FIGURE 7-1 **The Closed Barrier.** The digestive, respiratory, and genitourinary tracts and the skin form closed barriers between the internal organs and the environment. (From Grimes DE: *Infectious diseases,* St Louis, 1991, Mosby.)

The lung also produces and secretes a family of glycoproteins, **collectins,** which includes surfactant proteins A through D and mannose-binding lectin. The binding site of each collectin reacts with different affinities to a range of monosaccharides, enabling collectins to recognize a wide array of pathogenic microorganisms. Collectin binding facilitates recognition of the microorganism by macrophages, enhancing macrophage attachment, phagocytosis, and killing. Collectins play a major role in protection against respiratory tract infections.

Other *epithelial antimicrobials* include resistin-like molecule β, bactericidal/permeability-inducing protein, and antimicrobial lectins. **Resistin-like molecule** β is found in the intestinal goblet cells, where it appears to protect against helminth infections. **Bactericidal/permeability-inducing (BPI) protein** is stored in neutrophils and intestinal epithelium. BPI protein specifically reacts with lipopolysaccharide on the surface of gram-negative bacteria, resulting in bacterial lysis. **Antimicrobial lectins** are carbohydrates that are found in intestinal epithelium and have activity against gram-positive bacteria.

Bacteria-Derived Chemicals

The body's surfaces are colonized with a spectrum of microorganisms, the **normal microbiome.** Each surface, including the skin and the mucous membranes of the eyes, upper and lower gastrointestinal tracts, urethra, and vagina, is colonized by a combination of mostly bacteria and occasionally fungi that is unique to the particular location. The microorganisms in the microbiome do not normally cause disease, and although their relationship with humans has been referred to as *commensal* (to the benefit of one organism without affecting the other), the relationship may be more *mutualistic* (to the benefit of both organisms). Using the colon for an example, at birth the lower gut is relatively sterile but colonization with bacteria begins quickly, with the number, diversity, and concentration increasing progressively during the first year of life. To the benefit of humans, many of these microorganisms help digest fatty acids, large polysaccharides, and other dietary substances; produce biotin and vitamin K; and assist in the absorption of various ions, such as calcium, iron, and magnesium.[5]

These bacteria contribute to our innate protection against pathogenic microorganisms in the colon. They compete with pathogens for nutrients and block attachment to the epithelium. Members of the normal microbiome also produce chemicals (ammonia, phenols, indoles, and other toxic materials) and toxic proteins *(bacteriocins)* that inhibit colonization by pathogenic microorganisms. Prolonged treatment with broad-spectrum antibiotics can alter the normal intestinal microbiome, decreasing its protective activity, and lead to an overgrowth of pathogenic microorganisms, such as the yeast *Candida albicans* or the bacteria *Clostridium difficile* (overgrowth can cause pseudomembranous colitis, an infection of the colon). Additionally, the normal microbiome of the gut help train the adaptive immune system by inducing the growth of gut-associated lymphoid tissue (where cells of the adaptive immune system reside) and the development of both local and systemic adaptive immune systems.[6]

The bacterium *Lactobacillus* is a major constituent of the normal vaginal microbiome in healthy women.[7] This microorganism produces a variety of chemicals (e.g., hydrogen peroxide, lactic acid, bacteriocins) that help prevent infections of the vagina and urinary tract by other bacteria and yeast. Prolonged antibiotic treatment can diminish colonization with *Lactobacillus* and increase the risk for urologic or vaginal infections, such as vaginosis.

Some members of the normal bacterial microbiome are opportunistic; opportunistic microorganisms can cause disease

NUTRITION & DISEASE

Essential Fatty Acids and Inflammation

Both omega-3 and omega-6 polyunsaturated fatty acids are essential fatty acids available only in the diet. They are essential because human physiologic processes cannot add the necessary double bonds to the carbon chains. Omega-6 fatty acids are contained in vegetable oils, and most are linolenic acid. Omega-3 essential fatty acids, which are mostly alpha-linolenic acid, are found in green leafy vegetables, walnuts, flaxseed, and canola oil. The metabolic products of alpha-linolenic acid are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), and the richest source of these acids is in the oils of deep-sea cold-water fish. Both the omega-3 and omega-6 fatty acids use the same enzymes to produce their metabolic products, and they compete for this enzyme, delta-5-desaturase. *Delta-5-desaturase* converts EPA into anti-inflammatory prostaglandins (PGs) of the PGE_3 series. The omega-6 fatty acid dihomogamma-linolenic acid (DGLA) can be converted to either anti-inflammatory PG_1 or arachidonic acid (AA), a precursor of inflammatory PG_2 and leukotrienes. Conversion of DGLA into PG_1 does not require any enzymes, but conversion of DGLA into AA requires the enzymes delta-6- and delta-5-desaturase. When the diet is high in omega-3 fatty acids, most of the delta-5-desaturase will be used in the omega-3 pathway and the production of anti-inflammatory prostaglandins. Little delta-5-desaturase will be available to convert DGLA into arachidonic acid, and subsequent inflammatory mediators. DGLA ends up being converted into the anti-inflammatory PG_1, and, overall, inflammation is decreased. The resulting anti-inflammatory effects of omega-3 essential fatty acids decrease the risk for cardiovascular disease, cancer, and other conditions associated with inflammation. Omega-3 fatty acids have been shown to decrease blood triglyceride concentrations; decrease production of chemoattractants, growth factors, and adhesion molecules; lower blood pressure; increase nitric oxide production and endothelial relaxation and vascular compliance; decrease thrombosis and cardiac dysrhythmias; and stabilize atherosclerotic plaque. The American diet tends to be high in saturated and omega-6 fatty acids and deficient in omega-3 fatty acids, with a ratio estimated at about 15:1. The Mediterranean-style diet has more whole grains, fish, olive oil, fresh fruits and vegetables, and a more balanced ratio of omega-6 to omega-3 fatty acids estimated at about (3-4):1. Increasing omega-3 fatty acids in the diet may significantly improve health and reduce the risk of cardiovascular disease and cancer.

if the individual's defenses are compromised. These microorganisms are normally controlled by the innate and adaptive immune systems and contribute to our defenses. For example, *Pseudomonas aeruginosa* is a member of the normal microbiome of the skin and produces a toxin that protects against infections with staphylococcal and other bacteria. However, severe burns compromise the integrity of the skin and may lead to life-threatening systemic pseudomonal infections.

SECOND LINE OF DEFENSE: THE INFLAMMATORY RESPONSE

If cells and tissues are damaged the **inflammatory response** is usually activated (Figure 7-2). Injury can have a variety of causes including infection, mechanical damage, oxygen deprivation (ischemia), nutrient deprivation, genetic or immune defects, chemical agents, temperature extremes, or ionizing radiation. Inflammation (1) depends on the activity of both *cellular and chemical components*, and (2) is *nonspecific,* meaning that it takes place in approximately the same way regardless of the type of stimulus or whether exposure to the same stimulus has occurred in the past.

Vascular Response

Inflammation occurs in tissue that has a blood supply (vascularized) and results in a group of easily observable characteristics: *redness, heat, swelling,* and *pain*. This tetrad represents the "cardinal signs of inflammation" and was identified in the first century by a Roman writer, Celsus. Microscopically, inflammatory changes occur at the vascular level (Figure 7-3). The three characteristic changes in the microcirculation (arterioles, capillaries, and venules) near the site of an injury include the following:

1. Blood vessel dilation (vasodilation)
2. Increased vascular permeability and leakage of fluid out of the vessel
3. White blood cell adherence to the inner walls of vessels and their migration through vessel walls to the site of injury (diapedesis)

The effects of inflammation are visible within seconds. First, arterioles near the site of infection or injury constrict briefly. Vasodilation then causes slower blood velocity and increases local blood flow to the injured site. The increased flow and capillary permeability result in leakage of plasma from the vessels, causing swelling (edema) in the surrounding tissue. As plasma moves outward, blood remaining in the microcirculation flows more slowly and becomes more viscous. The increased blood flow and increasing concentration of red cells at the site of inflammation cause locally increased warmth and redness. Leukocytes adhere to vessel walls. At the same time, biochemical mediators (e.g., histamine, bradykinins, leukotrienes, prostaglandins) stimulate the endothelial cells that line capillaries and venules to retract, creating spaces at junctions between the cells,

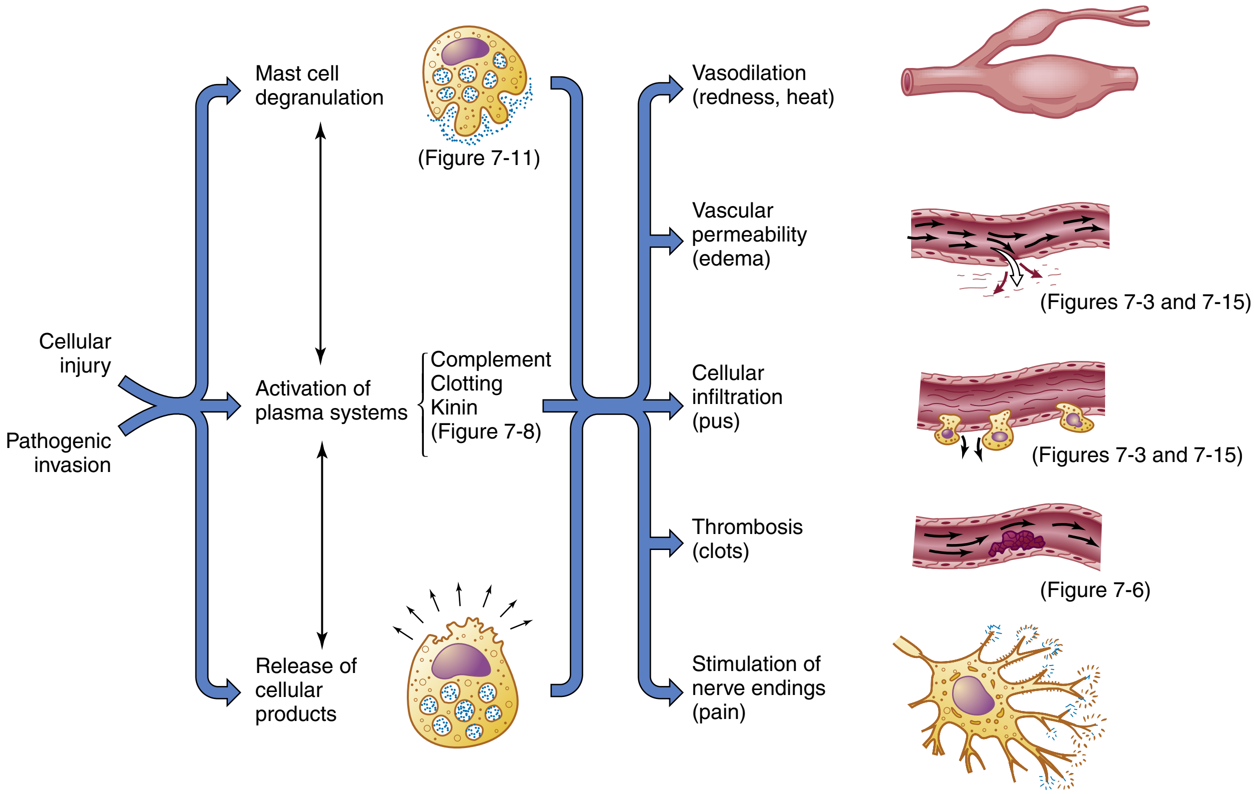

FIGURE 7-2 Acute Inflammatory Response. Inflammation is usually initiated by cellular injury, which results in mast cell degranulation, the activation of three plasma systems, and the release of subcellular components from the damaged cells. These systems are interdependent, so that induction of one (e.g., mast cell degranulation) can result in activation of the other two. The result is the development of microscopic changes in the inflamed site, as well as characteristic clinical manifestations. The figure numbers refer to those in which more detailed information may be found on that portion of the response.

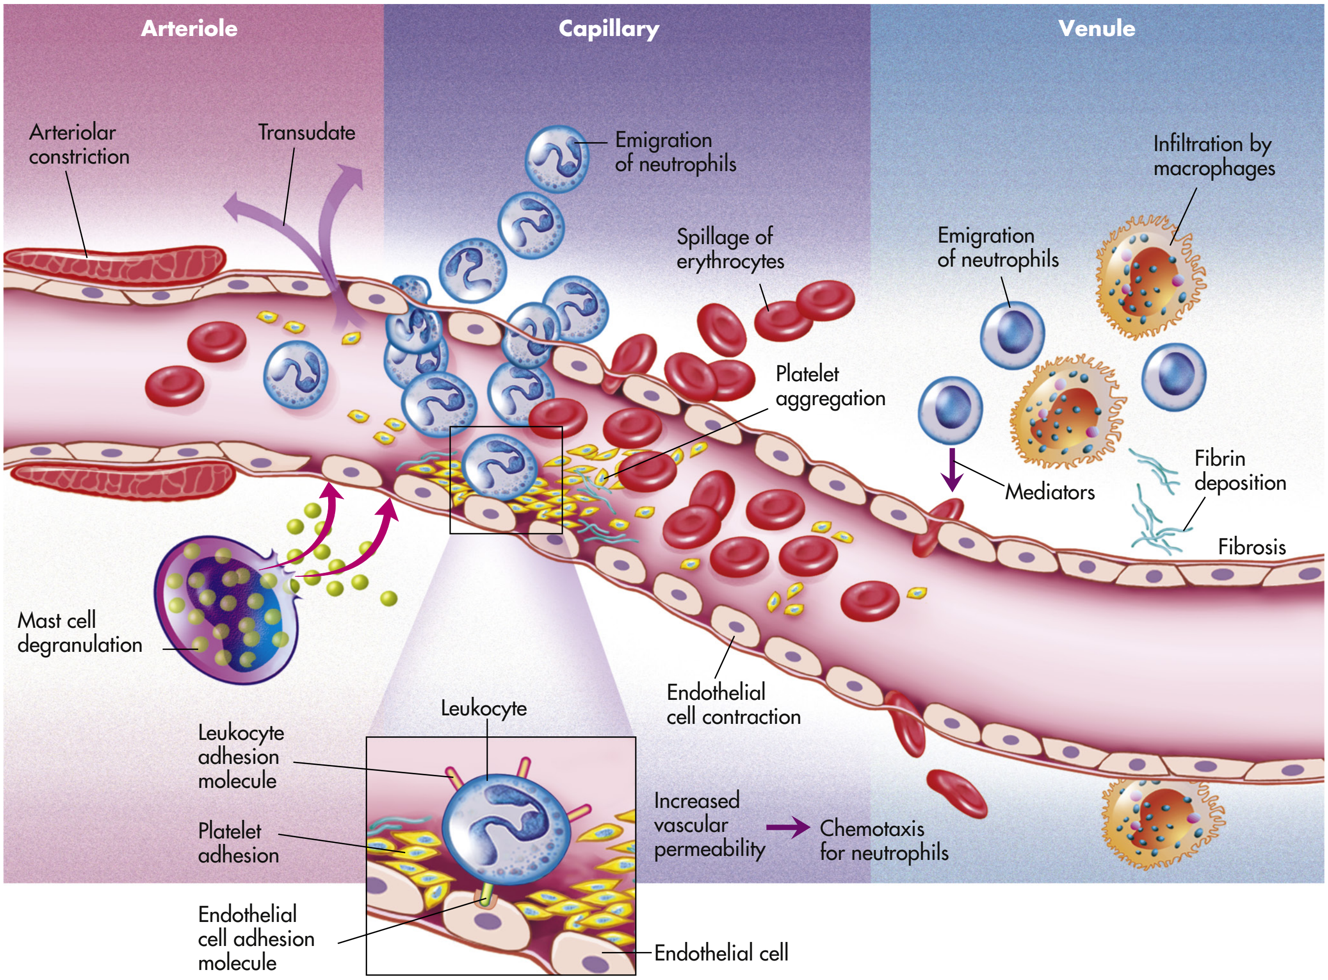

FIGURE 7-3 Sequence of Events in the Acute Inflammatory Response. See text for details.

allowing leukocytes and plasma to enter the surrounding tissue (intercellular junctions are described in Chapter 1).

Each of the characteristic changes associated with inflammation is the direct result of the activities and interactions of a host of chemicals and cellular components found in the blood and tissues. The vascular changes deliver leukocytes, plasma proteins, and other biochemical mediators to the site of injury. Once in the tissues, the cells and chemicals associated with the inflammatory response act in concert to do the following:

1. Prevent infection and further damage by contaminating microorganisms through the influx of fluid to dilute toxins produced by bacteria and released from dying cells, the influx and activation of plasma protein systems that help destroy and contain bacteria (e.g., complement system, clotting system), and the influx of cells (e.g., neutrophils, macrophages) that "eat" and destroy cellular debris and infectious agents.
2. Limit and control the inflammatory process through the influx of plasma protein systems (e.g., clotting system), plasma enzymes, and cells (e.g., eosinophils) that prevent the inflammatory response from spreading to areas of healthy tissue.
3. Interact with components of the adaptive immune system to elicit a more specific response to contaminating pathogen(s) through the influx of macrophages and lymphocytes.[8]
4. Prepare the area of injury for healing through removal of bacterial products, dead cells, and other products of inflammation (e.g., by way of channels through the epithelium or drainage by lymphatic vessels) and initiation of mechanisms of healing and repair.

Fluid and debris that accumulate at an inflamed site are drained by lymphatic vessels. This process also facilitates the development of adaptive immunity because microbial antigens in lymphatic fluid pass through the lymph nodes, where they activate both B and T lymphocytes. (This process is discussed in Chapter 8, and the lymphatic system is described in Chapter 27.)

Inflammation and repair can be divided into several phases (Figure 7-4). The characteristics of the early (i.e., acute) inflammatory response differ from those of the later (i.e., chronic) response, and each phase involves different biochemical mediators and cells that function together. The acute inflammatory response is of short duration; that is, it continues only until the immediate threat to the host is eliminated. This usually takes

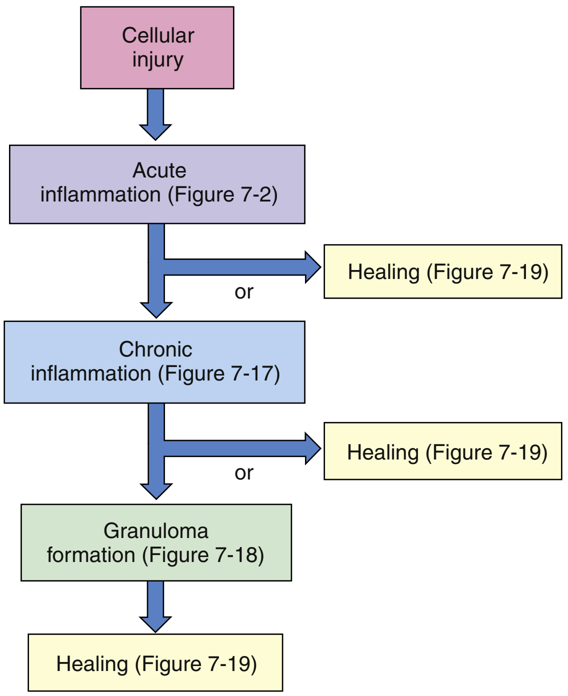

FIGURE 7-4 Inflammatory Phases. Cellular injury leads to acute inflammation and may result in resolution and healing of the injured site or may progress into chronic inflammation. Chronic inflammation in turn may result in healing or progress to development of a granuloma. The final step of the inflammatory process is usually healing and reconstruction of the damaged tissue. The figure numbers refer to those in which more detailed information on that portion of the process may be found.

8 to 10 days from onset to healing. The acute inflammatory response begins immediately after cellular injury or infection occurs and involves a vascular response, activation of plasma protein systems, and activation of a variety of cells. (Mechanisms of cellular injury are described in Chapter 2.)

Plasma Protein Systems

Three key **plasma protein systems** are essential to an effective inflammatory response. These are the complement system, the clotting system, and the kinin system (Figures 7-5, 7-6, and 7-7, respectively). Although each system has a unique role in inflammation, they also have many similarities. Each system consists of multiple proteins in the blood. To prevent activation in unnecessary situations, each protein is normally in an inactive form. Several of the proteins are enzymes that circulate in inactive forms as **proenzymes.** Each system contains a few proteins that can be activated by products of tissue damage or infection. Activation of the first component of a system results in sequential activation of other components, leading to a biologic function that helps protect the individual. This sequential activation is referred to as a *cascade*. Thus, we refer to the complement cascade, the clotting cascade, or the kinin cascade. In some cases, activation of a protein may require that it be enzymatically cut into two pieces or fragments of different size. Usually the larger fragment continues the cascade by activating the next component, and the smaller fragment frequently has potent biologic activities to promote inflammation.

Complement System

The complement system consists of several plasma proteins (sometimes called *complement components*) that together constitute about 10% of the total circulating serum protein. The complement system is extremely important because activation of the **complement cascade** may destroy pathogens directly and can activate or collaborate with virtually every other component of the inflammatory response. Proteins of the complement system are among the body's most potent defenders, particularly against bacterial infection.

Activation of the complement system can be accomplished in three different pathways, all of which converge at the third component (C3) of the pathway:

1. **Classical pathway:** activated by proteins of the adaptive immune system (antibodies) bound to their specific targets (antigen)
2. **Lectin pathway:** activated by mannose-containing bacterial carbohydrates
3. **Alternative pathway:** activated by gram-negative bacterial and fungal cell wall polysaccharides

The principal routes by which the complement cascade may be activated are shown in Figure 7-5.

Activation of the *classical pathway* begins with the activation of complement protein C1 and is preceded by formation of a complex between an antigen and an antibody to form an **antigen-antibody complex (immune complex)** (discussed in Chapter 8). The antigen may be a unique chemical component of the surface of a bacterium or other microorganism. Most pathogens express multiple antigens; therefore, multiple antibodies are usually bound in the complex. The first component of the classical complement cascade, C1, has six sites that can bind to antibodies, and efficient activation of the complement cascade usually requires concurrent binding of C1 to at least two antibody molecules. The complex formed by antigen-antibody-complement binding is shown in Figure 7-5. C1 is a macromolecular complex consisting of C1q and two molecules each of C1r and C1s. A conformational change in C1 results in an enzymatically active molecule whose substrates are C4 and C2. The resultant complex formed by the interaction of C1, C4, and C2 uses C3 as a substrate, resulting in the production of C3a and C3b. A complex that has C3 as a substrate is generally referred to as a **C3 convertase.** The addition of C3b to the complex changes the substrate specificity to C5, resulting in the conversion of C5 to C5a and C5b. A complex that has C5 as a substrate is generally called a **C5 convertase.** Thus activation of C1 initiates the sequential enzymatic activation of all other components of the classical pathway, ultimately resulting in the activation of C5. The classical pathway also can be activated to a lesser degree by biologic molecules other than antibody, including heparin (a charged molecule that prevents clotting), deoxyribonucleic acid (DNA) or ribonucleic acid (RNA), and C-reactive protein, which is increased in the blood during inflammation.

Even under normal conditions small amounts of circulating C3 are spontaneously broken down into C3b and C3a by a number of naturally occurring enzymes in the blood. The rate of C3 spontaneous activation is generally very low, and C3b is readily inactivated by complement regulator proteins in the

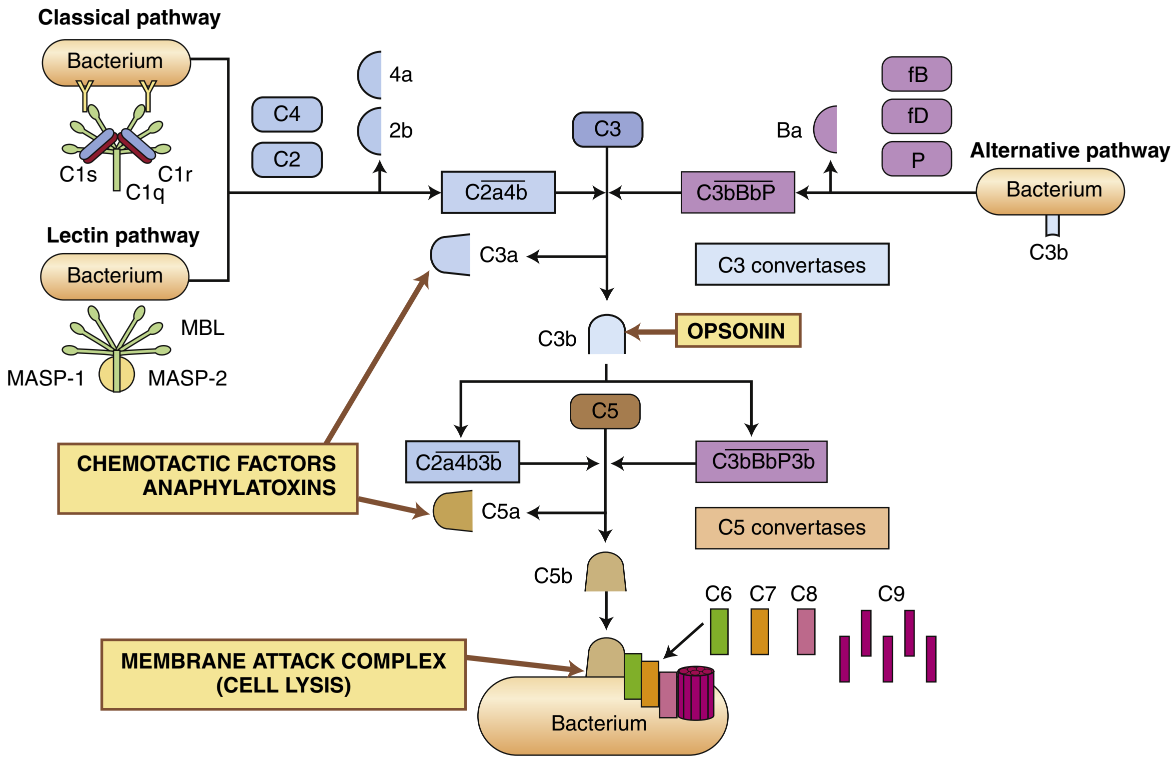

FIGURE 7-5 **Pathways of Complement Cascade Activation.** The complement system is activated by three pathways: the classical pathway, the lectin pathway, and the alternative pathway. During activation, many complement components are cleaved into fragments (2b, 4a, Ba, C3a, and C5a). The smaller fragments frequently have potent biologic activities and may serve as chemotactic factors and anaphylatoxins. The larger activated fragments are usually converted into active enzymes (indicated by the bar above the names) and form complexes with additional components in the cascade. The classical pathway is usually activated by antigen-antibody complexes through component C1, which consists of C1q and two C1r and C1s molecules. As indicated, the C1q must simultaneously bind to two antibody molecules (indicated by Y-shaped structures). The lectin pathway is activated by mannose-binding lectin (MBL), which binds to two mannose-rich pathogen-associated molecular patterns on the surface of a bacterium. MBL contains two associated enzymes, MASP-1 and MASP-2, and functions in a manner similar to C1. C1 and MBL each activate complement components C4 and C2. The alternative pathway is activated by many agents, such as bacterial polysaccharides, which bind and stabilize C3b, which is produced by normal breakdown of C3 in the blood. The C3b forms the site of binding of factor B (fB), which is activated by factor D (fD) into Bb and the small fragment Ba. Properdin (P) helps stabilize the complex. Each pathway produces C3 and C5 convertases, which are enzymatically active complexes that activate C3 and C5, respectively. C3b produced by the C3 convertase can function as an opsonin. C5b initiates assemblage of the membrane attack complex (MAC), which results in multiple C9 molecules forming a pore in the bacterial membrane.

blood (e.g., factor H and factor I). However, materials produced by some infectious microorganisms (e.g., lipopolysaccharides [endotoxins] on the bacterial surface, yeast cell wall carbohydrates [zymosans]) can bind the naturally produced C3b and protect it from inactivation. This will initiate activation of the *alternative complement pathway*. The C3b bound to bacterial products can react with another normally occurring component, factor B. The complex of C3b and factor B is recognized by an enzyme, factor D, which activates factor B, producing factor Bb. The resultant C3b/Bb complex is very unstable unless it binds to properdin (P). The C3b/Bb/P complex is a C3 convertase that produces further C3b, resulting in a C3b/Bb/P/C3b complex that is a C5 convertase, which activates C5.

The *lectin pathway* is similar to the classical pathway but is antibody independent. It is activated by a plasma protein called *mannose-binding lectin (MBL)*. MBL is similar to C1q and binds to bacterial polysaccharides containing the carbohydrate mannose. MBL-associated serine proteases (MASP-1 and MASP-2) substitute for C1r and C1s and activate C4 and C2 to create a C3 convertase.

After activation of C5, the cascade continues through the terminal components C6, C7, C8, and C9. Components C5b through C9 assemble to form complexes *(membrane attack complex,* or *MAC)* capable of creating pores in cell membranes and permitting the influx of water and ions and may ultimately result in **cell lysis.**

The most important result of complement activation is the production of fragments during the activation of C4, C2, C3, and C5. The fragments C4a, C2b, C3a, and C5a are soluble and of low-molecular-weight that contribute in other ways to the inflammatory response. C2b affects smooth muscle, causing vasodilation and increased vascular permeability. C3a and C5a, and to a limited extent C4a, are **anaphylatoxins;** that is, they induce rapid **mast cell degranulation** (release of granular

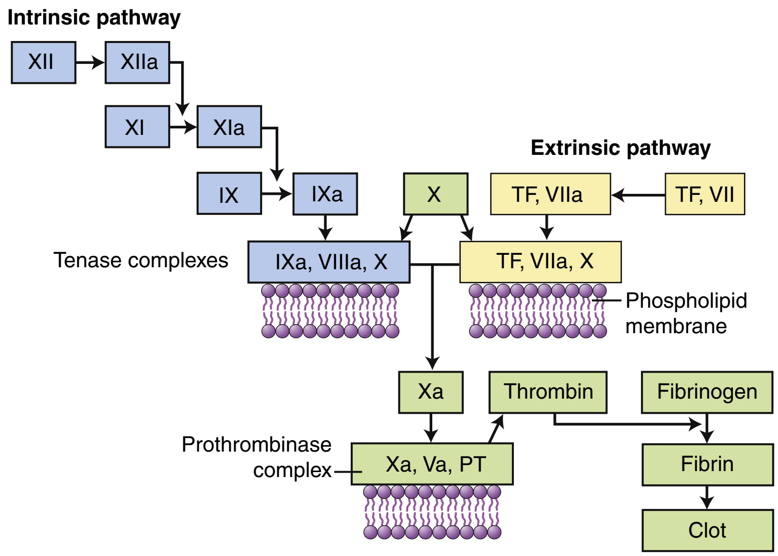

FIGURE 7-6 Coagulation Cascade. Clotting is activated through two pathways: the intrinsic pathway and the extrinsic pathway. The intrinsic pathway is initiated by the activation of Hageman factor (XII) into XIIa (activated factors are enzymes and are indicated by a lowercase a). The sequential activation of other intrinsic pathway components results in formation of a complex of IXa, VIIIa, and X. The extrinsic pathway is activated by exposure of tissue factor (TF) during tissue damage. TF complexes with factor VII, which is activated (VIIa) and forms a complex with factor X (TF, VIIa, X). Both the intrinsic and the extrinsic pathway complexes are dependent on calcium, form on phospholipid membranes that are rich in phosphatidylserine, and have "tenase" activity (can activate factor X into Xa). Factor X begins a common pathway in which Xa complexes with Va and prothrombin (PT), with calcium and phospholipid membranes, to form an active prothrombinase (activates prothrombin into thrombin). Thrombin is an enzyme that cuts high-molecular-weight fibrinogen into fibrin molecules. Fibrin polymerizes to form a clot.

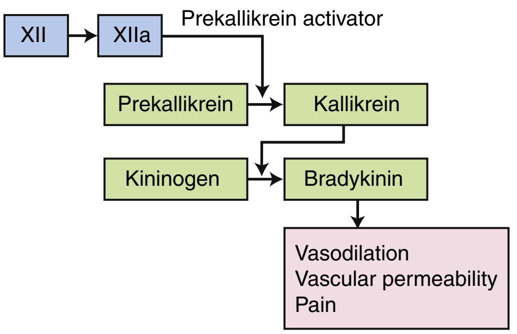

FIGURE 7-7 Plasma Kinin Cascade. The kinin pathway is activated by factor XIIa from the clotting system, which functions as an enzyme (prekallikrein activator) to convert prekallikrein into kallikrein. Enzymatically active kallikrein converts kininogen into bradykinin.

contents) and the release of histamine (see Figure 7-11, p. 206), causing vasodilation and increased capillary permeability.[9] C5a is the major chemotactic factor for neutrophils. C3a is approximately 100 times less potent in chemotactic and anaphylatoxic activity. A **chemotactic factor** is a biochemical substance that attracts leukocytes to the site of inflammation.

The dual functions of a chemotactic factor and an anaphylatoxin are not needed simultaneously or to the same degree. Anaphylatoxic activity is necessary early in inflammation and occurs close to the inflammatory site to induce local mast cell degranulation and to increase the number of soluble mediators available to enhance vascular permeability and vasodilation. Chemotactic activity, on the other hand, is required for a much longer period and occurs distal to the inflammatory site to attract leukocytes from the circulation. Thus it is beneficial to an effective inflammatory response to limit the range of anaphylatoxic activity while allowing widespread chemotactic activity. A plasma enzyme, a **carboxypeptidase,** removes a terminal arginine on both C3a and C5a peptides, thereby producing "C3a desArg" and "C5a desArg," which are inactive as anaphylatoxins but retain chemotactic activity. Thus chemotactic activity is retained, while not inducing distal mast cell degranulation that would result in considerable enlargement of the inflammatory response to the detriment of surrounding healthy tissue.

C3b adheres to the surface of a pathogenic microorganism and serves as an efficient opsonin. **Opsonins** are molecules that "tag" microorganisms for destruction by cells of the inflammatory system (primarily neutrophils and macrophages [see pp. 208 and 209]). C3b on the cell surface also can be broken down by several enzymes in the blood into inactive fragments (e.g., iC3b), which retain opsonic activity.

In summary, the complement cascade can be activated by at least three different means, and its products have four functions: (1) anaphylatoxic activity resulting in mast cell degranulation, (2) leukocyte chemotaxis, (3) opsonization, and (4) cell lysis.

Clotting System

The clotting (coagulation) system is a group of plasma proteins that form a fibrinous meshwork at an injured or inflamed site. This (1) prevents the spread of infection to adjacent tissues, (2) traps microorganisms and foreign bodies at the site of inflammation for removal by infiltrating cells (e.g., neutrophils and macrophages), (3) forms a clot that stops bleeding, and (4) provides

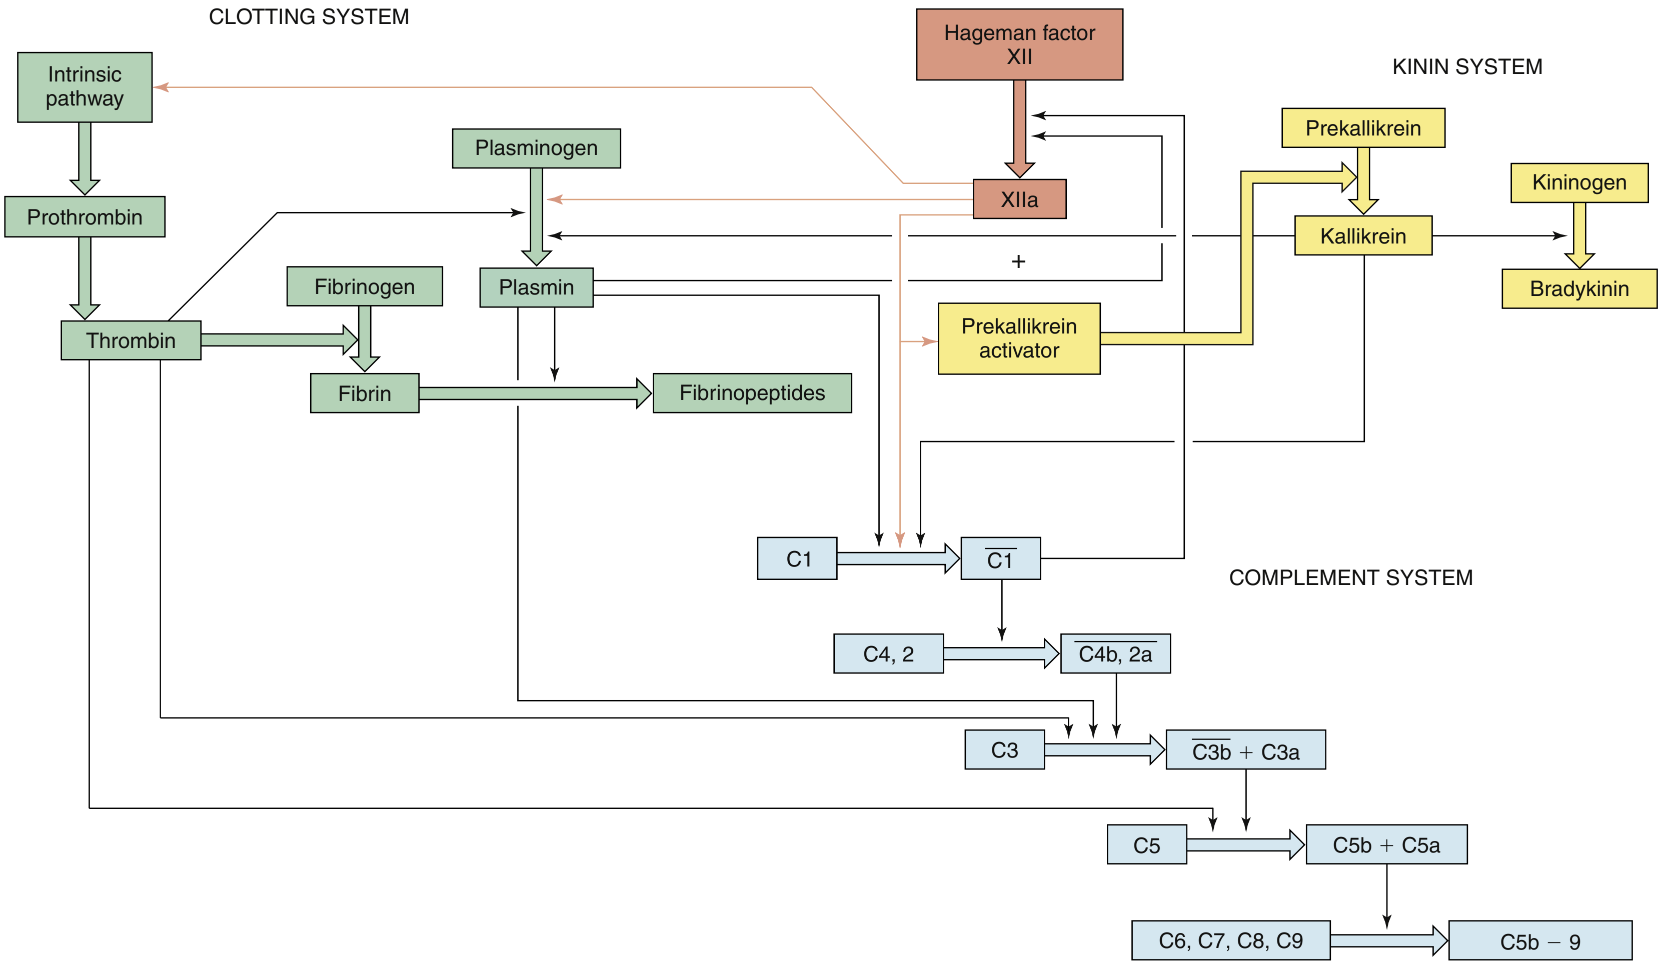

FIGURE 7-8 Interactions Between the Complement, Clotting, and Kinin Systems. *Thick colored arrows* denote the activation of factors within a system. *Thin arrows* denote where a particular factor activates another system.

a framework for future repair and healing. The main substance in this fibrinous mesh is an insoluble protein called *fibrin* that is the end product of the **coagulation cascade.**

The clotting system can be activated by many substances that are released during tissue injury and infection, including collagen, proteinases, kallikrein, and plasmin, as well as by bacterial products such as endotoxins. Like the complement cascade, the coagulation cascade can be activated through different convergent pathways (see Figure 7-6). The tissue factor (extrinsic) pathway is activated by tissue factor (TF) (also called tissue thromboplastin) that is released by damaged endothelial cells in blood vessels and reacts with activated factor VII (VIIa). The contact activation (intrinsic) pathway is activated when the vessel wall is damaged and Hageman factor (factor XII) in plasma contacts negatively charged subendothelial substances. The pathways converge at factor X. Activation of factor X begins a common pathway leading to activation of fibrin that polymerizes to form a fibrin clot. The coagulation system is discussed in more detail and illustrated again in Chapter 27.

As with the complement system, activation of the clotting system produces fragments that enhance the inflammatory response. Two low-molecular-weight fibrinopeptides, A and B, are released from fibrinogen when fibrin is produced. Both fibrinopeptides (especially fibrinopeptide B) are chemotactic for neutrophils and increase vascular permeability by enhancing the effects of bradykinin (formed from the kinin system).

Kinin System

The third plasma protein system, the **kinin system,** augments inflammation in several ways. The primary kinin produced from the kinin system is **bradykinin,** which causes dilation of blood vessels, acts with prostaglandins to stimulate nerve endings and induce pain, causes smooth muscle cell contraction, increases vascular permeability, and may increase leukocyte chemotaxis (see Figure 7-2). Bradykinin induces smooth muscle contraction more slowly than histamine and, along with prostaglandins of the E series, is probably responsible for endothelial cell retraction and increased vascular permeability in the later phases of inflammation (endothelial cell retraction is shown in Figures 7-3 and 7-15).

The kinin system is activated by stimulation of the **plasma kinin cascade** (see Figure 7-7). The conversion of plasma prekallikrein to kallikrein is induced by *prekallikrein activator,* which is identical to factor XIIa (the product that results from activation of Hageman factor—factor XII) of the clotting cascade. Kallikrein then converts kininogen to bradykinin. Although the plasma kinin cascade is one pathway that leads to the production of bradykinin, tissue kallikreins in saliva, sweat, tears, urine, and feces provide other sources for this inflammatory mediator. These tissue kallikreins convert serum kininogens to kallidin, also known as *Lys-bradykinin,* which may be converted to bradykinin by plasma aminopeptidase. In order to limit the extent of inflammation, kinins are rapidly degraded by **kininases,** enzymes present in plasma and tissues.

Interactions Among the Plasma Protein Systems

The three plasma protein systems are highly interactive so that activation of one system results in the production of a large number of very potent, biologically active substances that further activate the other systems (Figure 7-8). Very tight control of these processes is essential for two reasons:

1. The inflammatory process is critical for an individual's survival; thus, efficient activation must be guaranteed regardless of the cause of tissue injury.
2. The biochemical mediators generated during these processes are so potent and potentially detrimental to the host itself that their actions must be strictly confined to injured or infected tissues only.

Therefore, multiple mechanisms are available to either *activate* or *inactivate (regulate)* these plasma protein systems. As an example, **plasmin** regulates clot formation by degrading fibrin and fibrinogen, and it can activate the complement cascade through components C1, C3, and C5. Plasmin can activate the plasma kinin cascade as well by activating **Hageman factor (factor XII)** and producing prekallikrein activator. This activation of Hageman factor has four effects that impact all three of the plasma protein systems:

1. Activation of the clotting cascade through factor XI
2. Control of clotting through conversion of plasminogen proactivator to plasminogen activator, resulting in the generation of plasmin
3. Activation of the kinin system by activated Hageman factor (prekallikrein activator)
4. Activation of C1 in the complement cascade

The activity of plasmin itself is also regulated because it is synthesized as a proenzyme, plasminogen. Plasminogen is converted to plasmin by several factors, including plasminogen activator generated from the kallikrein system, thrombin generated from the clotting system, bacterial factors such as streptokinase produced by hemolytic streptococci, plasminogen activators produced by endothelial cells, and several cellular enzymes released during tissue destruction.

Many enzymes from the plasma regulate the activity of these pathways, such as carboxypeptidase that inactivates the anaphylatoxic activities of C3a and C5a, and kininases that degrade kinins. Many other natural inhibitors are present, including enzymes that degrade histamine (histaminase), activated complement components, kallikrein, and plasmin. Another example of a common regulator is **C1-esterase inhibitor (C1-inh).**[10] C1-inh inhibits complement activation through reactivity with C1 (classical pathway), MASP-2 (lectin pathway), and C3b (alternative pathway). It is also a major inhibitor of the clotting and kinin pathways (e.g., kallikrein, activated Hageman factor XIIa). A genetic defect in C1-inh (C1-inh deficiency) results in **hereditary angioedema,** which is a self-limiting edema of cutaneous and mucosal layers resulting from stress, illness, or relative minor or unapparent trauma. The disease is characterized by hyperactivation of all three plasma protein systems, although excessive production of bradykinin appears to be the principal cause of increased vascular permeability.

Cellular Mediators of Inflammation

Inflammation is a process in vascular tissue; thus the cellular components of inflammation are found in the blood and in the tissue surrounding the blood vessels. The vessels are lined

with endothelial cells, which under normal conditions actively maintain normal blood flow. During inflammation the vascular endothelium becomes a principal coordinator of blood clotting and the passage of cells and fluid into the tissue. The tissue close to the vessels contains mast cells, which are probably the most important activators of inflammation. The tissue also contains dendritic cells, which connect the innate and adaptive immune responses. The blood contains a complex mixture of cells (see Figure 7-3). Blood cells are divided into erythrocytes (red blood cells), platelets, and leukocytes (white blood cells). Erythrocytes carry oxygen to the tissues, and platelets are small cell fragments involved in blood clotting. Leukocytes are subdivided into **granulocytes** (containing many enzyme-filled cytoplasmic granules), monocytes, and lymphocytes. Granulocytes are the most common leukocytes and are classified by the type of stains needed to visualize their granules (basophils, eosinophils, and neutrophils). Monocytes are precursors of macrophages that are found in the tissues. Various forms of lymphocytes participate in the innate (natural killer [NK] cells) and the adaptive immune response (B and T cells).

The cells of the inflammatory system secrete and respond to biochemical mediators. Thus most of these cells are recruited and activated by products of the plasma protein systems and by biochemicals released during cell destruction, secreted by other inflammatory cells, or produced by microbes. These inflammatory cells and protein systems, along with the substances they produce, preferably act at the site of tissue injury to confine the extent of damage, kill microorganisms, and remove the debris of "battle" in preparation for healing: tissue regeneration or repair (processes known as *resolution*).

Cellular Receptors

Cells of both innate and adaptive immunity must recognize and respond to their environment, whether to products of damaged cells or to potential pathogenic microorganisms. Each cell has receptors on the cell surface that specifically bind soluble substances (ligands) produced during tissue damage or infection. The binding of a ligand to its receptor results in activation of intracellular signaling pathways and activation of the cell. As will be discussed in Chapter 8, B and T lymphocytes of the adaptive immune system have evolved surface receptors (i.e., the T-cell receptor, or TCR, and the B-cell receptor, or BCR) that bind a large spectrum of antigens. Cells involved in innate resistance have evolved a different set of receptors that recognize a much more limited array of specific molecules. These are referred to as **pattern recognition receptors (PRRs),** and they recognize molecular "patterns" on infectious agents or their products **(pathogen-associated molecular patterns,** or **PAMPs),** or products of cellular damage (necrosis or apoptosis; **damage-associated molecular patterns,** or **DAMPs**). PRRs are generally found on cells at the interface of the host and environment (i.e., skin, respiratory tract, gastrointestinal tract, genitourinary tract), where they monitor for products of cellular damage and potentially infectious microorganisms. Although most PRRs are on the cell surface, some are secreted or intracellular.[11] An example of a secreted PRR is mannose-binding lectin of the lectin pathway of complement activation. Cellular PRRs include Toll-like receptors, complement receptors (CRs), scavenger receptors, glucan receptors, and mannose receptors. A group of intracellular protein complexes, called **inflammasomes,** function as PRRs within cells.[12] Inflammasomes primarily bind cellular stress–related molecules, a type of DAMPs, and control the production of interleukin-1β (IL-1β).[13]

In humans, at least 11 different **Toll-like receptors (TLRs)** have been described, 10 of which are functional.[14] They are expressed on the surface of many cells that have direct and early contact with potential pathogenic microorganisms. These include mucosal epithelial cells, mast cells, neutrophils, macrophages, dendritic cells, and some subpopulations of lymphocytes. (Dendritic cells are found in the skin, mucosa, and lymphoid tissues, where they have developed from Langerhans cells and function as highly specialized initiators of the adaptive immune response.) TLRs recognize a large variety of PAMPs located on the microorganism's cell wall or surface (e.g., bacterial lipopolysaccharide [LPS], peptidoglycans, and lipoproteins, yeast zymosan, viral coat proteins), other surface structures (e.g., bacterial flagellin), or microbial nucleic acid (e.g., bacterial DNA, viral double-stranded RNA). Some TLRs recognize host factors that are produced by "stressed" or damaged cells (e.g., breakdown products of extracellular matrix proteins, chromatin). Interactions between PAMPs and TLRs, with the collaboration of other cellular receptors (e.g., CD14), can result in activation of the cell and the release of soluble products (e.g., cytokines) that increase local resistance to the pathogenic microorganism. TLRs are also one of the bridges between innate resistance and the adaptive immune response through the induction of cytokines that increase the response of lymphocytes to foreign antigens on the pathogens. Genetic polymorphisms in TLRs may explain some observed differences among individuals' resistance and susceptibility to infections. Information on each of the TLRs found in humans is shown in Table 7-2.

Complement receptors are found on many cells of the innate and adaptive immune responses (e.g., granulocytes, monocytes/macrophages, lymphocytes, mast cells, erythrocytes, platelets), as well as some epithelial cells. They recognize several fragments produced through activation of the complement system. Under a variety of normal and disease-related conditions, immune complexes of antibody, antigen, and complement form in the blood and are removed by cells expressing surface complement receptor-1 (CR1), which binds to C4b, C3b, and C3b breakdown products (e.g., iC3b). CR2 is found on B lymphocytes, as well as dendritic cells and some epithelial cells, and recognizes C3b breakdown products (particularly iC3b). CR2 appears to facilitate B-cell function and antibody production. Both CR3 and CR4 are integrins that primarily recognize C3b breakdown products (particularly iC3b). CR3 (integrin αMβ2, also called CD11b/CD18) facilitates phagocytosis by neutrophils and monocytes/macrophages. CR4 (αXβ2, also called CD11c/CD18) is found primarily on platelets. (**Integrins** are cell surface receptors that have a role in cell adhesion and attachment and mediate intracellular signaling within the extracellular matrix [see Figure 1-14, p. 15].)

Scavenger receptors are primarily expressed on macrophages and facilitate recognition and phagocytosis of bacterial

TABLE 7-2 CELLULAR SOURCE AND MICROBIAL TARGET FOR EACH TOLL-LIKE RECEPTOR (TLR)

RECEPTOR	CELLULAR EXPRESSION PATTERN	PAMP RECOGNITION
TLR1	Cell surface (ubiquitous): neutrophils, monocytes/macrophages, dendritic cells, T cells, B cells, NK cells	Fungal, bacterial, viral; forms heterodimer with TLR2 (see TLR2 recognition)
TLR2	Cell surface: neutrophils, monocytes/macrophages, dendritic cells	Fungal (yeast zymosan), bacterial (gram-positive bacterial peptidoglycan, lipoproteins), viral (lipoproteins)
TLR3	Intracellular: monocytes/macrophages, dendritic cells, T cells, NK cells, epithelial cells	Double-stranded RNA produced by many viruses
TLR4	Cell surface: granulocytes, monocytes/macrophages, dendritic cells, T cells, B cells, epithelial cells	Bacterial (primarily gram-negative bacterial LPS, lipoteichoic acids), viral (RSV F protein, hepatitis C)
TLR5	Cell surface: granulocytes, monocytes/macrophages, dendritic cells, NK cells, epithelial cells	Bacterial (flagellin); forms heterodimer with TLR4
TLR6	Cell surface: monocytes/macrophages, dendritic cells, B cells, NK cells	Fungal, bacterial, viral; forms heterodimer with TLR2 (see TLR2 recognition)
TLR7	Intracellular: monocytes/macrophages, dendritic cells, B cells	Natural ligand uncertain; may bind viral single-strand RNA
TLR8	Cell surface: monocytes/macrophages, dendritic cells, NK cells	Natural ligand uncertain; may bind fungal PAMPs or viral single-stranded RNA
TLR9	Intracellular: monocytes/macrophages, dendritic cells, B cells	Bacterial (unmethylated DNA [CpG dinucleotides])
TLR10	Cell surface: monocytes/macrophages, dendritic cells, B cells	Natural ligand uncertain; may form heterodimers with TLR2
TLR11	TLR11 gene does not code a full length protein in humans	No known immune response

pathogens, as well as damaged cells and altered soluble lipoproteins associated with vascular damage (e.g., high-density lipoprotein [HDL], acetylated low-density lipoprotein [LDL], oxidized LDL). More than eight receptors have been identified. Some scavenger receptors (e.g., SR-PSOX) recognize the cell membrane phospholipid phosphatidylserine (PS). PS is normally sequestered on the cytoplasmic surface of the cell membrane, but is externalized under a very limited variety of conditions, including erythrocyte senescence and cellular apoptosis. Thus macrophages, through this receptor, can identify and remove old red blood cells and cells undergoing apoptosis. Another important scavenger receptor is CD14, which recognizes the complex of LPS and LPS-binding protein. LPS-binding protein is up-regulated during inflammation by the cytokines interleukin-6 (IL-6) and IL-1 and helps remove bacterial LPS (endotoxin) from the circulation.

Cellular Products

To elicit an effective inflammatory (or adaptive immune) response, it is necessary that many different kinds of cells cooperate. Many cells secrete soluble factors that contribute to the regulation of innate or adaptive resistance by affecting other neighboring cells (Figure 7-9). These factors are referred to as *chemokines* or **cytokines** and are either *proinflammatory* or *anti-inflammatory* in nature, depending on whether they respectively tend to induce or inhibit the inflammatory response. These molecules usually diffuse over short distances, bind to the appropriate target cells, and affect the function of the target cell. Some effects occur over long distances, such as the systemic induction of fever by some cytokines (i.e., endogenous pyrogens) that are produced at an inflammatory site. The binding of chemokines or cytokines to a target cell often induces synthesis of additional cellular products. For example, binding of the cytokine tumor necrosis factor-alpha (TNF-α) to a cell may result in synthesis and release of IL-1. Chemokine and cytokine binding is mediated through specific cell surface receptors that are themselves sometimes under the regulation of secreted cellular products.

The actions of chemokines and cytokines are *pleiotropic,* indicating that the same molecule may have a large variety of different biologic activities depending on the particular target cell to which it binds. In addition, the same molecule may be produced by a large spectrum of cells, many of which are not part of inflammation or the immune system. These molecules may be *synergistic,* so that their combined activity exceeds the sum of their individual activities, or have *antagonistic* properties that cause them to inhibit each other.[15] (A partial list of relevant cytokines is provided in Chapter 8, Table 8-5.)

Cytokines. The majority of important cytokines are classified as interleukins or interferons. Other critical cytokines, however, are not classified as either. Many of these same cytokines are produced by cells of the acquired immune system in response to specific antigens and are discussed further in Chapter 8.

The **interleukins (ILs)** are biochemical messengers produced predominantly by macrophages and lymphocytes in response to their recognition of a microorganism or stimulation by other products of inflammation. One important function of this class of cytokines is enhancement of the adaptive immune response against pathogenic microorganisms and other foreign substances. Interleukins, however, are both produced by and have effects on a large variety of cells, often independent of infection.

Two major proinflammatory cytokines are IL-1 and IL-6. IL-1 is produced mainly by macrophages that have been stimulated by substances associated with infection, including many of the PAMPs discussed earlier in this chapter, as well as by other cytokines. IL-1 is synthesized in two forms, α and β, that often elicit the same biologic responses. IL-1 is an endogenous pyrogen (i.e., fever-causing cytokine) that reacts with receptors on

cells of the hypothalamus and affects the body's thermostat. It also activates phagocytes and lymphocytes, thereby enhancing both innate and adaptive immunity, and acts as a growth factor for many cells. It has several effects on neutrophils, including induction of proliferation (resulting in an increase in the number of circulating neutrophils), chemotaxis, increased cellular respiration, and increased lysosomal enzyme activity. IL-6 is produced by macrophages, lymphocytes, fibroblasts, and other cells. IL-6 directly induces hepatocytes (liver cells) to produce many of the proteins needed in inflammation (acute-phase reactants, discussed later in this chapter). IL-6 also stimulates growth and differentiation of blood cells in the bone marrow and the growth of fibroblasts (required for wound healing).

Some cytokines are anti-inflammatory and diminish the inflammatory response. The most important are IL-10 and transforming growth factor-beta (TGF-β). IL-10 is primarily produced by lymphocytes and suppresses the growth of lymphocytes and the production of proinflammatory cytokines by macrophages, leading to the down-regulation of both inflammation and the adaptive immune response. TGF-β and other transforming growth factors are produced by many types of cells in response to inflammation and induce differentiation of other cell types, such as immature blood cells.

More than 30 human interleukins have been identified, although the functions of several have not yet been defined. Their varied effects include the following:

1. Alteration of adhesion molecule expression on many types of cells
2. Induction of leukocyte chemotaxis
3. Induction of proliferation and maturation of leukocytes in the bone marrow
4. General enhancement or suppression of inflammation (see Table 8-5)

Interferons (IFNs) are low-molecular-weight proteins that primarily protect against viral infections and modulate the inflammatory response. (Mechanisms of viral infection are described in Chapter 10.) IFNs are produced and released by virally infected cells in response to viral double-stranded RNA and other viral PAMPs. Different kinds of IFNs are produced by different types of cells—macrophages are the primary producers of type I interferons (IFN-α and IFN-β), whereas T lymphocytes release type II interferon (IFN-γ). These IFNs do not kill

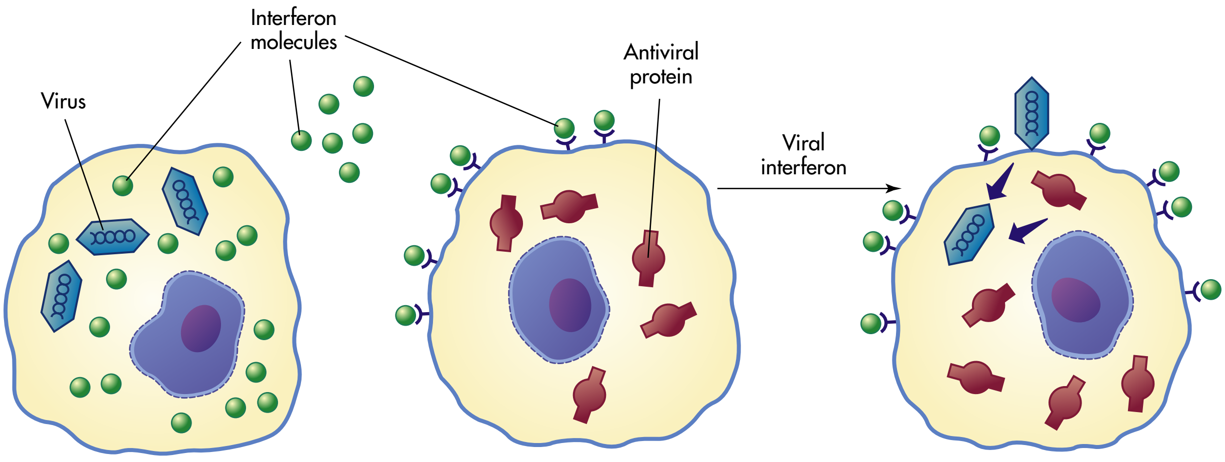

FIGURE 7-10 The Action of Interferon.

viruses directly but instead prevent them from infecting additional healthy cells.[16] Interferons also enhance the efficiency of developing an adaptive immune response.[17]

IFN-α and IFN-β induce production of antiviral proteins, thereby conferring protection on uninfected cells. IFN-α or IFN-β is released from virally infected cells, attaches to a receptor on a neighboring cell, and, if the neighboring cell is uninfected, stimulates the production of a variety of antiviral proteins that will interfere with transcription of viral nucleic acids or with viral replication[18] (Figure 7-10). These interferons have no effect on cells that have already been virally infected. IFN-γ enhances the inflammatory response by increasing the microbicidal activity of macrophages. This cytokine also facilitates development of the adaptive immune response against viral antigens on infected cells. Interferons are species specific, meaning that human interferon is effective only in humans; however, these cytokines are not virus specific, meaning that they are effective against almost all viruses.

Despite the numerous interleukins and interferons, other essential cytokines are needed to mount an efficient inflammatory response. One of the most important of these is **tumor necrosis factor-alpha (TNF-α).**[19] Macrophages secrete TNF-α in response to recognition of PAMPs by TLRs. Other cells, such as mast cells, are additional and crucial sources of this proinflammatory cytokine. TNF-α is initially synthesized as a membrane-spanning protein, which is cleaved into a soluble form by a membrane-associated protease, TNF-converting enzyme (TACE). Soluble TNF-α induces a multitude of proinflammatory effects, including enhancement of endothelial cell adhesion molecule expression and induction of chemokine production by both endothelial cells and macrophages. When secreted in large amounts, TNF-α has systemic effects as well:

1. Induces fever by acting as an endogenous pyrogen
2. Causes increased synthesis of proinflammatory proteins by the liver
3. Causes muscle wasting (cachexia) and intravascular thrombosis as a consequence of prolonged production in cases of severe infection or cancer
4. Probably responsible for fatalities from shock caused by gram-negative bacterial infections

Chemokines. **Chemokines** are members of a family of low-molecular-weight (8 to 10 kDa) peptides that function primarily to induce leukocyte chemotaxis. This response can be elicited either by soluble chemokines or by chemokines that are bound to extracellular glycosaminoglycan carbohydrates. Chemokines can be synthesized by multiple cell types, including macrophages, fibroblasts, and endothelial cells, in response to proinflammatory cytokines. Macrophages can be stimulated to produce chemokines by recognition of either infectious microorganisms or a β-defensin (both through TLR4). To date, more than 40 different human chemokines have been described, the vast majority of which are classified as either CC-chemokines (β-chemokines) or CXC-chemokines (α-chemokines), depending on the arrangement of cysteine amino acids in the protein. This amino acid arrangement also determines which target cell(s) will respond to a given chemokine. CC-chemokines affect mainly monocytes, lymphocytes, and eosinophils, whereas CXC-chemokines generally affect neutrophils. Examples of CC-chemokines include RANTES (regulated on activation, normal T expressed and secreted), monocyte/macrophage chemotactic proteins (MCP-1, MCP-2, and MCP-3), and macrophage inflammatory proteins (MIP-1α and MIP-1β). CXC-chemokines include IL-8 and epithelial-dermoid neutrophil attractant (ENA-78).

Mast Cells

A central cell in inflammation is the mast cell. **Mast cells,** first described by Paul Ehrlich[20] in 1877, are cellular bags of granules located in the loose connective tissues close to blood vessels (Figure 7-11). They are found in large numbers in areas directly exposed to the environment including the skin and the linings of the gastrointestinal and respiratory tracts. A great number of stimuli cause mast cells to become activated, resulting in initiation of the inflammatory response.[21] Typical causes of mast cell activation include (1) physical injury (e.g., heat,

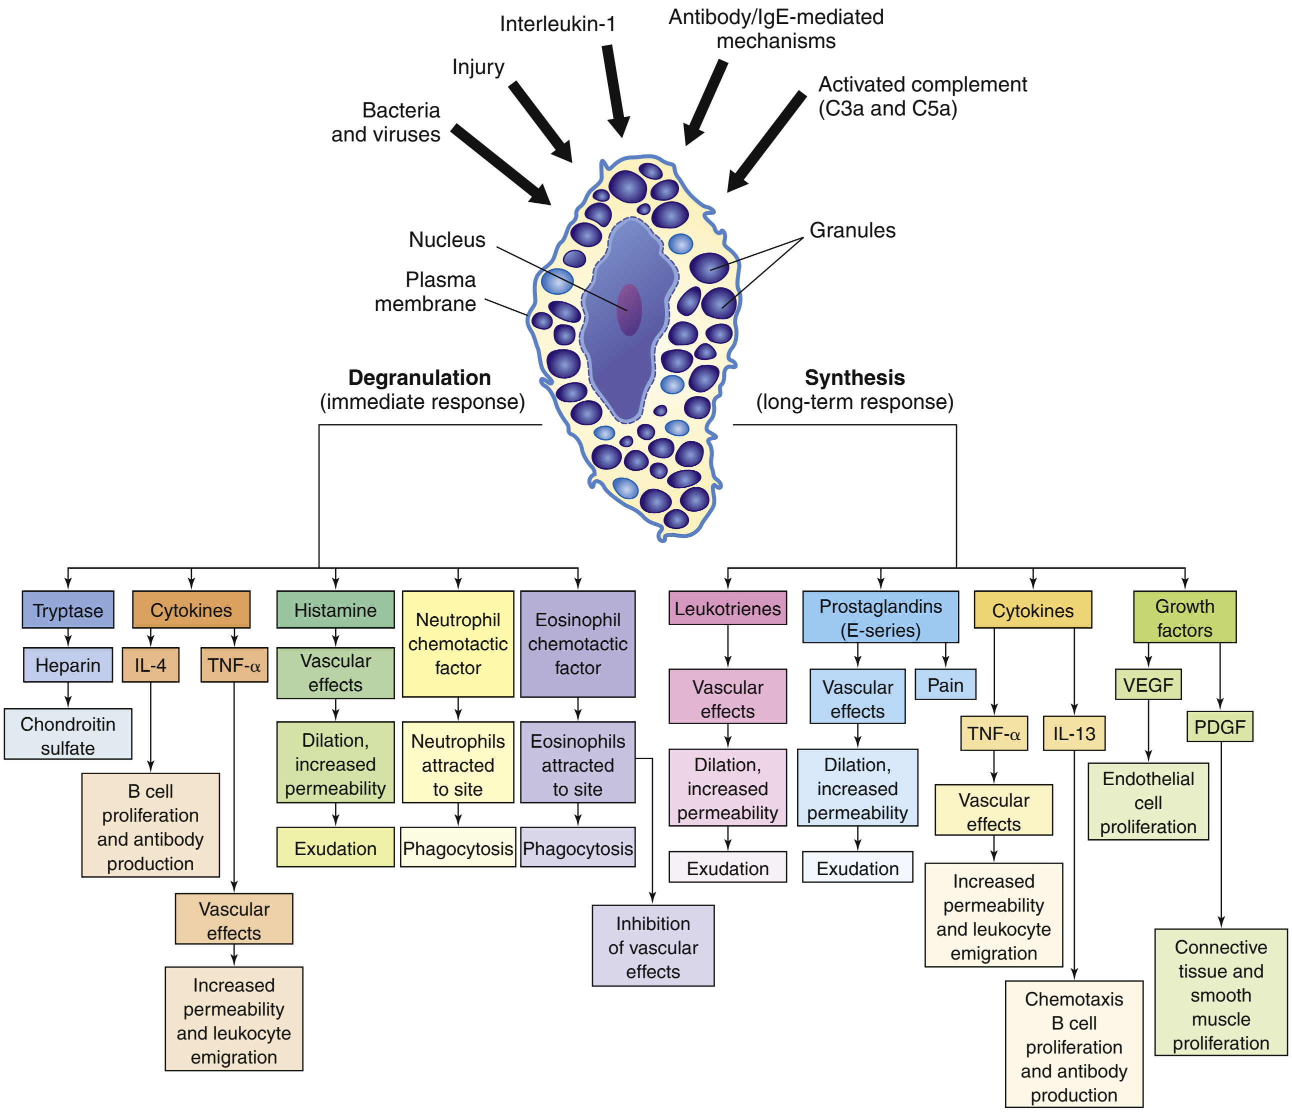

FIGURE 7-11 Effects of Degranulation *(left)* and Synthesis *(right)* by Mast Cells. The depiction of a tissue mast cell shows darkly stained granules in the cytoplasm. *IL-4*, Interleukin-4; *IL-13*, interleukin-13; *PDGF*, platelet-derived growth factor; *TNF-α*, tumor necrosis factor-alpha; *VEGF*, vascular endothelial growth factor.

mechanical trauma, ultraviolet light, and x-rays), (2) chemical agents (e.g., toxins, snake and bee venoms, proteolytic enzymes, and antimicrobial peptides), (3) immunologic means (e.g., anaphylatoxins released during activation of complement components or particular types of antibody [e.g., immunoglobulin E (IgE)] produced by cells of the adaptive immune response [see Chapter 8]), and (4) activation of TLRs by bacteria and viruses. Soluble and extremely potent chemicals from the mast cell are responsible for its effects on inflammation. These are released in two ways: by release of the contents of their preformed granules *(degranulation)* and by new synthesis of lipid-derived inflammatory mediators. Mast cells are also involved in initiating many allergic responses (discussed in Chapters 8 and 9).

Mast Cell Degranulation. In response to a stimulus, biochemical mediators in the mast cell granules, including histamine, chemotactic factors (e.g., neutrophil chemotactic factor, **eosinophil chemotactic factor of anaphylaxis** or **ECF-A**), and cytokines (e.g., TNF-α, IL-4), are released within seconds and exert their effects immediately (see Figure 7-11).

Histamine is a vasoactive amine that causes temporary, rapid constriction of the large vessel walls and dilation of the postcapillary venules, both of which result in increased blood flow into the microcirculation. Histamine also causes increased vascular permeability resulting from retraction of endothelial cells lining the capillaries (see Figure 7-3). The pharmacologic effects of histamine are partially determined by histamine receptors on the person's target cells. Two main histamine receptors are the H1 and H2 receptors (Figure 7-12), and two other receptors, H3 and H4, have been described. Binding of histamine to the *H1 receptor* is essentially proinflammatory; that is, it promotes inflammation. On the other hand, binding to the *H2 receptor* is generally anti-inflammatory because it results in suppression of leukocyte function. The H1 receptor is present on smooth muscle cells, especially those of the bronchi, and causes bronchial smooth

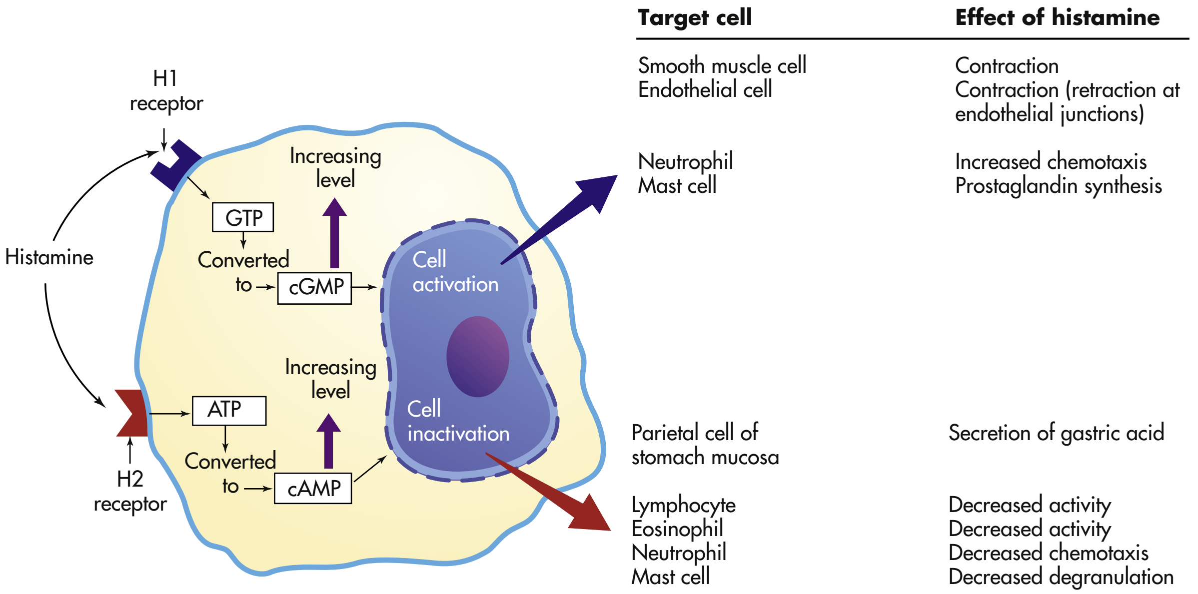

FIGURE 7-12 **Effects of Histamine Through H1 and H2 Receptors.** Effects depend on (1) density and affinity of H1 or H2 receptors on the target cell, and (2) the identity of the target cell. *ATP,* Adenosine triphosphate; *cAMP,* cyclic adenosine monophosphate; *cGMP,* cyclic guanosine monophosphate; *GTP,* guanosine triphosphate.

muscle to contract (bronchoconstriction) when stimulated. Both types of receptors are distributed among many different cells and are often present on the same cells and may act in an antagonistic fashion. For instance, neutrophils express both types of receptors, with stimulation of H1 receptors resulting in the augmentation of neutrophil chemotaxis, and H2 stimulation resulting in its inhibition. The H2 receptor is especially abundant on parietal cells of the stomach mucosa and induces the secretion of gastric acid as part of the normal physiology of the stomach. The role of H1 and H2 receptors is discussed further in Chapter 9.

Two chemotactic factors, neutrophil chemotactic factor and ECF-A, are also released during mast cell degranulation. **Chemotaxis** is directional movement of cells along a chemical gradient formed by a chemotactic factor (see Figure 7-3). **Neutrophil chemotactic factor** attracts neutrophils, and ECF-A attracts eosinophils to the site of inflammation. Neutrophils are the predominant leukocytes at work during the early phases of acute inflammation, and eosinophils have several functions in the inflammatory process; both of these important inflammatory cells are discussed in more detail later in this chapter.

Mast Cell Synthesis of Mediators. Activated mast cells begin new synthesis of other mediators of inflammation, including those derived from plasma membrane lipids, cytokines (TNF-α, various interleukins), and factors that stimulate cell growth and angiogenesis. Leukotrienes, prostaglandins, and platelet-activating factor are lipid-derived products that are synthesized during mast cell activation (Figure 7-13). Leukotrienes are a product of another lipid, arachidonic acid, which is released from mast cell membranes by an intracellular phospholipase that acts on membrane phospholipids.[22] **Leukotrienes** are acidic, sulfur-containing lipids that produce effects similar to those of histamine, namely, smooth muscle contraction, increased vascular permeability, and perhaps neutrophil and eosinophil chemotaxis. Leukotrienes appear to be important in the later stages of the inflammatory response because they stimulate slower and more prolonged responses than do histamines.[23]

The mast cell also synthesizes **prostaglandins,** which, like leukotrienes, are a product of arachidonic acid and cause increased vascular permeability and neutrophil chemotaxis. Prostaglandins also induce pain. They are long-chain unsaturated fatty acids produced by the action of the enzyme *cyclooxygenase* and are classified into groups (E, D, A, F, and B) according to their structure. Prostaglandins E_1 and E_2 cause increased vascular permeability and smooth muscle contraction, apparently acting directly on postcapillary venules.[24] They can inhibit some aspects of inflammation by suppressing both the release of histamine from mast cells and the release of lysosomal enzymes (enzymes responsible for killing and digesting microorganisms) from neutrophils. Enhancement or suppression of the inflammatory response may be related to the concentration of prostaglandins. Aspirin and some other nonsteroidal anti-inflammatory drugs (NSAIDs) block the synthesis of prostaglandins of the E series and other arachidonic acid derivatives, thereby inhibiting inflammation.

Platelet-activating factor (PAF), another mast cell–derived lipid, is produced by removal of a fatty acid from the plasma membrane phospholipid phosphatidylcholine by phospholipase A_2. Although mast cells are a major source of PAF, this molecule also can be produced during inflammation by neutrophils, monocytes, endothelial cells, and platelets. The biologic activity of PAF is virtually identical to that of leukotrienes, namely, causing endothelial cell retraction to increase vascular permeability, leukocyte adhesion to endothelial cells, and platelet activation.

Endothelium

The blood vessel walls consist of a layer of endothelial cells that adhere to an underlying matrix of connective tissue that

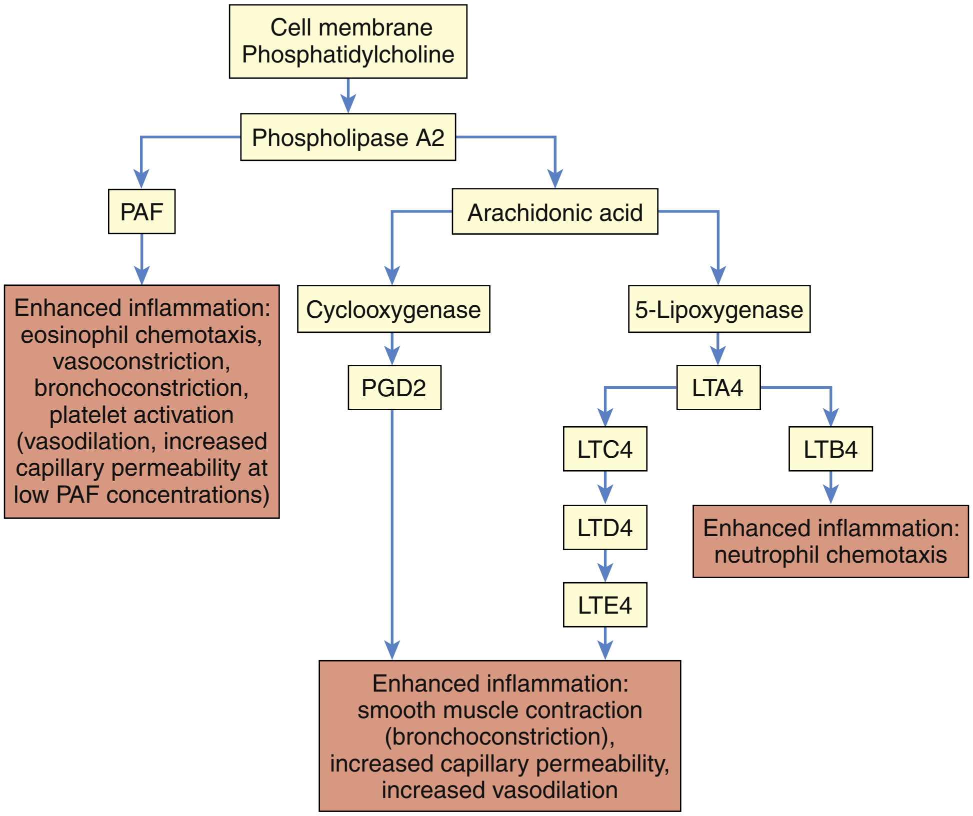

FIGURE 7-13 Production of Lipid Vasoactive Substances by Mast Cells. *LTA4, LTC4, LTD4, LTE4, LTB4,* Various leukotriene molecules; *PAF,* platelet-activating factor; *PGD2,* prostaglandin D2.

contains a variety of proteins, including collagen, fibronectin, and laminins. Circulating cells and platelets and components of plasma protein systems continually contact endothelial cells, which contribute to regulation of normal blood flow by preventing spontaneous activation of platelets and members of the clotting system. Endothelial cells produce nitric oxide (NO) from arginine and prostacyclin (PGI_2) from arachidonic acid. Both NO and PGI_2 maintain blood flow and pressure and inhibit platelet activation. PGI_2 and NO are synergistic. NO is released continually to relax vascular smooth muscle and suppress the effects of low levels of cytokines, thus maintaining vascular tone. PGI_2 production varies a great deal and is increased when additional regulation is needed.

Damage to the endothelial cell lining of the vessel exposes the subendothelial connective tissue matrix, which is prothrombogenic, and initiates platelet activation and formation of clots (the contact activation [intrinsic] clotting pathway). Proinflammatory cytokines affect the endothelium, resulting in adherence of leukocytes to the vessel surface, invasion of leukocytes into the tissue, and efflux of plasma from the vessel.

Platelets

Platelets (thrombocytes) are cellular fragments formed from megakaryocytes. They circulate in the bloodstream until vascular injury occurs, after which platelets can be activated by many products of both the innate and the adaptive immune responses, including collagen, thrombin, thromboxane, PAF, and antigen-antibody complexes.[25] Activation results in (1) the interaction of platelets with components of the coagulation cascade to stop bleeding, and (2) degranulation. Platelets contain alpha (α) granules and dense granules. *Alpha granules* generally contain polypeptides that affect inflammation, including coagulation proteins (e.g., fibrinogen, factor V), soluble adhesion molecules (e.g., von Willebrand factor, vitronectin), growth factors (e.g., platelet-derived growth factor, epidermal growth factor), protease inhibitors (e.g., plasminogen activator inhibitor-1, α_2-antiplasmin), and membrane adhesion molecules (e.g., P-selectin, αIIbβ3). *Dense granules* contain several small molecules, including adenosine diphosphate (ADP), serotonin, calcium, and magnesium. Serotonin is a vasoactive amine with vascular effects similar to those of histamine. (Platelet function is described in detail in Chapter 27.)

Phagocytes

The primary role of most granulocytes (neutrophils, eosinophils, basophils) and monocytes/macrophages is **phagocytosis;** the process by which a cell ingests and disposes of damaged cells and foreign material, including microorganisms.

Neutrophils. The **neutrophil,** or **polymorphonuclear neutrophil (PMN),** is a member of the granulocytic series named for the characteristic staining pattern of its granules as well as its multilobed nucleus. Neutrophils are the predominant **phagocytes** in the early inflammatory site, arriving within 6 to 12 hours after the initial injury, where they ingest (phagocytose) bacteria, dead cells, and cellular debris. Several inflammatory mediators (e.g., some bacterial proteins, complement fragments

C3a and C5a, and mast cell neutrophil chemotactic factor) specifically attract neutrophils from the circulation and activate them. Macrophages and lymphocytes, on the other hand, enter the site later, usually after 24 hours, and gradually replace the neutrophils.

Because the neutrophil is a mature cell incapable of division and sensitive to the acidic environment of inflammatory lesions, it is short-lived at the inflammatory site and becomes a component of the purulent exudate, or *pus,* which is removed from the body through the epithelium or through the lymphatic system. (The lymphatic system is described in Chapter 27.) The primary roles of the neutrophil are removal of debris in sterile lesions, such as burns, and phagocytosis of bacteria in nonsterile lesions.

Eosinophils. Another population of granulocytes is the **eosinophil.** Eosinophils have two specific functions: (1) they serve as the body's primary defense against parasites and (2) they help regulate vascular mediators released from mast cells. Their role in resistance to parasites occurs in collaboration with specific antibodies produced by the adaptive immune system and will be discussed in Chapter 8.

The second function, regulation of mast cell–derived inflammatory mediators, is a critical function of eosinophils. As with most defense systems of the body, the acute inflammatory response is usually needed only in a circumscribed area and for a limited time. Therefore, control mechanisms are necessary to prevent biochemical mediators from evoking more inflammation than is needed. Mast cells produce ECF-A, which attracts eosinophils to the site of inflammation. Eosinophil lysosomes contain several enzymes that degrade vasoactive molecules, thereby controlling the vascular effects of inflammation. These enzymes include histaminase, which mediates the degradation of histamine, and arylsulfatase B, which mediates the degradation of some of the lipid-derived mediators produced by mast cells.

Basophils. The **basophil** is the least prevalent granulocyte in the blood. It is very similar to mast cells in the content of its granules and, in addition, is an important source of the cytokine IL-4, which is a key regulator of the adaptive immune response. Although often associated with allergies and asthma, its primary role is yet unknown.

Monocytes and Macrophages. **Monocytes** are the largest normal blood cells (14 to 20 μm in diameter) and have a nucleus that is often indented, or horseshoe shaped. Monocytes are produced in the bone marrow, enter the circulation, and migrate to the inflammatory site where they develop into macrophages. Monocytes also appear to be the precursors of macrophages that are found in tissues (tissue macrophages, discussed in Chapter 8), including Kupffer's cells in the liver, alveolar macrophages in the lungs, and microglia in the brain.[26] **Macrophages** are generally larger (20 to 40 μm) and are more active as phagocytes than their monocytic precursors. Macrophages, particularly those residing in the tissues, are often important cellular initiators of the inflammatory response (Figure 7-14).

Phagocytosis. Because most phagocytes are circulating in the blood, they must leave the bloodstream and migrate to the site of inflammation before initiating phagocytosis (Figure 7-15). Under normal conditions, the circulation in the capillaries and venules is rapidly moving with red blood cells in the main stream and neutrophils and other leukocytes tending to flow more slowly along the vessel's periphery. Many of the biochemical products produced early at inflammatory sites (e.g., histamine, TNF-α, bradykinin, leukotrienes, prostaglandins) diffuse to the vessels and affect both leukocytes and endothelial cells. Both cell populations respond by producing new **adhesion molecules** (selectins and integrins) on their surfaces (Table 7-3) (see p. 202 for integrins). **Selectins** are adhesion molecules that bind carbohydrate ligands. The reciprocal change in adhesion molecules on leukocytes, as well as platelets, promotes their interaction with the endothelial cells. The initial change of surface molecules increases the adhesion, or stickiness, between leukocytes and endothelial cells, causing the leukocytes to adhere more avidly to the walls of the capillaries and venules in a process called **margination,** or **pavementing.** Adhesion molecules that are expressed later lead to **diapedesis,** or emigration of the cells through the endothelial junctions that have retracted in response to the same mediators. The leukocytes digest the basement membrane and migrate into the surrounding tissues.

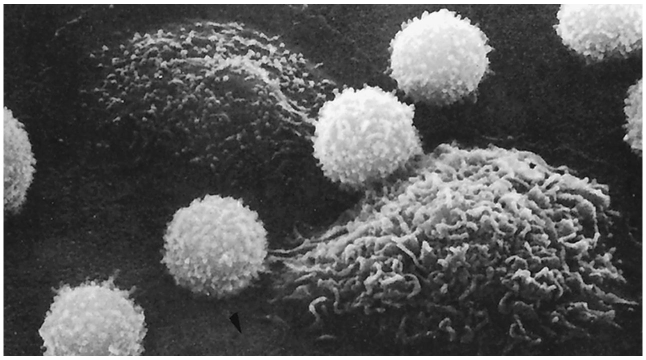

FIGURE 7-14 **Scanning Electron Micrograph of Lymphocytes and Macrophages.** The lymphocytes are small and spherical; the macrophages are larger and more irregular in shape. (From Raven PH, Johnson GB: *Biology,* St Louis, 1992, Mosby.)

Additionally, **endothelial cells** release NO, a gas that under normal conditions maintains vascular tone. Inflammation induces additional endothelial nitric oxide synthase, increasing the amount of NO production. Effects of NO on inflammation include vasodilation by inducing relaxation of vascular smooth muscle, a response that is local and short-lived, and suppression of mast cell function as well as platelet adhesion and aggregation.

Once inside the connective tissue in the perivascular space, leukocytes migrate to the inflammatory site by means of chemotaxis. They detect chemotactic factors in the environment through chemoreceptors at multiple locations on their plasma membranes and migrate in the direction of highest concentration (see Figure 7-15). The primary chemotactic factors include many bacterial products, complement fragments C3a and C5a, kallikrein, plasminogen activator, products of fibrin degradation (fibrinopeptides), and chemokines. Eosinophils and neutrophils also respond to chemotactic factors

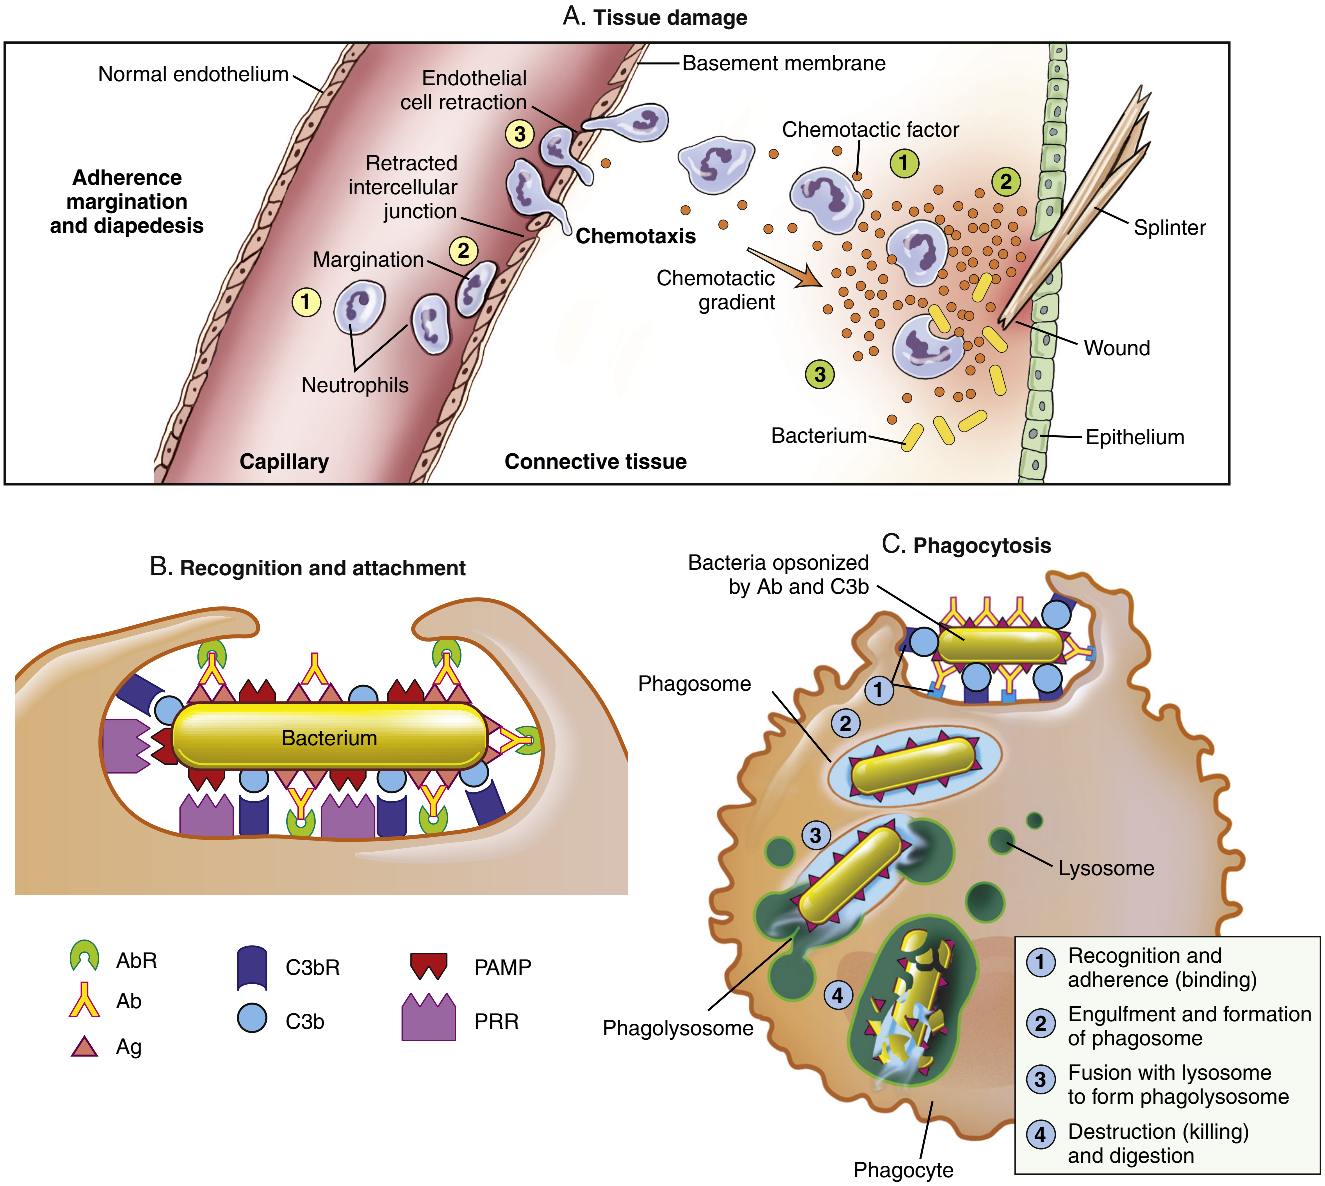

FIGURE 7-15 **Process of Phagocytosis.** The process that results in phagocytosis is characterized by three interrelated steps: adherence and diapedesis, tissue invasion by chemotaxis, and phagocytosis. **A, Tissue damage.** *Adherence, margination, and diapedesis:* The primary phagocyte in the blood is the neutrophil, which usually moves freely within the vessel **(1).** At sites of inflammation, the neutrophil progressively develops increased adherence to the endothelium, leading to accumulation along the vessel wall (margination or pavementing) **(2).** At sites of endothelial cell retraction the neutrophil exits the blood by means of diapedesis **(3).** *Chemotaxis:* In the tissues, the neutrophil detects chemotactic factor gradients through surface receptors **(1)** and migrates towards higher concentrations of the factors **(2).** The high concentration of chemotactic factors at the site of inflammation immobilizes the neutrophil **(3). B, Recognition and attachment.** *Specific receptors and ligands for recognition and attachment.* **C, Phagocytosis. (1)** Opsonized microorganisms bind to the surface of a phagocyte through specific receptors. **(2)** The microorganism is engulfed (ingested) into a phagocytic vacuole, or phagosome. **(3)** Lysosomes fuse with the phagosome, resulting in the formation of a phagolysosome. During this process the microorganism is exposed to products of the lysosomes, including a variety of enzymes and products of the hexose-monophosphate shunt (e.g., H_2O_2, O_2^-). **(4)** The microorganism is killed and digested. *Ab,* Antibody; *AbR,* antibody receptor; *Ag,* antigen; *C3b,* complement component C3b; *C3bR,* complement C3b receptor; *PAMP,* pathogen-associated molecular pattern; *PRR,* pattern recognition receptor.

released from mast cells (ECF-A, neutrophil chemotactic factor [NCF]). Monocytes are attracted toward a factor (monocyte chemotactic factor) that has been released by neutrophils already at the site of injury. And although histamine is not itself chemotactic, it may facilitate the chemotactic effects of other factors.

Once the phagocytic cell enters the inflammatory site, the process of phagocytosis involves four steps: (1) *opsonization (recognition* of the target and *adherence* of the phagocyte to it); (2) *engulfment* (ingestion or endocytosis) and *formation of phagosome;* (3) *fusion* with lysosomal granules within the phagocyte (phagolysosome); and (4) *destruction* of the target

(see Figure 7-15, *C*) (lysosomes are described in Chapter 1). Throughout the process, both the target and the digestive enzymes are isolated within membrane-bound vesicles. Isolation protects the phagocyte itself from the harmful effects of the target microorganisms, as well as its own enzymes.

Most phagocytes can trap and engulf bacteria using cellular PRRs and PAMPs normally expressed on the bacterial surface (see Figure 7-15, *B*). However, that process is slow and inefficient. Opsonization, usually by antibody or complement component C3b, greatly enhances both recognition and adherence. Phagocytosis of an opsonized (antibody and/or complement-protein coated) red blood cell is illustrated in Figure 7-16. Opsonins function as "glue" between the phagocyte and the target cell because receptors on the phagocyte are specific for sites on the opsonin (Fc receptors for antibody, C3b receptors for C3b). This enables the phagocyte to bind an opsonized target very tightly to its surface. Antibody forms a stronger attachment, but C3b facilitates phagocytosis to a greater extent.

Although the inflammatory response is considered to be nonspecific, opsonins and other recognition molecules add a degree of specificity to efficient phagocytosis. Antibodies on the surface of bacteria are directed against antigens that are highly specific to that particular microorganism. If the complement fragment C3b serves as an opsonin, those bacteria with certain polysaccharide coatings are particularly sensitive to activation of the alternative and lectin pathways of complement activation.

Engulfment (endocytosis) is carried out by small pseudopods that extend from the plasma membrane and surround the adherent microorganism (see Figures 7-15 and 7-16), forming an intracellular phagocytic vacuole, or **phagosome.** The membrane that surrounds the phagosome consists of inverted plasma membrane. After the formation of the phagosome, lysosomes converge, fuse with the phagosome, and discharge their contents, creating a **phagolysosome.** The **primary lysosomal granules** *(azurophilic granules)* contain a variety of bactericidal molecules, including myeloperoxidase, lysozyme, defensins, acid hydrolases, elastase, and others. Most phagocytes also contain **secondary granules** *(specific granules)* with molecules that are bactericidal and involved in remodeling the surrounding tissue, including lysozyme, collagenase, lactoferrin, and other proteases. Destruction of the bacterium takes place within the phagolysosome and is accomplished by both oxygen-dependent and oxygen-independent mechanisms.

Phagocytosis is accompanied by a burst of oxygen uptake by the phagocyte, termed the "respiratory burst," which results from a shift in much of the cell's glucose metabolism to the hexose-monophosphate shunt. The nicotinamide adenine dinucleotide phosphate (NADPH) that is produced because of this shift is used by a membrane-associated enzyme, NADPH oxidase, to generate superoxide, a reactive oxygen intermediate that is converted to hydrogen peroxide and other reactive oxygen species. These steps comprise the *oxygen-dependent killing mechanism.* Many of the reactive oxygen species are directly toxic to the microorganism. Hydrogen peroxide also can collaborate with the lysosomal enzyme *myeloperoxidase* and halide anions (Cl^- and Br^-) to form acids, such as hypochlorous (HClO) and hypobromous (HBrO) acids.[27] These acids probably kill bacteria and fungi by adding Cl^- or Br^- to the surface of these cells. *Oxygen-independent mechanisms* of microbial killing are likely the result of (1) the acidic pH (3.5 to 4.0) of the phagolysosome caused by lactic acid production; (2) the presence of cationic proteins, such as defensins and cathelicidins, that bind to and damage target cell membranes; (3) enzymatic attack of the mucopeptides in the target cell wall by lysozyme and elastase; and (4) inhibition of bacterial growth by lactoferrin binding of iron.

When a phagocyte dies at an inflammatory site, it frequently lyses (breaks open) and releases its cytoplasmic contents, including the lysosomal enzymes, into the tissue. Enzymes released from lysosomes can digest the connective tissue matrix, causing much of the tissue destruction associated with inflammation. The destructive effects of many enzymes released by dying phagocytes are minimized by natural inhibitors found in the blood, such as **α_1-antitrypsin,** a plasma protein produced by the liver. An inherited deficiency of α_1-antitrypsin often results in chronic lung damage and emphysema as a result of inflammation. (The pulmonary effects of α_1-antitrypsin deficiency are described in Chapter 35.) Released lysosomal products also may contribute to inflammation by increasing vascular permeability, attracting additional monocytes, and activating the complement and kinin systems.

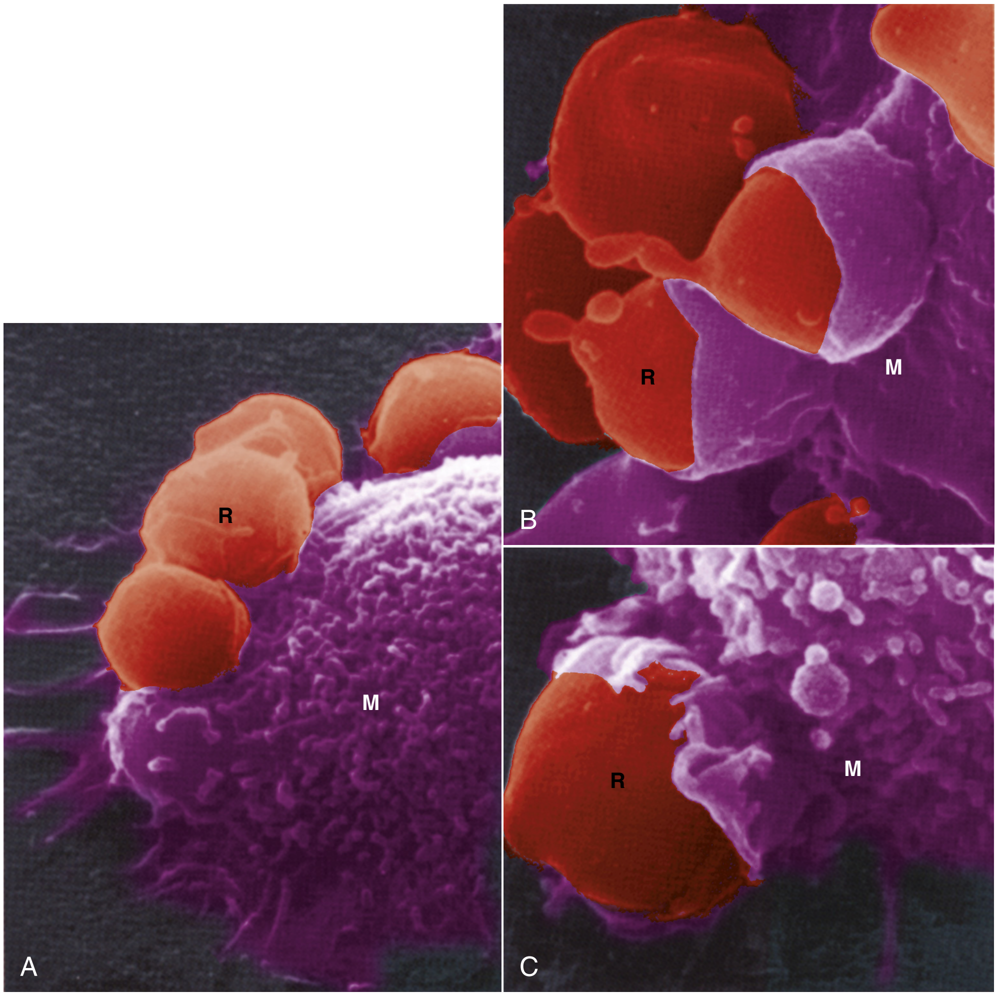

FIGURE 7-16 **Steps in Phagocytosis.** This scanning electron micrograph shows the progressive steps in phagocytosis. **A,** Red blood cells *(R)* attach to the surface of a macrophage *(M)*. **B,** Part of the macrophage *(M)* membrane starts to enclose the red cell *(R)*. **C,** The red blood cells are almost totally engulfed by the macrophage. (From King DW, Fenoglio CM, Lefwitch JH: *General pathology: principles and dynamics,* Philadelphia, 1983, Lea & Febiger.)

Monocyte-derived macrophages from the circulation may appear at the inflammatory site as soon as 24 hours after the initial neutrophil infiltration, but usually arrive 3 to 7 days later. They migrate to the site more slowly than neutrophils because they move more sluggishly and also because many of the chemotactic factors that attract them, such as macrophage chemotactic factor, must first be released by neutrophils.[28] Macrophages are better suited than neutrophils to long-term defense against infectious agents because macrophages can survive and divide in the acidic inflammatory site or where there is low oxygen tension.

Neutrophils and monocytes/macrophages differ chiefly in the following ways:

1. *Speed:* Neutrophils arrive at the injury site first.
2. *Active life span:* Macrophages survive and divide in the inflammatory site, whereas neutrophils cannot.
3. *Chemotactic factors:* Neutrophils and macrophages are not attracted by the same factors.
4. *Enzymatic content of their lysosomes, or digestive vacuoles, differs.*
5. *Role in the immune response:* Macrophages, but not neutrophils, are involved in activation of the adaptive immune system.
6. *Role in wound repair:* Macrophages are the primary cells that infiltrate tissue in wounds, remove cells and cellular debris, and produce cytokines that suppress further inflammation and initiate healing.

Macrophage Activation. Several bacteria are resistant to killing by granulocytes and can even survive inside macrophages. Microorganisms such as *Mycobacterium tuberculosis* (tuberculosis), *Mycobacterium leprae* (leprosy), *Salmonella typhi* (typhoid fever), *Brucella abortus* (brucellosis), and *Listeria monocytogenes* (listeriosis) can remain dormant or even multiply inside the phagolysosomes of macrophages. However, the bactericidal activity of macrophages can be markedly increased with the help of inflammatory **cytokines** produced by cells of the adaptive immune system (subsets of T lymphocytes) or cells activated through Toll-like receptors (TLRs). (Cytokines were discussed in detail earlier in this chapter [see p. 203]) Macrophages have cell surface receptors

for these cytokines and are further activated to become more effective killers of infectious microorganisms.

Macrophage activation results in increased (1) phagocytic activity, (2) size, (3) plasma membrane area, (4) glucose metabolism, and (5) number of lysosomes. Activated macrophages also secrete factors that stimulate the growth, differentiation, and activation of additional inflammatory cells as well as control the initiation of healing processes. These include granulocyte colony-stimulating factor (G-CSF), interferon-gamma (IFN-γ), interleukin-1β (IL-1β), angiogenic factor, fibroblast activating factor, and growth factors that promote regrowth of damaged tissues. Macrophages are also the primary cells that infiltrate wounds to remove cellular debris and initiate the regenerative process. In some cases, inadequate macrophage activation results from defects in the adaptive immune responses and deficits in the production of appropriate cytokines. For example, a form of leprosy called *lepromatous leprosy* is characterized by the survival of phagocytosed *M. leprae* bacteria in macrophage phagolysosomes. In individuals with lepromatous leprosy, cells of the adaptive immune system have failed to secrete the cytokines necessary to transform macrophages into highly efficient killing cells.

Natural Killer Cells and Lymphocytes

The main function of **natural killer (NK) cells** is recognition and elimination of cells infected with viruses, although they are also somewhat effective at elimination of other abnormal host cells, specifically cancer cells. NK cells seem to be more efficient in this role when they encounter an infected cell within the circulatory system as opposed to within tissues.[29] Along with TLRs, NK cells have additional inhibitory and activating receptors that allow differentiation between infected or tumor cells and normal cells. If the NK cell binds to a target cell through activating receptors, it produces several cytokines and toxic molecules that can kill the target. NK cells and lymphocytes, which are the principal cells of the adaptive immune response, will be discussed in much more detail in Chapter 8.

LOCAL MANIFESTATIONS OF INFLAMMATION

The cells and plasma protein systems described previously interact to produce all the characteristics of inflammation, whether local or systemic, as well as determine the duration of inflammation, either acute or chronic. Local inflammation accompanies all types of cellular and tissue injury, whether infected or sterile, from fractures or strains of the musculoskeletal system to burn injuries (see Chapter 2), and is responsible for initiating healing.

All the *local* manifestations of acute inflammation (i.e., swelling, pain, heat, and redness) result from vascular changes and the subsequent leakage of circulating components into the tissue. **Heat** and **redness** are the result of vasodilation and increased blood flow through the injured site. **Swelling** occurs as exudate (fluid and cells) accumulates. Swelling is usually accompanied by **pain** caused by pressure exerted by exudate accumulation, as well as the presence of soluble biochemical mediators such as prostaglandins and bradykinin. Loss of function may be associated with these manifestations.

Exudate varies in composition, depending on the stage of the inflammatory response and, to some extent, the injurious stimulus. In early or mild inflammation, the exudate is watery **(serous)** with very few plasma proteins or leukocytes. An example of serous exudate is the fluid in a blister. In more severe or advanced inflammation, the exudate may be thick and clotted **(fibrinous exudate),** such as in the lungs of individuals with pneumonia. If a large number of leukocytes accumulate, as in persistent bacterial infections, the exudate consists of pus and is called a **purulent (suppurative) exudate.** Purulent exudate is characteristic of walled-off lesions **(cysts** or **abscesses).** If bleeding occurs, the exudate is filled with erythrocytes and is described as a **hemorrhagic exudate.**

Although the local manifestations of inflammation can affect all vascularized tissues, lesions vary depending on the organ or tissue involved. The lesion resulting from widespread cellular death (necrosis), for example, differs in myocardial (heart muscle), brain, and hepatic (liver) tissues. Cellular death resulting from myocardial infarction (deprivation of oxygen caused by cessation of blood flow) causes a response that proceeds to replacement of the dead tissue with a fibrinous scar. The same injury to brain tissue is more likely to result in the formation of an abscess filled with necrotic tissue (types of necrosis are described in Chapter 2). Destruction of liver tissue stimulates the regrowth, or regeneration, of liver cells.

SYSTEMIC MANIFESTATIONS OF ACUTE INFLAMMATION

The three primary *systemic* changes associated with the acute inflammatory response are fever, leukocytosis (a transient increase in the levels of circulating leukocytes), and plasma protein synthesis (increased levels of circulating plasma proteins).

Fever

An early systemic response is **fever,** which is partially induced by specific cytokines, for example, IL-1 released from neutrophils and macrophages. These fever-causing cytokines are known as **endogenous pyrogens** to differentiate them from pathogen-produced *exogenous pyrogens.* Pyrogens act directly on the hypothalamus, the portion of the brain that controls the body's thermostat. The release of endogenous pyrogens by inflammatory cells occurs after phagocytosis, after exposure to bacterial endotoxins, or after exposure to antigen-antibody complexes. (Mechanisms of temperature regulation are discussed in Chapter 16.)

The generation of a febrile response can be beneficial because the microorganisms that cause some conditions (e.g., syphilis, gonococcal urethritis) are highly sensitive to small increases in body temperature. On the other hand, fever may have some harmful side effects because it may enhance the person's susceptibility to the effects of endotoxins associated with gram-negative bacterial infections (bacterial toxins are described in Chapter 2).

Leukocytosis

Another systemic change associated with acute inflammation is **leukocytosis.** During many infections, the numbers of

TABLE 7-4 CIRCULATING LEVELS OF ACUTE-PHASE REACTANTS DURING INFLAMMATION

FUNCTION	INCREASED	DECREASED
Coagulation components	Fibrinogen Prothrombin Factor VIII Plasminogen	None
Protease inhibitors	α_1-Antitrypsin α_1-Antichymotrypsin	Inter-α-antitrypsin
Transport proteins	Haptoglobin Hemopexin Ceruloplasmin Ferritin	Transferrin
Complement components	C1s, C2, C3, C4, C5, C9, factor B, C1 inhibitor	Properdin
Miscellaneous proteins	α_1-Acid glycoprotein Fibronectin Serum amyloid A (SAA) C-reactive protein (CRP)	Albumin Prealbumin α_1-Lipoprotein β-Lipoprotein

circulating leukocytes, primarily neutrophils, increase. This increase is usually accompanied by a "left shift" in the ratio of immature to mature neutrophils, so that the more immature forms of neutrophils, such as band cells, metamyelocytes, and occasionally myelocytes, are present in relatively greater than normal proportions. (Chapter 27 discusses the development and maturation of blood cells.) Production of immature leukocytes increases primarily because proliferation and release of granulocyte and monocyte precursors in the bone marrow are stimulated by several products of inflammation, including complement product C3a and G-CSF.

Plasma Protein Synthesis

The synthesis of many plasma proteins, most of which are products of the liver, is increased during the primary stages of inflammation. These proteins, which can be either proinflammatory or anti-inflammatory in nature, are referred to as **acute-phase reactants** (Table 7-4). Acute-phase reactants reach maximal circulating levels within 10 to 40 hours of initial infection. In addition to inducing fever, IL-1 also indirectly induces the synthesis of acute-phase reactants. IL-1 up-regulates release of IL-6, which then increases synthesis of acute-phase reactants directly by stimulating liver cells. Administration of IL-1 into animals leads to fever and elevation of most acute-phase reactants, including fibrinogen, C-reactive protein, haptoglobin, amyloid A, α_1-antitrypsin, and ceruloplasmin.

Acute inflammation can be verified by a series of hematologic tests, which are described in detail in Chapter 27. For example, an increase in blood levels of acute-phase reactants, primarily fibrinogen, is usually associated with an increased erythrocyte sedimentation rate. The alteration in plasma proteins probably leads to an enhanced erythrocyte rouleaux formation (stacking of erythrocytes, as in a stack of coins) and thereby an increased rate of sedimentation. Although increased erythrocyte sedimentation is a nonspecific reaction, it is considered a good indicator of an acute inflammatory response. Other symptoms of acute inflammation include somnolence (drowsiness), malaise (generalized feeling of discomfort or illness), anorexia (lack of desire to eat), and muscle aching.

CHRONIC INFLAMMATION

Superficially, the difference between acute and chronic inflammation is purely one of duration, in that chronic inflammation lasts 2 weeks or longer, regardless of cause. Characteristic histologic and mechanistic differences also may be present (Figure 7-17). Chronic inflammation is sometimes preceded by an unsuccessful acute inflammatory response. For example, if bacterial contamination or foreign objects (e.g., dirt, wood splinters, glass) persist in a traumatic wound, an acute response may be prolonged beyond 2 weeks. Pus formation, suppuration (purulent discharge), and incomplete wound healing may characterize this type of chronic inflammation.

Chronic inflammation can occur also as a distinct process without much previous acute inflammation. Some microorganisms (e.g., mycobacteria that cause tuberculosis) have cell walls with a very high lipid and wax content, making them relatively insensitive to degradation by phagocytes and therefore relatively resistant to clearance in an acute inflammatory response. Other microorganisms, such as those that cause leprosy, syphilis, and brucellosis, can survive within the macrophage and thereby also avoid clearance by the acute inflammatory response. In addition, some microorganisms produce toxins that stimulate tissue-damaging reactions even after they themselves are killed. Persistent inflammation can result from prolonged irritation by these toxins. Finally, chemicals, particulate matter, or physical irritants (e.g., inhaled dusts, wood splinters, and suture material) also can cause an inflammatory response that lasts longer than 2 weeks.

Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. If macrophages are unable to limit the tissue damage or infection, the body attempts to wall off and isolate the infected area, thus forming a **granuloma** (Figure 7-18).[30] Granulomas may form if neutrophils and macrophages are unable to destroy microorganisms during the acute inflammatory response. For example, infections caused by some bacteria (*Listeria* sp., *Brucella* sp.), fungi (histoplasmosis, coccidioidomycosis), and parasites (leishmaniasis, schistosomiasis, toxoplasmosis) can result in granuloma formation. Large antigen-antibody complexes such as those present in rheumatoid arthritis also can result in the formation of these structures. The process of granuloma formation begins when some of the macrophages differentiate into large **epithelioid cells,** cells that are incapable of phagocytosing large bacteria but are capable of taking up debris and other small particles. Other macrophages fuse into multinucleated **giant cells,** which are active phagocytes that can engulf very large particles—larger than those that can be engulfed by a single macrophage. These two types of differentiated macrophages form the center of the granuloma, which is surrounded by a wall of lymphocytes. The granuloma itself is also often encapsulated by fibrous deposits of collagen and may become cartilaginous or possibly calcified by deposits of calcium carbonate and calcium phosphate.

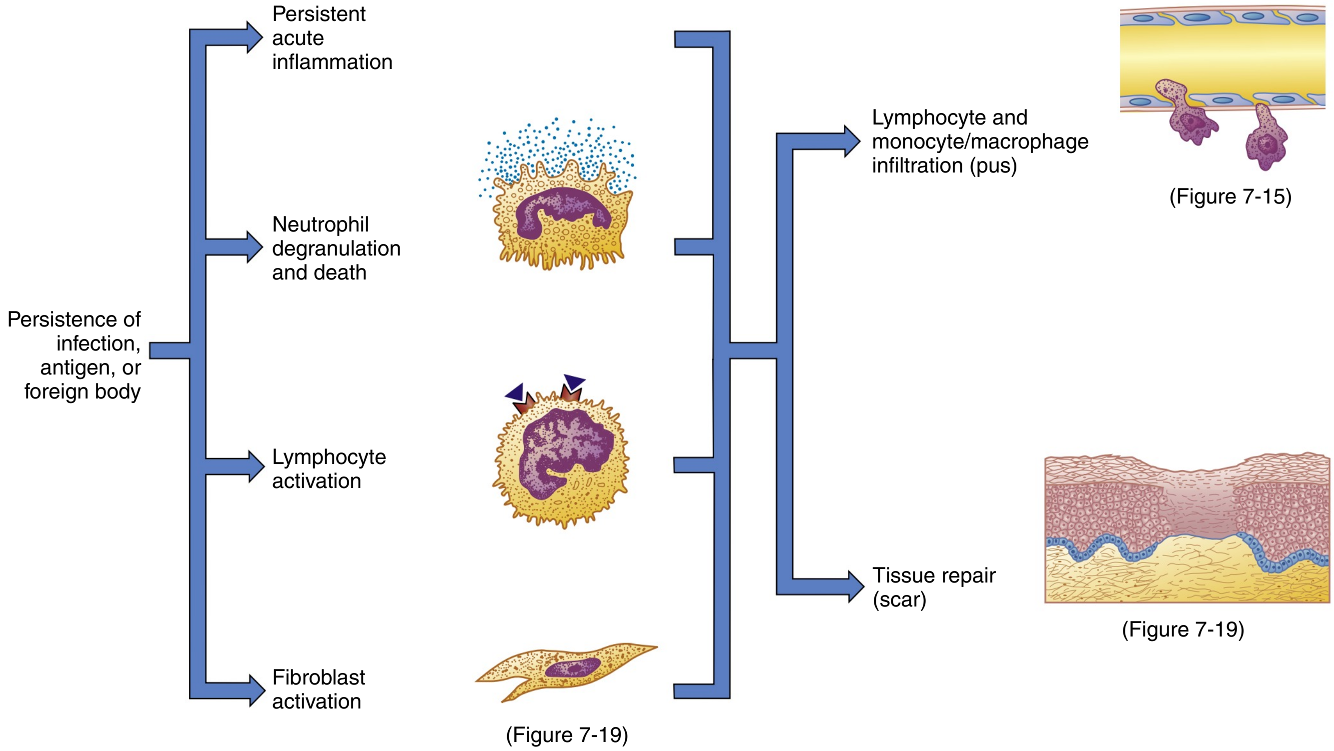

FIGURE 7-17 The Chronic Inflammatory Response. Inflammation usually becomes chronic because of the persistence of an infection, an antibody, or a foreign body in the wound. Chronic inflammation is characterized by the persistence of many of the processes of acute inflammation. In addition, the presence of large amounts of neutrophil degranulation and death, the activation of lymphocytes, and the concurrent activation of fibroblasts result in the release of mediators that induce the infiltration of more lymphocytes and monocytes/macrophages and the beginning of wound healing and tissue repair.

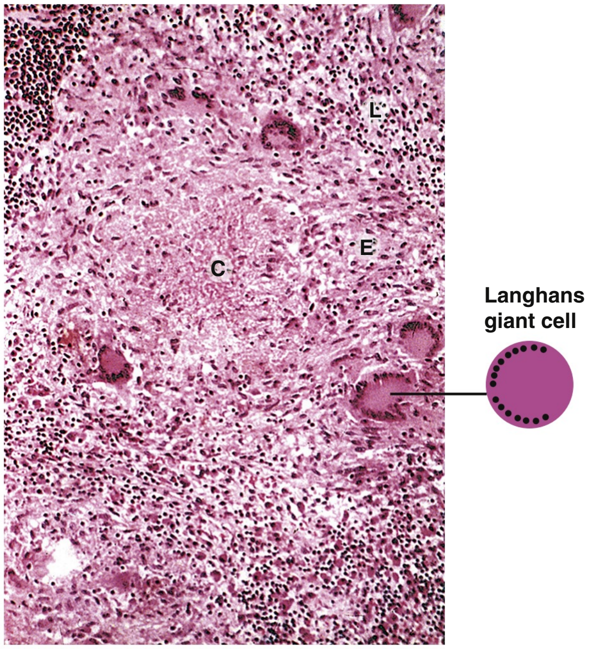

FIGURE 7-18 Tuberculous Granuloma. A central area of amorphous caseous necrosis *(C)* is surrounded by a zone of lymphocytes *(L)* and enlarged epithelioid cells *(E)*. Activated macrophages frequently fuse to form multinucleated cells (Langhans giant cells). In tuberculoid granulomas the nuclei of the giant cells move to the cellular margins in a horseshoe-like formation.

The classic granuloma associated with tuberculosis is characterized by a wall of epithelioid cells surrounding a center of dead and decaying tissue (caseous necrosis, see Chapter 2) and mycobacteria. Decay of cells within the granuloma results in the release of acids and the enzymatic contents of lysosomes from dead phagocytes. In this inhospitable environment, the cellular debris is broken down and a clear fluid remains (liquefaction necrosis, see Chapter 2). Eventually this fluid diffuses out and leaves a hollow, thick-walled structure in the tissue that may remain for the life of the individual.

RESOLUTION AND REPAIR

Destruction of tissue is followed by a period of healing that begins during acute inflammation and may not be complete for as long as 2 years. The most favorable outcome of healing is tissue **regeneration** with complete return to normal structure and function. This is an ideal that is often not possible, particularly in adults. If damage is minor, no complications occur, and destroyed tissues are capable of regeneration, it is possible to return injured tissues to an approximation of their original structure and physiologic function. This restoration is called **resolution.** If extensive damage is present, injury occurs in tissues not capable of regeneration, infection results in abscess or granuloma formation, or fibrin persists in the lesion, resolution is not possible and repair takes place instead. **Repair** is the replacement of destroyed tissue with scar tissue. **Scar tissue** is

composed primarily of collagen that seals the lesion and restores tensile strength but cannot execute the physiologic functions of destroyed tissue.

Both regeneration and repair actually begin with phagocytosis of the particulate matter found at the site of injury (fibrin from dissolved clots, microorganisms, erythrocytes, and dead tissue cells). This cleanup of the lesion, which also involves dissolution of fibrin clots (or scabs) by fibrinolytic enzymes, is called **débridement.** After débridement, the remaining debris is drained away by blood vessels and lymphatics, and the vascular dilation and permeability associated with inflammation are reversed, thus preparing the lesion for either regeneration or repair.

Healing always involves processes that (1) fill in, (2) seal, and (3) shrink the wound.[31] These common denominators of healing vary in importance and duration among different types of wounds. A clean incision, such as a paper cut or a sutured surgical wound, heals primarily through the process of collagen synthesis. Because sealing of this type of wound has already been facilitated by minimal tissue loss and close apposition of the wound edges, very little sealing **(epithelialization)** and shrinkage **(contraction)** are required for healing. Wounds that heal under conditions of minimal tissue loss are said to heal by **primary intention** (Figure 7-19).

Other wounds do not heal so neatly and easily. Healing of an open wound, such as a stage IV pressure sore (decubitus ulcer), requires a great deal more tissue replacement than healing of a sutured surgical incision. With an open wound, epithelialization, scar formation, and contraction take longer and healing occurs through **secondary intention** (see Figure 7-19). Healing by either primary or secondary intention may occur at different rates for different types of tissue injury.

Both resolution and repair occur in two overlapping phases. The first phase, called the **reconstructive phase,** begins 3 to 4 days after the initial injury and continues for as long as 2 weeks. During this phase the lesion is characterized by fibroblast (connective tissue cell) proliferation, followed by collagen synthesis by the fibroblasts, epithelialization, contraction of the wound, and cellular differentiation. The second phase, the **maturation phase,** begins several weeks after injury and is normally complete within 2 years. During this phase cellular differentiation, scar formation, and scar remodeling continue.

Reconstructive Phase

Because surgical wounds exhibit both the reconstructive and the maturation phases, they are useful models of both normal and abnormal (dysfunctional) healing. Such wounds are initially sealed off by a blood clot containing fibrin and trapped cells. The cross-linked mesh of fibrin is created by activation of the coagulation cascade and initially traps platelets to form a platelet plug that further seals damaged vessels (see Chapter 27). Most surgical wounds are completely sealed with platelet plugs within hours after closure. This sealing helps unite the wound edges and acts to create a physical barrier to bacterial invasion, although pathogenic invasion is not always prevented. The fibrin mesh ultimately acts as a scaffold for the collagen or regenerated tissue cells that ultimately fill the wound.

For healing to proceed, the fibrin clot must be dissolved and then replaced by normal tissue (for resolution) or scar tissue (for repair). Enzymatic digestion of the clot usually occurs after activation of the plasma fibrinolytic system (plasmin generation, see Chapter 27) or release of lysosomal enzymes from dead neutrophils. Macrophages invade the dissolving clot and, by phagocytosis, clear away debris and dead cells. Débridement by macrophages and remaining neutrophils is followed by regeneration of destroyed cells (resolution) or, if regeneration is not possible, by repair (see Figure 7-19).

The process of healing begins as **granulation tissue** grows inward from surrounding healthy connective tissue. Granulation tissue is filled with new capillaries (angiogenesis) that give it a red, granular appearance and is surrounded by fibroblasts and macrophages. First, capillary buds sprout from vascular endothelial cells around the wound and extend into the débrided areas. Loops form when the young capillaries join *(anastomose).* The loops are more fragile and permeable than mature vessels, resulting in leakage of erythrocytes and neutrophils. The erythrocytes are phagocytosed by macrophages and the neutrophils assist in further débridement of the inflammatory lesion. Many of the new capillaries differentiate into larger vessels as repair continues promoting influx of nutrients and removal of metabolic wastes. New lymphatic vessels also grow into the granulation tissue by a similar process.

In addition to their role in débriding, macrophages at the site of injury secrete several biochemical mediators and cytokines that orchestrate and promote healing. The following are some examples of these mediators:

1. **Transforming growth factor-beta (TGF-β)** stimulates fibroblasts entering the lesion to synthesize and secrete the collagen precursor **procollagen.**
2. **Angiogenesis factors,** such as vascular endothelial growth factor (VEGF) and fibroblast growth factor-2 (FGF-2), stimulate vascular endothelial cells to form capillary buds that grow into the wound.
3. **Matrix metalloproteinases (MMPs)** may function in the degradation and remodeling of extracellular matrix proteins (e.g., collagen and fibrin) at the site of injury.

As the clot or scab is being dissolved and granulation tissue is being formed, the healing wound must be protected. This is accomplished by epithelialization, the process by which epithelial cells grow into the wound from surrounding healthy tissue. Epithelial cells migrate through the collagenous matrix under the clot or scab using MMPs to unravel collagen as they travel. Unraveling the collagen enables the epithelial cells to move rather than remain immobile (see Figure 7-19); the intact collagen ahead of them provides a pathway on which they can maneuver forward. Eventually the migrating epithelial cells contact similar cells from all sides of the wound and seal it, thereby halting migration and proliferation. The epithelial cells undergo differentiation to give rise to the various epidermal layers (see Chapter 46). Epithelialization of a skin wound can be hastened if the wound is kept moist, preventing the fibrin clot from becoming a scab.

Fibroblasts are the most important cells during the reconstructive phase of wound healing because they synthesize and

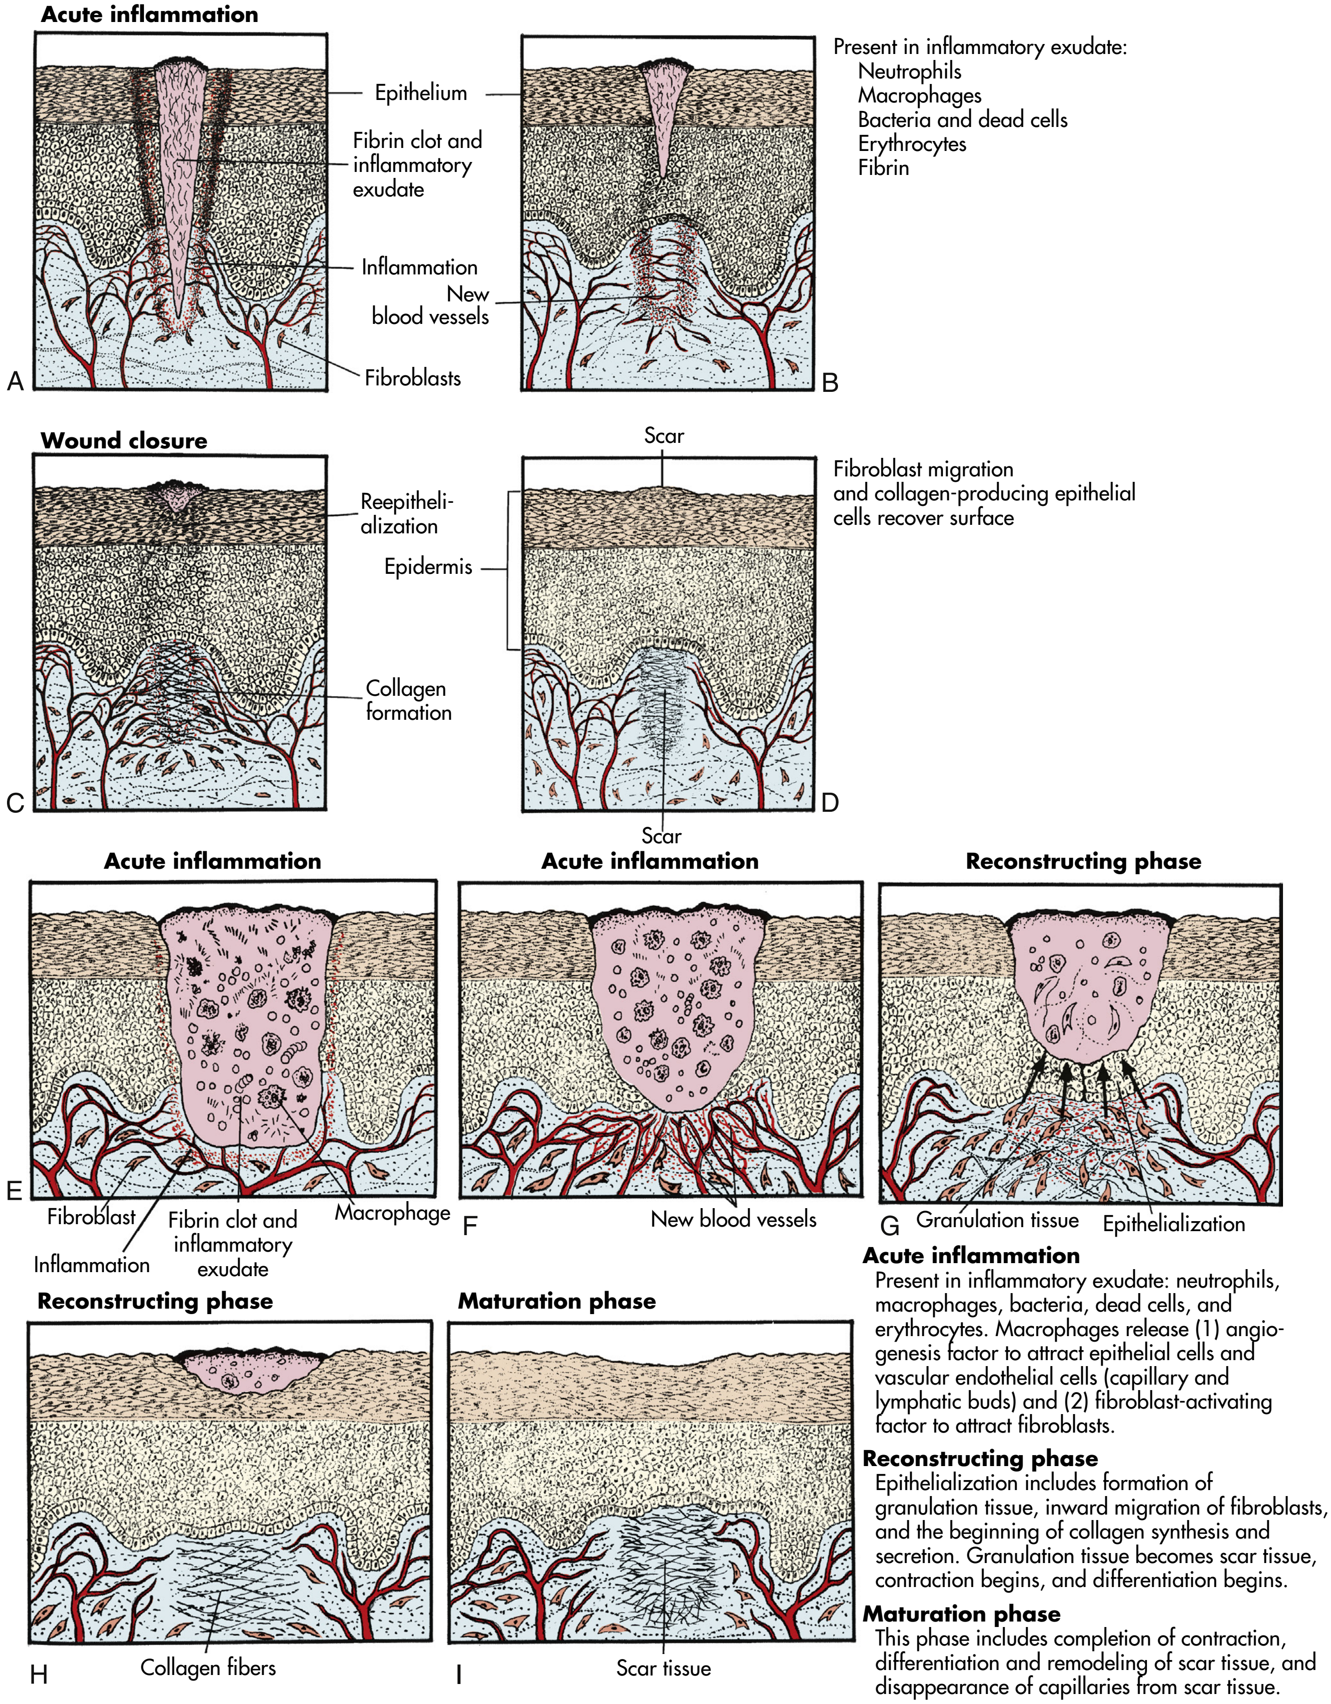

FIGURE 7-19 Wound Repair by Primary or Secondary Intention. **A-D,** Healing by primary intention. **E-I,** Healing by secondary intention.

secrete collagen and other connective tissue proteins. Fibroblasts are stimulated by macrophage-derived TGF-β to proliferate, enter the lesion, and produce these proteins. The collagen and connective tissue proteins produced by fibroblasts are deposited in débrided areas about 6 days after the fibroblasts have entered the lesion. **Collagen** is the most abundant protein in the body. It contains high concentrations of the amino acids glycine, proline, and lysine, although many of the proline and lysine amino acids are enzymatically modified as the protein is being synthesized. Modification of these amino acids requires several cofactors and is absolutely necessary for proper collagen polymerization and function. The required cofactors include iron, ascorbic acid (vitamin C), and molecular oxygen (O_2); the absence of any of these results in incomplete or impaired wound healing.

Immature collagen (i.e., procollagen) is secreted by fibroblasts as a complex of three polypeptide chains cross-linked by intermolecular bonds. Procollagen is converted to mature collagen by the proteolytic removal of small polypeptide sequences at both ends of the trimer. As healing progresses, collagen molecules are cross-linked by intramolecular covalent bonds to form collagen fibrils that are further cross-linked to form collagen fibers. The process of complete collagen matrix assembly takes several months because collagen is initially deposited randomly but then is remodeled by repeated dissolution (by MMPs) and reassembly. During this remodeling period, collagen fibers orient along the lines of mechanical stress; further cross-linking adds strength to the final collagen matrix.

Wound contraction is the final process of the reconstructive phase of healing. It is necessary for closure of all wounds, but especially those that heal by secondary intention. Contraction is noticeable 6 to 12 days after injury and may amount to inward movement of the wound edge by approximately 0.5 mm/day in normal healing. The granulation tissue of a healing wound contains **myofibroblasts**—specialized cells that are likely responsible for wound contraction. As their name implies, myofibroblasts have features of both smooth muscle cells and fibroblasts. They appear microscopically similar to fibroblasts, but differ in that their cytoplasm contains bundles of parallel fibers similar to those found in smooth muscle cells. Wound contraction occurs as extensions from the plasma membrane of myofibroblasts establish connections between neighboring cells, contract their fibers, and exert tension on the neighboring cells while anchoring themselves to the wound bed.

Maturation Phase

Collagen matrix assembly, tissue regeneration, and wound contraction all *begin* during the reconstructive phase but are not yet completed when the reconstructive phase ends, about 2 weeks after injury. Therefore, these processes continue into the **maturation phase**—a phase that can persist for years. During the maturation phase scar tissue is remodeled and capillaries disappear, leaving the scar avascular. Within 2 to 3 weeks after maturation has begun, the scar tissue has gained about two thirds of its eventual maximal strength.

Neither epidermal wounds that heal by secondary intention nor unsutured internal lesions are completely restored by healing. At best, repaired tissue regains 80% of its original tensile strength. Only epithelial, hepatic (liver), and bone marrow cells are capable of the complete mitotic regeneration known as *compensatory hyperplasia* (hyperplasia is described in Chapter 2). In fibrous connective tissue such as joints and ligaments, normal healing results in replacement of the original tissue with new tissue that does not have exactly the same structure or function as that of the original tissue. Some tissues heal without replacement of cells. For example, damage resulting from myocardial infarction heals with a scar composed of fibrous tissue rather than with cardiac muscle cell replacement.[32] Although the composition of various healed tissues may differ, the healing process—reconstruction followed by wound maturation—is essentially the same for all wounds.

Dysfunctional Wound Healing

Dysfunctional wound healing may occur if any of the involved processes occurs abnormally. This can include abnormalities in the inflammatory response itself, insufficient or excessive repair, or reinfection of the wound. Abnormalities may result from a predisposing disease, such as diabetes mellitus, or from an adaptive condition, such as hypoxemia (insufficient oxygen concentration in arterial blood). Numerous drugs and nutritional deficiencies can affect wound healing as well.[33]

Dysfunction During Inflammatory Response

Healing may be prolonged if bleeding is not stopped during acute inflammation. *Hemorrhage* in a damaged area delays healing for several reasons. Initially the excess blood cells that accumulate at the site of injury must be cleared—a process that requires additional time. In addition to the cellular accumulation caused by excessive bleeding, formation of a clot increases the amount of space that granulation tissue has to fill and serves as a mechanical barrier to oxygen diffusion. The great amount of fibrin that is released during hemorrhage also must eventually be reabsorbed in order to prevent its organization into *fibrous adhesions.* Once formed, these **adhesions** can bind organs together by fibrous bands; with time, shrinkage of these bands can distort or strangulate nearby organs. This is clinically significant, particularly if they form within the pleural, pericardial, or abdominal cavities.

Accumulated blood as a result of hemorrhage also serves as an excellent culture medium for bacteria, promoting continued *infection* and prolonging inflammation by increasing purulent exudate formation. Prolonged infection can promote *excess scar formation* or even prevent healing completely. Continued infection of a wound, termed *wound sepsis,* can be clinically treated in several ways. Most important is the débridement of necrotic tissue and foreign bodies. This removal is accomplished either through surgery or through the use of absorbent dressings. Wound irrigation and antibiotic therapy also may assist in combating continued infection.

Although local hemorrhage during the inflammatory process can pose a huge impediment to healing, many additional factors, both physiologic and pharmacologic, also may adversely affect the healing of an inflamed tissue. *Hypovolemia*—decreased blood volume—hinders inflammation. The physiologic response

to hypovolemia is vessel constriction rather than the dilation required to deliver inflammatory cells to the site of injury. Optimal nutrition is important during all phases of healing because metabolic needs are increased. The most essential nutrients for healing are glucose, oxygen, and amino acids. Because leukocytes need glucose to produce the energy needed for chemotaxis, phagocytosis, and intercellular killing, the wounds of persons with diabetes who receive insufficient insulin heal poorly, mainly attributable to a prolonging of the infection. Persons with diabetes are also at risk for ischemic wounds because they are likely to have both small-vessel diseases that impair the microcirculation and altered (glycosylated) hemoglobin, which has an increased affinity for oxygen and thus does not readily release oxygen in tissues. (Hemoglobin's function as the oxygen-carrying component of blood is described in Chapter 27.) Oxygen delivery is also compromised by hypoxemic states because ischemic tissue is susceptible to infection. *Hypoproteinemia* prolongs inflammation because the associated decrease in available amino acids is an impediment to fibroblast proliferation. Finally, anti-inflammatory steroids can have an impact upon wound healing. These drugs prevent macrophages from migrating to the site of injury and inhibit their release of collagenase and plasminogen activator. *Anti-inflammatory steroids* also inhibit fibroblast migration into the wound during the reconstructive phase of healing and impair angiogenesis, wound contraction, and reepithelialization.

Dysfunction During Reconstructive Phase of Healing

Three of the essential processes that occur during the reconstructive phase are assembly and remodeling of the collagen matrix, epithelialization of the wound bed, and contraction of the wound. Dysfunctional wound healing can result from the impairment of any of these processes.

Impaired Collagen Matrix Assembly. A number of factors may interfere with the production of collagen in healing tissues, most being nutritional. Scurvy, for example, is a condition caused by a deficiency in ascorbic acid, one of the cofactors required for the amino acid modification that is necessary for proper collagen matrix assembly. The complication of scurvy is a poorly formed collagen matrix and, therefore, greatly impaired wound healing. Other nutrients, including iron, copper, and calcium, play additional roles in the enzymatic reactions required for collagen modification and assembly. Usually, however, such minute amounts of these substances are required that deficiencies are not clinically significant. Nutritionally, appropriate protein intake is also essential for collagen synthesis. The amino acid methionine that is found in proteins is converted to cysteine, the role of which in collagen synthesis is twofold: (1) it functions as an important cofactor in the enzymatic reactions required for collagen synthesis; and (2) it contains sulfur, which contributes to formation of the strong covalent bonds in cross-linked collagen fibrils.

Dysfunctional healing also may result from excessive production of collagen. Overproduction of collagen causes surface overhealing, which is manifested in the skin by formation of a keloid or a hypertrophic scar (Figure 7-20). A **keloid** is a raised scar that extends beyond the original boundaries of the wound.

FIGURE 7-20 Keloids. (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

It invades surrounding tissue and is likely to recur after surgical removal. A familial tendency toward keloid formation has been observed, with a greater incidence in blacks relative to whites. Similar to a keloid, a **hypertrophic scar** is also raised but differs in that it remains within the original boundaries of the wound. Hypertrophic scars tend to regress over time, whereas keloids do not. Both keloids and hypertrophic scars are caused by an imbalance between collagen synthesis and collagen degradation in which synthesis is increased relative to degradation. Although the precise mechanism of this imbalance is unknown, recent evidence suggests that keloid fibroblasts have lower rates of apoptosis and an inability to respond to normal suppressive feedback.

Impaired Epithelialization. The process of **epithelialization** is suppressed by anti-inflammatory steroids, hypoxemia, and nutritional deficiencies. Anti-inflammatory steroids inhibit phagocyte production of the biochemical mediators required for epithelialization, hypoxemia deprives cells of the energy required for the process, and dietary zinc is necessary for the MMP activity that is crucial to cellular migration.

Wound care techniques also may greatly influence epithelial cell migration. External wounds that are draining or healing by secondary intention often are clinically débrided and protected with dressings.[34] The ideal dressing is one that absorbs some drainage without being incorporated into the clot or granulation tissue. Because epithelial cells must migrate across the wound during healing, dressings that débride healthy epithelial cells along with necrotic tissue prolong epithelialization. Many solutions that traditionally have been used to clean or irrigate wounds are now known to be deleterious to the fragile new cells in the wound bed. Normal saline is the most innocuous solution that can be used to cleanse or irrigate a wound that is healing primarily by epithelialization. Solutions such as povidone-iodine and hydrogen peroxide are desiccating (drying) and, as such, inhibit rather than promote epithelial cell migration.

Impaired Contraction

Excessive wound contraction may result in a deformity or **contracture.** Burn wounds are especially susceptible to the development of contractures. Internal contractures may occur as well, and are common in cirrhosis of the liver. Internally, scar tissue that becomes contracted constricts blood flow that may contribute to the development of portal hypertension and esophageal varices. Other types of internal contraction deformity include duodenal strictures caused by dysfunctional healing of an ulcer and esophageal strictures caused by chemical burns.

Proper positioning and range-of-motion exercises, as well as surgery, are among the physical means used to overcome the excessive myofibroblast-derived tension that results in contractures. Clinical use of pharmacologic methods for control of wound contracture is still largely experimental, but includes control of myofibroblast contraction by the administration of smooth muscle cell inhibitors such as colchicine and inhibition of proper collagen matrix assembly with drugs that prevent either collagen cross-linking or MMP activity. These latter treatments are based on the knowledge that myofibroblast binding to collagen can "lock" contracted cells into position.

Wound Disruption

Finally, a potential complication in the healing of wounds that are sutured closed is **dehiscence,** in which the wound pulls apart at the suture line. The greatest incidence of dehiscence occurs 5 to 12 days after suturing, paradoxically at the time when collagen synthesis is at its peak. Approximately 50% of dehiscence occurrences are associated with wound sepsis, although dehiscence also may occur when sutures break as a result of excessive strain. Obesity increases the risk of suture breakage because adipose tissue is difficult to suture. Wound dehiscence usually is heralded by an increase in serous drainage from the wound. In addition, patients may report a feeling that "something gave way." Prompt surgical attention is required.

PEDIATRICS AND MECHANISMS OF SELF-DEFENSE

Neonates commonly have transiently depressed inflammatory and immune function. For example, neutrophils and perhaps monocytes may not be capable of efficient chemotaxis. Insufficient response to chemotactic factors appears to be caused by lack of fluidity in the phagocyte's plasma membrane so that pseudopod formation and migration are impaired. Neonates are prone to infections associated with chemotactic defects, including cutaneous abscesses caused by staphylococci and cutaneous candidiasis. Further, neutrophils in neonates who were stressed by in utero infection or respiratory insufficiency have diminished oxidative and bacterial responses. (Acquired phagocytic defects, which may be induced by a variety of infections, metabolic disorders, nutrition deficiencies, or drugs, are described in Chapter 9.)

Neonates also are partially deficient in complement, especially components of the alternative pathway. They tend to have a relative deficiency of factor B and to develop severe, overwhelming sepsis and meningitis when infected with bacteria against which there is no transferred maternal antibody. Low levels of mannose-binding lectin increase the risk for neonatal hospital-acquired sepsis.[35] Neonates also may be deficient in some of the collectins and collectin-like proteins. This is especially true of preterm neonates. Some preterm infants with respiratory distress syndrome are deficient in at least one collectin, which provides innate defense against respiratory tract infections.

AGING AND MECHANISMS OF SELF-DEFENSE

The older adult population is also at risk for impaired inflammation and wound healing. In some cases, impaired healing is not directly associated with aging in general but can instead be linked to a chronic illness such as cardiovascular disease or diabetes mellitus. In addition, many older adults require medications such as anti-inflammatory steroids that can interfere with the healing process.

Older adults have increased susceptibility to bacterial infections of the lungs, urinary tract, and skin. Because of impaired sensation or mobility and physiologic changes in the skin, older adults are at increased risk for sustaining various wounds. With aging, subcutaneous fat is lost, diminishing a layer of protection. Collagen fibers become thicker and a certain percentage of elastin is lost, further contributing to loss of protection. The regenerative capability of the skin is maintained with aging, but the epidermis undergoes age-associated changes that include atrophy of the underlying capillaries. The consequent decrease of perfusion makes older adults more susceptible than younger people to the adverse effects of hypoxia in the wound bed. In addition, aging fibroblasts may have a slower rate of proliferation, and therefore wound healing is attenuated.

Infections of other organ systems in older adults may be due to a diminished natural ability to ward off infection. Several cellular components of innate resistance are deficient in number (e.g., alveolar macrophages) or have diminished activity (e.g., neutrophil chemotaxis, degranulation, and phagocytosis). One explanation for this diminished inflammatory cellular activity is an age-related decrease in expression and function of several, if not all, TLRs.

SUMMARY REVIEW

Human Defense Mechanisms

1. There are two types of human defense mechanisms: innate resistance or immunity conferred by natural barriers and the inflammatory response; and the adaptive (acquired) immune system.

First Line of Defense: Physical, Mechanical, and Biochemical Barriers

1. Physical and mechanical barriers are the first lines of defense encountered by invading pathogens; these include the skin and mucous membranes.
2. Antibacterial peptides in mucous secretions, perspiration, saliva, tears, and other secretions provide a biochemical barrier against invading pathogens in the extracellular space.
3. Cathelicidins and defensins are two classes of antimicrobial peptides produced by epithelial cells.
4. The normal microbiome provides protection by inhibiting colonization by pathogens and by releasing chemicals that prevent infection.

Second Line of Defense: The Inflammatory Response

1. The inflammatory response, our body's second line of defense against invading microorganisms, is nonspecific, is rapidly initiated, and has no memory cells.
2. The vascular response in acute inflammation includes vasodilation, increased capillary permeability, and white blood cell adherence to inner vessel walls and their migration through vessel walls.
3. Three plasma protein systems provide a biochemical barrier against invading pathogens in the circulation. These include the complement system, the clotting system, and the kinin system.
4. The plasma protein systems work with each other as well as with antimicrobial peptides and the cellular component of the innate immune system to prevent microbial infection.
5. The complement proteins can be activated in three pathways: the classical pathway, the alternative pathway, and the lectin pathway.
6. Activation of the complement pathways results in opsonization, anaphylatoxin activation, cell lysis, and leukocyte chemotaxis.
7. The clotting (coagulation) cascade prevents spread of microorganisms, contains microorganisms and foreign bodies at the site of greatest inflammatory cell activity, and provides a framework for repair and healing.
8. The kinin system proteins promote vasodilation and increased capillary permeability and induce pain.
9. Plasmin and Hageman factor (factor XII) interact to activate the clotting cascade, the complement system, and the kinin proteins.
10. The plasma proteins are finely regulated to prevent injury to host tissue and to guarantee activation when needed. Some of the inhibitors in the plasma protein systems include carboxypeptidase, histaminases, kinases, and C1 esterase inhibitor.
11. Many different types of cells are involved in the inflammatory process including mast cells, granulocytes (neutrophils, eosinophils, basophils), monocytes/macrophages, NK cells and lymphocytes, and cellular fragments (platelets).
12. The cells of the innate immune system secrete many biochemical mediators that are responsible for the vascular changes associated with inflammation and for modulating the localization and activities of other inflammatory cells. The mediators include histamine, chemotactic factors, leukotrienes, prostaglandins, and platelet-activating factor.
13. The inflammatory response is initiated upon tissue injury or when PAMPs are recognized by PRRs on cells of the innate immune system.
14. The PRRs include TLRs, complement, scavenger, glycan, and mannose receptors.
15. TLRs recognize PAMPs, complement receptors recognize complement fragments, and scavenger receptors promote phagocytosis.
16. Cytokines are soluble factors that regulate the inflammatory response and include interleukins, interferons, and tumor necrosis factor.
17. ILs are biochemical messengers primarily produced by macrophages and lymphocytes and significantly help regulate the inflammatory response.
18. IFNs provide protection from viral infection in uninfected cells.
19. Tumor necrosis factor is primarily produced by macrophages and promotes inflammation with both local and systemic effects.
20. Chemokines are synthesized by a number of different cells and induce leukocyte chemotaxis, and are classified as either CC or CXC, depending on their amino acid arrangement. CC chemokines affect monocytes, lymphocytes, and eosinophils. CXC chemokines generally affect neutrophils.
21. Mast cells are central cells of inflammation and release histamine, chemotactic factors, cytokines, leukotrienes, prostaglandins, growth factors, and other mediators.
22. H1-histamine receptors promote inflammation, and H2-histamine receptors inhibit the inflammatory response.
23. Endothelial cells line the circulatory system (vascular endothelium) and maintain normal blood flow by preventing spontaneous activation of platelets and clotting.
24. During inflammation the endothelium expresses receptors that help leukocytes leave the circulation and retract to allow fluid to pass into the tissues.
25. Platelets interact with the coagulation cascade to stop bleeding and release a number of mediators that promote and control inflammation.
26. Neutrophils are the predominant phagocyte of early inflammation. They are attracted to the inflammatory site by chemotactic factors.
27. Eosinophils help control mast cell vascular mediators and defend against parasite infection.
28. Basophils are granulocytes that are very similar to mast cells.

SUMMARY REVIEW—cont'd

29. The monocyte/macrophage is the predominant phagocyte in the late inflammatory response, is highly phagocytic, is responsive to cytokines, and promotes wound healing.
30. Phagocytosis is the destruction of microorganisms and cellular debris.
31. The stages of phagocytosis include recognition and adherence, engulfment, lysosomal fusion, and destruction.
32. Opsonins, such as antibody and complement component C3b, coat microorganisms and make them more susceptible to phagocytosis.
33. Phagocytic killing can be oxygen-dependent with the production of reactive oxygen intermediates or oxygen-independent with lysosomal enzymes.
34. Monocytes and macrophages arrive at the inflammatory site later than neutrophils and remain longer to clean up debris and promote wound healing.
35. NK cells recognize and eliminate viruses, cancer cells, and other abnormal cells.

Local Manifestations of Inflammation

1. Local manifestations of inflammation are the result of the vascular changes associated with the inflammatory process, including vasodilation and increased capillary permeability. The symptoms include redness, heat, swelling, and pain.
2. The functions of the vascular changes are to dilute toxins, carry plasma proteins and leukocytes to the injury site, and carry bacterial toxins and debris away from the site.

Systemic Manifestations of Acute Inflammation

1. The three primary systemic effects of inflammation are fever, leukocytosis, and increase in levels of circulating plasma proteins.
2. Acute-phase reactants are proteins produced by the liver during acute inflammation and include fibrinogen, C-reactive protein, haptoglobin, amyloid A, α_1-antitrypsin, and ceruloplasmin.

Chronic Inflammation

1. Chronic inflammation can be a continuation of acute inflammation that lasts 2 weeks or longer. It also can occur as a distinct process without much preceding acute inflammation.
2. Chronic inflammation is characterized by a dense infiltration of lymphocytes and macrophages. The body may wall off and isolate the infection to protect against tissue damage by formation of a granuloma.

Resolution and Repair

1. Resolution (regeneration) is the return of tissue to nearly normal structure and function. Repair is healing by scar tissue formation.
2. Inflammatory lesions proceed to resolution, meaning that original tissue structure and function have been restored if little tissue has been lost or injured tissue is capable of regeneration. This is called *healing by primary intention.*
3. Inflammatory lesions that involve extensive damage or tissues incapable of regeneration heal by the process of repair that results in the formation of a scar. This is called *healing by secondary intention.*
4. Resolution and repair occur in two separate phases: the *reconstructive phase,* in which the wound begins to heal, and the *maturation phase,* in which the healed wound is remodeled.
5. Dysfunctional wound healing can occur as a result of abnormalities in either the inflammatory response or the reconstructive phase of resolution and repair.

Pediatrics and Mechanisms of Self-Defense

1. Neonates commonly have transiently depressed inflammatory function.
2. Infants often have deficiencies in complement and in a number of collectins, making them more susceptible to bacterial infection.

Aging and Mechanisms of Self-Defense

1. Older adults are at risk for impaired wound healing, often because of underlying illnesses.
2. Diminished immune function may interfere with an older adult's natural ability to ward off infection.

CHAPTER OUTLINE

The third line of defense in the human body is **adaptive (acquired) immunity,** often called the immune response or **immunity.**[1] Once external barriers have been compromised and inflammation (see Chapter 7) has been activated, the adaptive immune response is called into action. The molecules and cells of the immune response are closely integrated with those of the innate response. Both systems are essential for complete protection against infectious disease: inflammation is relatively rapid, nonspecific, and short-lived, whereas adaptive immunity is slower acting, specific, and very long-lived. Thus, inflammation is the "first responder" that contains the initial injury and slows spread of infection, whereas adaptive immunity slowly augments the initial defenses against infection and provides long-term security against reinfection. The collaborative and beneficial nature of inflammation and adaptive immunity can, on occasion, fail. Chapter 9 discusses these medically relevant aberrations in both inflammation and immunity, including allergies, diseases that involve unwanted immunologic destruction of healthy tissue, and diseases that are caused by a deficiency in the normal immune or inflammatory responses. Chapter 10 presents an overview of infection and Chapter 11 discusses the connection between stress and

TABLE 8-1 CLINICAL USE OF ANTIGEN OR ANTIBODY

ANTIGEN SOURCE	PROTECTION: COMBAT ACTIVE DISEASE	PROTECTION: VACCINATION	DIAGNOSIS	THERAPY
Infectious agents	Neutralize or destroy pathogenic microorganisms (e.g., antibody response against viral infections)	Induce safe and protective immune response (e.g., recommended childhood vaccines)	Measure circulating antigen from infectious agent or antibody (e.g., diagnosis of hepatitis B infection)	Passive treatment with antibody to treat or prevent infection (e.g., administration of antibody against hepatitis A)
Cancers	Prevent tumor growth or spread (e.g., immune surveillance to prevent early cancers)	Prevent cancer growth or spread (e.g., vaccination with cancer antigens)	Measure circulating antigen (e.g., circulating PSA for diagnosis of prostate cancer)	Immunotherapy (e.g., treatment of cancer with antibodies against cancer antigens)
Environmental substances	Prevent entrance into body (e.g., secretory IgA limits systemic exposure to potential allergens)	No clear example	Measure circulating antigen or antibody (e.g., diagnosis of allergy by measuring circulating IgE)	Immunotherapy (e.g., administration of antigen for desensitization of individuals with severe allergies)
Self-antigens	Immune system tolerance to self-antigens, which may be altered by an infectious agent leading to autoimmune disease (see Chapter 9)	Some cases of vaccination alter tolerance to self-antigens leading to autoimmune disease	Measure circulating antibody against self-antigen for diagnosis of autoimmune disease (see Chapter 9)	No clear example

PSA, Prostate-specific antigen.

disease and the interrelatedness of the immune, nervous, and endocrine systems.

GENERAL CHARACTERISTICS OF ADAPTIVE IMMUNITY

The immune system of the normal adult is continually challenged by a spectrum of substances that it may recognize as foreign, or "non-self." These substances, called foreign **antigens,** are often associated with pathogens such as viruses, bacteria, fungi, or parasites, although they are also found on noninfectious environmental agents such as pollens, foods, and bee venom, and still others are associated with clinically derived drugs, vaccines, transfusions, and transplanted tissues (Table 8-1). Unlike inflammation, which is nonspecifically activated by damage to cells as well as by the action of pathogenic microorganisms, the immune response is primarily designed to afford long-term specific protection (i.e., immunity) against particular invading microorganisms; that is, it has a "memory" function. The products of the adaptive immune response include a type of serum protein—**immunoglobulins,** or **antibodies**—and a type of blood cell—**lymphocytes** (Figure 8-1).

Specificity and memory are the primary characteristics that differentiate the immune response from other protective mechanisms. This chapter first discusses the nature of that specificity by defining the various types of antigens that may be seen by the immune system, the ways in which they are recognized by antibodies and lymphocytes, and the specific intercellular recognition molecules that are necessary for effective immune responses. After the recognition molecules are defined, the development of the immune response is discussed. An immune response can be divided into two phases (Figure 8-2). Before birth, humans produce a large population of **T lymphocytes**

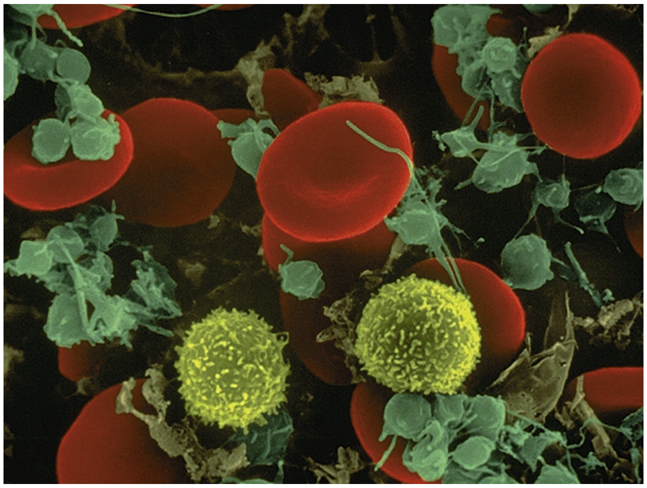

FIGURE 8-1 Scanning Electron Micrograph Showing Lymphocytes (Yellow), Red Blood Cells, and Platelets. (Copyright Dennis Kunkel Microscopy, Inc.)

(T cells) and **B lymphocytes (B cells)** that have the capacity to recognize almost any foreign antigen found in the environment. Each individual T or B cell, however, specifically recognizes only one particular antigen, but the sum of the population of lymphocyte specificities may represent millions of foreign antigens. This process is called the *generation of clonal diversity* and occurs in specialized (primary) lymphoid organs—the thymus for T cells and the bone marrow for B cells. While passing through these tissues, the lymphocytes mature and undergo changes that commit them to becoming either B or T cells. Lymphocytes are released from these organs into the circulation as immature cells that have the capacity to react with antigen **(immunocompetent).** These cells migrate to other (secondary) lymphoid organs in the body in preparation for exposure to antigen (Figure 8-3).

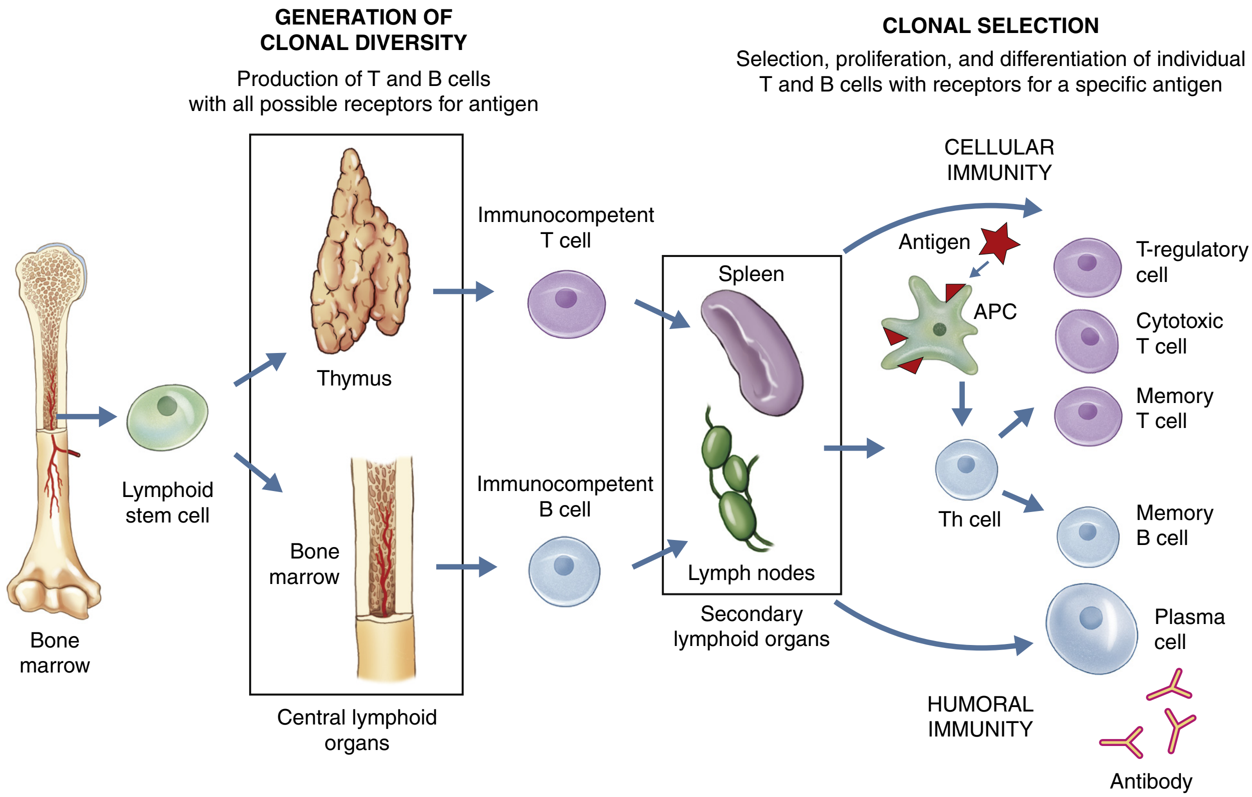

FIGURE 8-2 Overview of Immune Response. The immune response can be separated into two phases: the *generation of clonal diversity* and *clonal selection.* During the generation of clonal diversity, lymphoid stem cells from the bone marrow migrate to the central lymphoid organs (the thymus or regions of the bone marrow), where they undergo a series of cellular division and differentiation stages resulting in either immunocompetent T cells from the thymus or immunocompetent B cells from the bone marrow. (This process is outlined in more detail in Figures 8-10 and 8-12.) These cells are still naïve in that they have never encountered foreign antigen. The immunocompetent cells enter the circulation and migrate to the secondary lymphoid organs (e.g., spleen and lymph nodes), where they take up residence in B- and T-cell–rich areas. The clonal selection phase is initiated by exposure to foreign antigen. The antigen is usually processed by antigen-presenting cells (APCs) for presentation to helper T cells (Th cells) (more detail in Figure 8-16). The intercellular cooperation among APCs, Th cells, and immunocompetent T and B cells results in a second stage of cellular proliferation and differentiation (more details in Figures 8-19 and 8-22). Because antigen has "selected" those T and B cells with compatible antigen receptors, only a small population of T and B cells undergo this process at one time. The result is an active cellular immunity or humoral immunity, or both. Cellular immunity is mediated by a population of "effector" T cells that can kill targets (cytotoxic T cells) or regulate the immune response (T-regulatory cells), as well as a population of memory cells (memory T cells) that can respond more quickly to a second challenge with the same antigen. Humoral immunity is mediated by a population of soluble proteins (antibodies) produced by plasma cells and by a population of memory B cells that can produce more antibody rapidly to a second challenge with the same antigen.

The lymphocytes remain dormant until antigen initiates the second phase of the immune response, *clonal selection*. This process involves a complex interaction among cells. To initiate an effective immune response, most antigens must be "processed" because they cannot react directly with cells of the immune system but must be shown or "presented" to the immune cells in a very specific manner. This is the job of antigen-processing (antigen-presenting) cells, generally referred to as APCs. In general, three groups of cells must cooperate to make an immune response. The APCs interact with subpopulations of T cells that facilitate immune responses (T-helper cells), and immunocompetent B or T cells, resulting in differentiation of B cells into active antibody-producing cells (plasma cells) and T cells into effector cells, such as T-cytotoxic cells. The last portion of this chapter discusses how these products (antibody and T cells) protect against infection, including how they interact with components of the inflammatory process.

Humoral and Cell-Mediated Immunity

The immune response has two arms: antibody and T cells, both of which protect against infection.[2] Antibody circulates in the blood and binds to antigens on infectious agents. This interaction can result in direct inactivation of the microorganism or activation of a variety of inflammatory mediators (e.g., complement, phagocytes) that will destroy the pathogen. Antibody is primarily responsible for protection against many bacteria and viruses. This arm of the immune response is termed **humoral immunity.**

T cells also undergo differentiation during an immune response and develop into several subpopulations of cells that

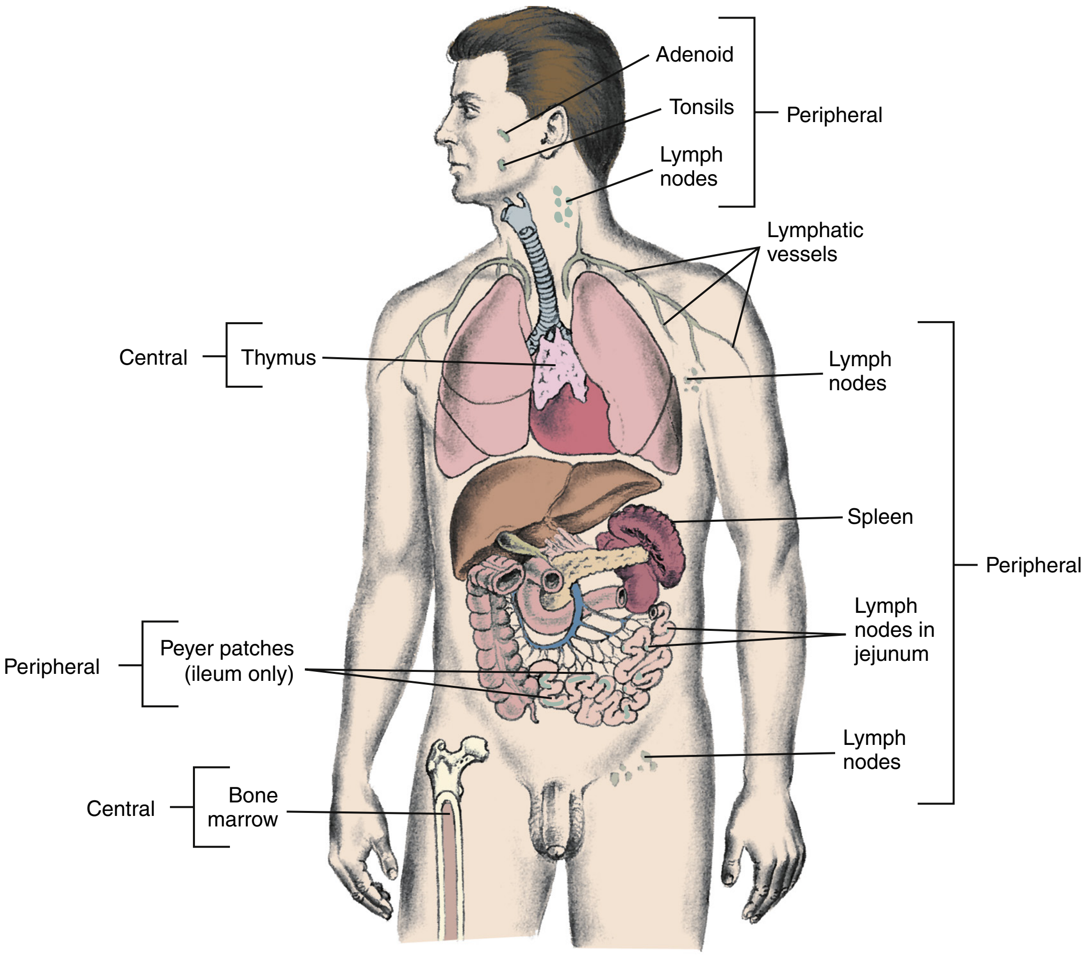

FIGURE 8-3 **Lymphoid Tissues: Sites of B-Cell and T-Cell Differentiation.** Immature lymphocytes migrate through central (primary) lymphoid tissues: the bone marrow (central lymphoid tissue for B lymphocytes) and the thymus (central lymphoid tissue for T lymphocytes). Mature lymphocytes later reside in the T and B lymphocyte–rich areas of the peripheral (secondary) lymphoid tissues.

react directly with antigen on the surface of infectious agents. Some develop into T cells that can stimulate the activities of other leukocytes via cell-to-cell contact or through the secretion of cytokines. Others develop into T-cytotoxic cells (Tc cells) that attack and kill targets directly. Targets for Tc cells include cells infected by a variety of viruses, as well as cells that have become cancerous. This arm of the immune response is termed **cellular immunity.** As discussed in this chapter, the humoral and cellular immune responses are interdependent at many levels. In the end, the success of an acquired immune response depends on the functions of both the humoral and the cellular responses, as well as the appropriate interactions between them. Additionally, both arms produce specialized subpopulations of **memory cells** that are long-lived and capable of "remembering" the antigen and responding more rapidly and efficiently on subsequent exposure to the same antigen. On reexposure, memory cells do not require much further differentiation and will therefore rapidly become new plasma cells or effector T cells.

Active vs. Passive Immunity

Adaptive immunity can be either active or passive, depending on whether the antibodies or T cells are produced by the individual in response to antigen or are administered directly. **Active acquired immunity** (**active immunity**) is produced by an individual either after natural exposure to an antigen or after immunization, whereas **passive acquired immunity** (**passive immunity**) does not involve the host's immune response at all. Rather, passive immunity occurs when preformed antibodies or T lymphocytes are transferred from a donor to the recipient. This can occur naturally, as in the passage of maternal antibodies across the placenta to the fetus, or artificially, as in a clinic using immunotherapy for a specific disease. Unvaccinated individuals who are exposed to particular infectious agents (e.g., hepatitis A virus, rabies virus) often will be given immunoglobulins that are prepared from individuals who already have antibodies against that particular pathogen. Whereas active acquired immunity is long-lived, passive immunity is only temporary because the donor's antibodies or T cells are eventually destroyed.

RECOGNITION AND RESPONSE

The foundation of any successful immune response is the specific recognition of antigen by antibody or receptors on the

TABLE 8-2 **SELECT CD MOLECULES AND THEIR FUNCTIONS**

CD MOLECULES	PRIMARY LOCATION	FUNCTIONS
CD1	APCs	Presents lipid antigens
CD2	All T cells, NK cells	T-cell marker; adhesion molecule that binds to CD58 (LFA-3) and provides a co-stimulatory signal
CD3	All T cells	Associated with TCR and provides intracellular signaling
CD4	Th cells	Binds to MHC class II as co-receptor with the TCR
CD8	Tc cells	Binds to MHC class I as co-receptor with the TCR
CD19	B cells	Complexes with CD21 to form a co-receptor for B cells
CD20	B cells	Major regulator of B-cell function
CD21	B cells	Receptor for complement that complexes with CD19 to form a co-receptor for B cells
CD25	Activated T cells	α-Chain of IL-2 receptor
CD28	T cells	Adhesion molecule that binds to CD80 to provide co-stimulatory signal for Tc cells
CD40	B cells, macrophages	Adhesion molecule that binds to CD154 to provide co-stimulatory signal for B cells
CD45	All lymphocytes	Has multiple types; augments antigen signal
CD58 (LFA-3)	Most cells	Adhesion molecule that binds to CD2 to provide a co-stimulatory signal
CD80 (B7-1)	APCs	Adhesion molecule that binds to CD28 to provide a co-stimulatory signal
CD154 (CD40L)	Th2 cells	Adhesion molecule that binds to CD40 to provide a co-stimulatory signal

surface of B or T cells, followed by a set of complex intercellular communications among a variety of antigen-presenting cells and lymphocytes. To fully understand the immune response, it is necessary to initially understand the basis for that recognition. Many of the molecules discussed in this chapter are part of a nomenclature that uses the prefix "CD" followed by a number (e.g., CD1 or CD2) (Table 8-2). The definition of the **CD (cluster of differentiation)** format has changed over time. It was originally used to describe proteins found on the surface of lymphocytes. Currently, CD is the accepted format for labeling a very large family of proteins found on the surface of many cells. Many have alternative names, which may be used in this chapter. The list of identified molecules is constantly increasing (the number of molecules with a CD designation is probably in excess of 250). In a similar fashion, the list of known cytokines is continually growing, with more than 100 having been identified so far. A large number of CD molecules and cytokines contribute to the acquired immune response. We have attempted to focus on a small number of highly important examples to illustrate the immensely complicated, but highly effective, interactions that take place to produce a protective immune response.

Antigens and Immunogens

An **antigen** is a molecule that can *react with* antibodies or antigen receptors on B and T cells. Most, but not all, antigens are also **immunogens.** An antigen that is **immunogenic** will induce an immune response resulting in the production of antibodies or functional T cells. Although the terms *antigen* and *immunogen* commonly are used as synonyms, there are some differences between the two, so a substance may be antigenic yet not be immunogenic.

To function as an antigen, at least a portion of a molecule's chemical structure must be recognized by and bound to an antibody and/or to specific receptors on a lymphocyte. The precise portion of the antigen that is configured for recognition and binding is called its **antigenic determinant,** or **epitope.** The matching portion on the antibody or the lymphocyte receptor is sometimes referred to as the *antigen-binding site,* or **paratope.** The size of an antigenic determinant is relatively small, perhaps just a few amino acids or carbohydrate residues on the surface of a large molecule (Figure 8-4). Therefore, macromolecules (e.g., proteins, polysaccharides, nucleic acids) usually contain multiple and diverse antigenic determinants, and the immune response against the macromolecule will usually consist of a mixture of specific antibodies against several of these determinants.

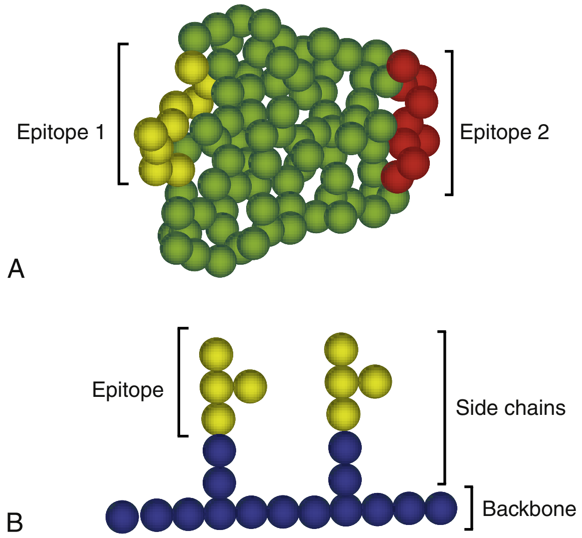

FIGURE 8-4 **Antigenic Determinants (Epitopes).** Shown are generic examples of epitopes on protein **(A)** and polysaccharide **(B)** molecules. In **A,** an antigenic protein may have multiple different epitopes (epitopes 1 and 2) that react with different antibodies. Each sphere represents an amino acid with the yellow spheres representing epitope 1 and the red spheres representing epitope 2. Individual epitopes may consist of eight or nine amino acids. In **B,** a polysaccharide is constructed of a backbone with branched side chains. Each sphere represents an individual carbohydrate with the yellow spheres representing the carbohydrates that form the epitope. In this example, two identical epitopes are shown that would bind two identical antibodies.

Certain criteria influence the degree to which an antigen is immunogenic. These include: (1) being foreign to the host, (2) being appropriate in size, (3) having an adequate chemical complexity, and (4) being present in a sufficient quantity.

Foremost among the criteria for immunogenicity is the antigen's foreignness. A **self-antigen** that fulfills all these criteria *except* foreignness does not normally elicit an immune response. Thus most individuals are tolerant to their own antigens. The immune system has an exquisite ability to distinguish self (self-antigens) from non-self (foreign antigens). **Tolerance,** once thought to be a state of nonresponsiveness in which the immune system passively allowed self-antigens to persist, is now known to have a variety of mechanisms. In some cases, a state of **central tolerance** exists, in which lymphocytes with receptors against self-antigens have been eliminated. In other cases, tolerance is **peripheral tolerance** and part of the adaptive immune response. Rather than merely tolerating some self-antigens, the immune system actively prevents their recognition by lymphocytes and antibodies. The response to self-antigens may be actively regulated by specialized T lymphocytes called *T-regulatory (Treg) cells* (see Figure 8-2). Some pathogens have a survival advantage by their capacity to mimic self-antigens and avoid inducing an immune response.

Molecular size also contributes to an antigen's immunogenicity. In general, large molecules (those bigger than 10,000 daltons), such as proteins, polysaccharides, and nucleic acids, are most immunogenic. Low-molecular-weight molecules, such as amino acids, monosaccharides, fatty acids, and the purine and pyrimidine bases, tend to be unable to induce an immune response. Many small molecules can function as **haptens:** antigens that are too small to be immunogens by themselves but become immunogenic in combination with larger molecules that function as **carriers** for the hapten. For example, the antigens of penicillin and poison ivy are haptens, but they initiate allergic responses only after binding to large-molecular-weight proteins in the allergic individual's blood or skin. Antigens that induce an allergic response are also called **allergens.**

Chemical complexity affects immunogenicity. The best immunogens contain a diversity of chemically different components. For instance, a large synthetic protein consisting only of alanine amino acids would not be very immunogenic, despite its size and foreignness. However, if other amino acids, such as tyrosine, tryptophan, or phenylalanine, were inserted into the structure, the degree of immunogenicity would increase greatly.

Finally, antigens that are present in extremely small or large quantities may be unable to elicit an immune response and therefore by definition are also nonimmunogenic. In many cases, high or low extremes of antigen quantities may induce a state of tolerance rather than immunity.

Even if an antigen fulfills all these criteria, the quality and intensity of the immune response may still be affected by a variety of additional factors. For example, the route and vehicle of antigenic entry or administration are critical to the immunogenicity of some antigens. This has important clinical implications. The most common routes for clinical administration of antigen, such as vaccines, are intravenous, intraperitoneal, subcutaneous, intranasal, and oral. Each route preferentially stimulates a different set of lymphocyte-containing (lymphoid) tissues and therefore results in the induction of different types of cell-mediated or humoral immune responses. For some vaccines, the route may affect the protectiveness of the immune response so that the individual is protected if immunized by one route, but may remain susceptible to infection if administered through a different route. Immunogenicity of an antigen also may be altered by being delivered along with substances that stimulate the immune response; these substances are known as *adjuvants.* Finally, the genetic makeup of a host can play a critical role in the immune system's ability to respond to many antigens; some individuals appear to be unable to respond to immunization with a particular antigen, whereas they respond well to other antigens. For instance, a small percentage of the population fails to produce a measurable immune response to the most common vaccines, despite multiple injections. Many other factors can modulate the immune response. These include the individual's age, nutritional status, genetic background, and reproductive status, as well as exposure to traumatic injury, concurrent disease, or the use of immunosuppressive medications.

Molecules That Recognize Antigen

Antigen is directly recognized by three molecules: circulating antibody and antigen receptors on the surface of B lymphocytes (**B-cell receptor,** or **BCR**) and T lymphocytes (**T-cell receptor,** or **TCR**) (Figure 8-5).

Antibody

An **antibody,** or immunoglobulin, is a serum glycoprotein produced by plasma cells in response to a challenge by an immunogen. The term *immunoglobulin* is used to denote all molecules that are known to have specificity for antigen, whereas the term *antibody* is generally used to denote one particular set of immunoglobulins with specificity against a known antigen. There are five molecular classes of immunoglobulins (IgG, IgA, IgM, IgE, and IgD) that are characterized by antigenic, structural, and functional differences (Figure 8-6). Within two of the immunoglobulin classes are several distinct subclasses including four subclasses of IgG and two subclasses of IgA.

Classes. IgG is the most abundant class of immunoglobulins; they constitute 80% to 85% of those circulating in the body and account for most of the protective activity against infections (Tables 8-3 and 8-4). As a result of selective transport across the placenta, maternal IgG is also the major class of antibody found in blood of the fetus and newborn. Four subclasses of IgG have been described: IgG1, IgG2, IgG3, and IgG4.

IgA can be divided into two subclasses, IgA1 and IgA2. IgA1 molecules are found predominantly in the blood, whereas IgA2 is the predominant class of antibody found in normal body secretions. The IgA molecules found in bodily secretions are dimers anchored together through a J chain and "secretory piece." This secretory piece is attached to the IgAs inside mucosal epithelial cells and may function to protect these immunoglobulins against degradation by enzymes also found in the secretions.

IgM is the largest of the immunoglobulins and usually exists as a pentamer that is stabilized by a J (joining) chain. It is the

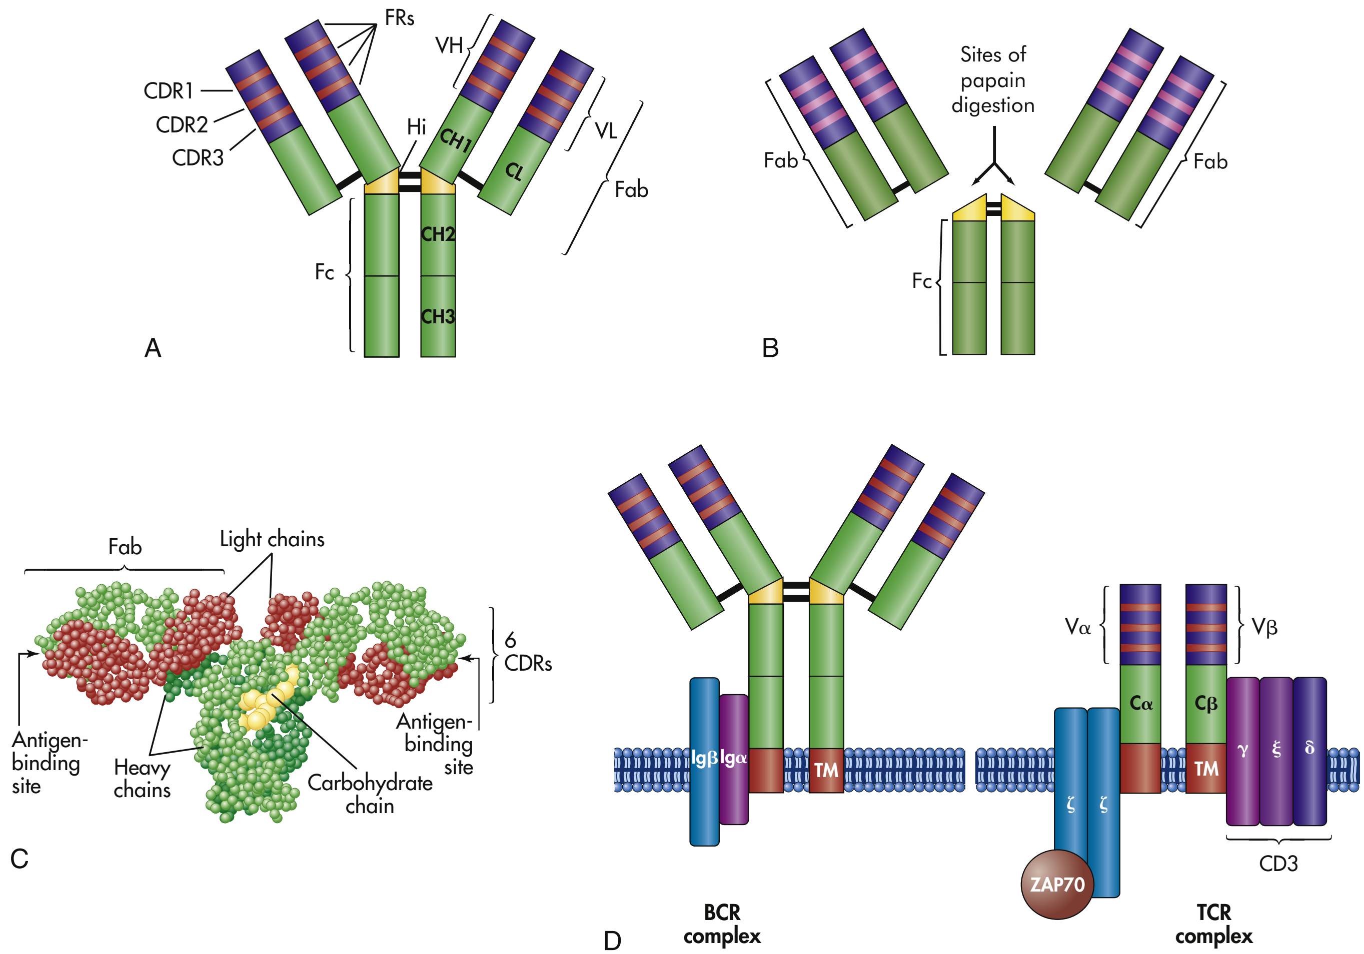

FIGURE 8-5 **Antigen-Binding Molecules.** Antigen-binding molecules include soluble antibody **(A, B, C)** and cell surface receptors **(D). A,** The typical antibody molecule consists of two identical heavy chains and two identical light chains connected by interchain disulfide bonds (– between chains in the figure). Each heavy chain is divided into three regions with relatively constant amino acid sequences (CH1, CH2, and CH3) and a region with a variable amino acid sequence (VH). Each light chain is divided into a constant region (CL) and a variable region (VL). The hinge region (Hi) provides flexibility in some classes of antibody. Within each variable region are three highly variable complementary-determining regions (CDR1, CDR2, CDR3) separated by relatively constant framework regions (FRs). **B,** Fragmentation of the antibody molecule by limited digestion with the enzyme papain has identified three important portions of the molecule: an Fc and two identical Fab fragments. Both Fab fragments bind antigen. As the antibody folds **(C),** the CDRs are placed in proximity to form the antigen-binding site. **D,** The antigen receptor on the surface of B cells (BCR complex) is a monomeric antibody with a structure similar to that of circulating antibody, with an additional hydrophobic transmembrane region (TM) that anchors the molecule to the cell surface. The active BCR complex contains molecules (Igα and Igβ) that are responsible for intracellular signaling after the receptor has bound antigen. The T-cell receptor (TCR) consists of an α-chain and a β-chain joined by a disulfide bond. Each chain consists of a constant region (Cα and Cβ) and a variable region (Vα and Vβ). Each variable region contains CDRs and FRs in a structure similar to that of antibody. The active TCR is associated with several molecules that are responsible for intracellular signaling. These include CD3, which is a complex of γ (gamma), ε (epsilon), and δ (delta) subunits, and a complex of two ζ (zeta) molecules. The ζ molecules are attached to a cytoplasmic protein kinase (ZAP70) that is critical to intracellular signaling. (**C** from Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2012, Mosby.)

first antibody produced during the initial, or primary, response to antigen. IgM is synthesized early in neonatal life, and its synthesis may be increased as a response to infection in utero.

Information on the role of IgD is limited. This class of immunoglobulins is found in very low concentrations in the blood, where they do not appear to have a known function. IgD is located primarily on the surface of developing B lymphocytes, where they function as one type of B-cell antigen receptor.

IgE is the least concentrated of any of the immunoglobulin classes in the circulation. It appears to have very specialized functions as a mediator of many common allergic responses (see Chapter 9) and in the defense against parasitic infections.

Molecular Structure. Structural analysis of immunoglobulins began with Porter's early studies on the effects of the enzyme papain on IgG.[3] The nomenclature of antibody structure originated from that work. Limited digestion with the enzyme papain cleaved IgG into three fragments, two of which were

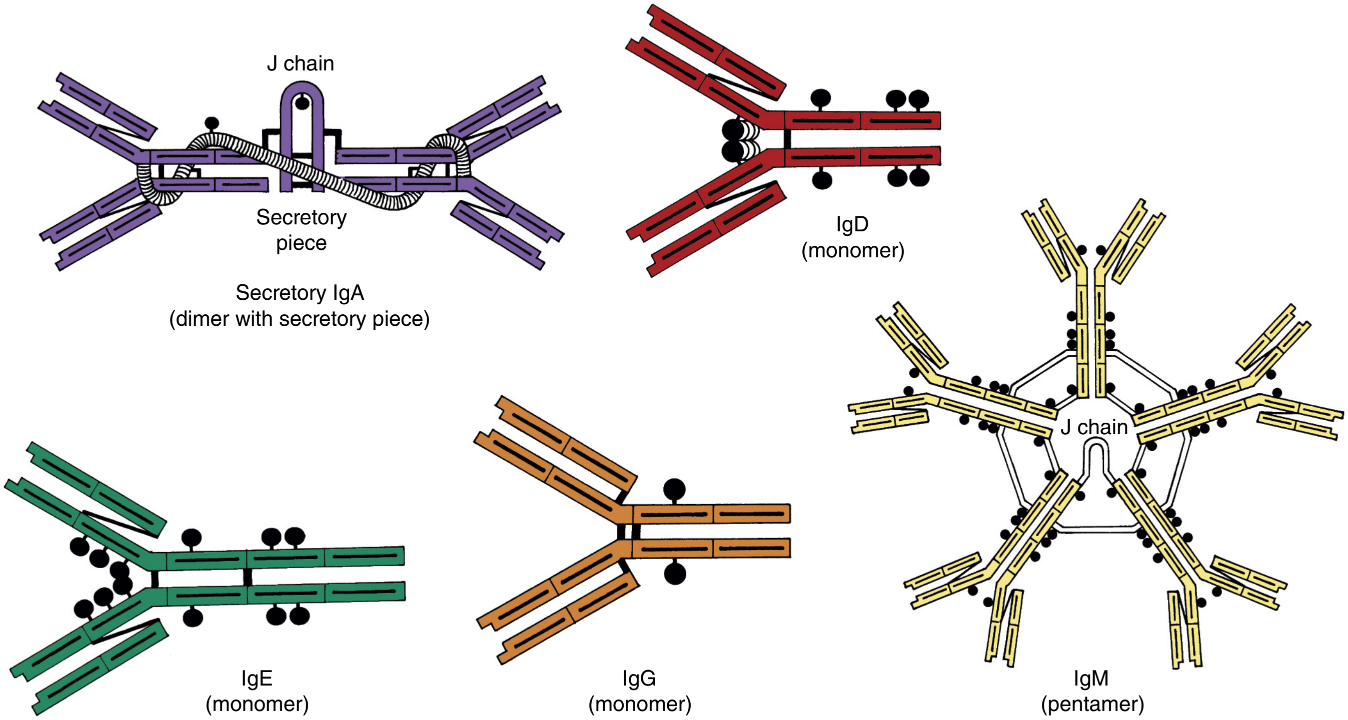

FIGURE 8-6 **Structure of Different Immunoglobulins.** Secretory IgA, IgD, IgE, IgG, and IgM. The black circles attached to each molecule represent carbohydrate residues.

identical. The two identical fragments were found to retain the ability to bind antigen, and each was termed an **antigen-binding fragment (Fab).**[4] The third fragment crystallized when separated from the Fab portions and was termed the **crystalline fragment (Fc)** (see Figure 8-5).

What Porter learned about the structure of IgG still applies not only to this class of immunoglobulins but also to each of the other classes. The Fab portions of an immunoglobulin contain the recognition sites (receptors) for antigenic determinants and confer the molecule's specificity toward a particular antigen. The Fc portion is responsible for most of the biologic functions of antibodies, including activation of the complement cascade and opsonization by binding to Fc receptors on the surface of the cells of the innate immune system.

The basic structure of the antibody molecule consists of four polypeptide chains—two identical light (L) chains and two identical heavy (H) chains (see Figure 8-5). Within the same molecule, the two heavy chains are identical and the two light chains are identical. The class of antibody is determined by which heavy chain is used: gamma (IgG), mu (IgM), alpha (IgA), epsilon (IgE), or delta (IgD). The light chains of an antibody molecule are of either the kappa (κ) or the lambda (λ) type. The light and heavy chains are held together by two major forces: noncovalent bonds and disulfide linkages. A set of disulfide linkages between the heavy chains occurs in the **hinge region** and in some instances lends a degree of molecular flexibility at that site so that the Fab regions can move.

Light and heavy chains are further subdivided into constant (C) and variable (V) regions. The constant regions have relatively stable amino acid sequences within a particular immunoglobulin class or subclass. Thus the amino acid sequence of the constant region of one IgG1 should be almost identical with the sequence of the same region of another IgG1, even if they react with different antigens. Conversely, among different antibodies, the sequences of the variable regions are characterized by a large number of amino acid differences. Therefore, two IgG1 molecules against different antigens may have many differences in the amino acid sequence of their variable regions. The variable region can be further subdivided because most of the region's variability in amino acid sequence is localized in three areas of the variable region. These three areas were once called *hypervariable regions,* but are now called **complementary-determining**

regions (CDRs). The four regions separating the CDRs have relatively stable amino acid sequences and are called **framework regions (FRs).**

Antigen Binding

The combined amino acid sequences of the variable regions of both the heavy (V_H) and light (V_L) chains determine the conformation of the antigen-binding site and therefore the antigenic specificity of the immunoglobulin molecule. Most proteins will naturally fold and take on secondary or tertiary structures. As the immunoglobulin molecules fold, the FRs control the accuracy of folding in the variable region, and the CDRs in both variable regions are moved into proximity, resulting in an antigen-binding site formed by the three CDRs of the heavy chain and the three CDRs of the light chain. The chemical nature of the particular amino acids in those sites, as well as the topography of the site, determines the specificity toward a particular antigen. The antigen that will bind most strongly must have complementary chemistry and topography with the binding site formed by the antibody. The antigen fits into this binding site with the specificity of a key into a lock and is held there by noncovalent chemical interactions (Figure 8-7). In some cases the substitution of a single critical amino acid in a CDR may have a significant effect on the shape of the binding site and thus the specificity of the antibody molecule.

Because the heavy and light chains are identical within the same antibody molecule, the two binding sites are also identical and have specificity for the same antigen. The number of functional binding sites is called the antibody's **valence.** Most antibody classes (i.e., IgG, IgE, IgD, and circulating IgA) have a valence of 2, but secretory IgA has a valence of 4. IgM, being a pentamer, has a theoretical valence of 10, but can simultaneously use only about five binding sites because a large antigen binding to one site blocks antigen binding to another site.

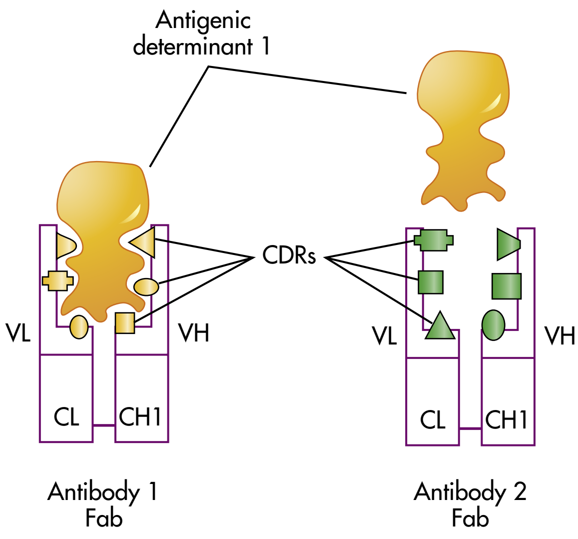

FIGURE 8-7 **Antigen-Antibody Binding.** The specificity required for antibody binding with an antigen is determined by the shape and chemistry of the six complementary-determining regions (CDRs) in the combining site on the variable region of the antibody. This figure indicates two different antibodies (Fab portions of antibody 1 and antibody 2) that have different sets of CDRs and therefore different specificities. As indicated, the antigenic determinant that reacts well with antibody 1 is unable to react with antibody 2 because of differences in the antibody combining site. *C,* Constant; *CH,* constant region of the heavy chain; *CL,* constant region of the light chain; *Fab,* antigen-binding fragment, *V,* variable; *VH,* variable heavy chain, *VL,* variable light chain.

B-Cell Receptor Complex

The **B-cell receptor (BCR) complex** is located on the surface of B lymphocytes (see Figure 8-5). Its role is to recognize antigen, but unlike circulating antibody, the receptor must communicate that information to the cell's nucleus. Therefore, the BCR complex consists of antigen-recognition molecules and accessory molecules involved in intracellular signaling (Igα and Igβ). BCRs on the surface of immunocompetent B cells are membrane-associated IgM (mIgM) and IgD (mIgD) immunoglobulins that are produced from the same genes that are used by plasma cells to produce soluble antibodies. As a BCR, however, mIgM is a monomer rather than the pentamer primarily found in the blood.

The BCR signaling complex consists of two Igα and Igβ heterodimers that are closely associated with the BCR and contain tyrosine kinase signaling activity. The antibody portion of the BCR complex is responsible for recognition and binding to an antigen, but by itself cannot provide the intracellular signals required to activate the B cell and complete its maturation and the production of antibodies. That message is conveyed by the Igα and Igβ heterodimers.

T-Cell Receptor Complex

T lymphocytes use a similar but distinct array of proteins in their recognition and response to antigens. The **T-cell receptor (TCR) complex** is composed of an antibody-like transmembrane protein (TCR) and a group of accessory proteins (collectively referred to as CD3) that are involved in intracellular signaling (see Figure 8-5). Similar to activation of the B lymphocyte, the TCR is responsible for recognition and binding to the antigen, whereas the accessory proteins are responsible for the intracellular signaling necessary for activation and differentiation of the T cell. Each of the individual components of the TCR complex is important, and several severe defects in the T-cell immune response have been related to mutations in individual components of the complex (see Chapter 9).

Molecules That Present Antigen

For an effective immune response, most antigens must be processed within cells and expressed on the surface of those cells in a very specific manner. Some types of antigen are managed only by highly specialized cells: **antigen-presenting cells,** or **APCs.** Other types of antigens can be processed and presented by almost any type of cell. Several sets of cell surface molecules have the responsibility for appropriately presenting antigen. These molecules are described below.

Major Histocompatibility Complex

An essential set of recognition molecules are members of the **major histocompatibility complex (MHC).** Most antibody and cellular immune responses are dependent on antigen presentation by APCs. Additionally, the role of T-cytotoxic cells in killing virally infected cells depends on presentation of the viral antigen on the infected cell's surface. **Antigen presentation** is the primary role of molecules of the MHC.

MHC molecules are glycoproteins found on the surface of all human cells except red blood cells. They are divided into two general classes, class I and class II, based on their molecular structure, distribution among cell populations, and function in antigen presentation. MHC class I molecules are heterodimers composed of a large α-chain along with a smaller chain called *β2-microglobulin.* MHC class II molecules are also heterodimers with both α- and β-chains. The general properties of each of the MHC classes are summarized in Figure 8-8.

Molecules of the two MHC classes are encoded from different genetic loci that are located as a large complex of genes on the short arm of human chromosome 6 (see Figure 8-8). The MHC also contains other genes that control the quality and quantity of an immune response, which are commonly referred to as class III MHC genes. The primary **MHC class I genes** consist of three closely linked loci on this chromosome labeled A, B, and C. The primary **MHC class II genes** are located within the D region, which actually consists of three separate and independent loci: DR, DP, and DQ.

The class I and class II MHC loci are the most genetically diverse (polymorphic) of any human genetic loci. Within the human population, the number of possible different alleles (i.e., forms of the gene) expressed by each locus is astounding: 649 at the A locus, 1029 at the B locus, 350 at the C locus, 643 at the DR locus (α and β), 125 at the DQ locus (α and β), and 154 at the DP locus (α and β). These numbers are based on the polymorphism of observed DNA sequences and may not reflect differences in function. Clearly, not every allele is expressed in the same individual. Humans have two copies of each MHC locus (one inherited from each parent) that are codominant so that molecules encoded by each parent's genes are expressed on the cell surface. Within an individual, each locus will be expressing only one allele. For instance, each person will have only two different A proteins (one from each parent). However, with the tremendous number of possible alleles that can be expressed, it is likely that any two unrelated individuals will have different sets of MHC molecules on their cell surfaces so that each of us is distinct.

Transplantation. The diversity of MHC molecules becomes clinically relevant during organ transplantation. Cells in transplanted tissue or organs from one individual will have a different set of MHC surface antigens than those of the recipient; therefore, the recipient can mount an immune response against the foreign MHC antigens, resulting in rejection of the transplanted tissue. As a result of studies of transplantation, the human MHC molecules are also referred to as **human leukocyte antigens (HLAs),** and the different MHC genetic loci are commonly called HLA-A, HLA-B, HLA-C, HLA-DR, HLA-DQ, and HLA-DP. To minimize the chance of tissue rejection, the donor and recipient are often *tissue typed* beforehand to identify differences in HLA antigens. The more similar two individuals are in their HLA tissue type, the more likely a transplant from one to the other will be successful.

Although a large number of alleles exist at the molecular level, the diversity is considerably less at the antigenic level: there are approximately 67 different HLA-A antigens, 149 HLA-B antigens, and 39 HLA-C antigens. Because of the large number of different alleles, it is highly unlikely that a perfect "match" can be found in the general population between a potential donor and the recipient.

The specific combination of alleles at the six major HLA loci on one chromosome (A, B, C, DR, DQ, and DP) is termed a **haplotype.** Each individual has two HLA haplotypes, one from the paternal chromosome 6 and another from the maternal chromosome. Because the different HLA loci within the MHC are in such close proximity to one another, haplotypes are not *usually* disrupted by recombination and are thus inherited intact. Each parent passes on one HLA haplotype to each of his or her offspring, meaning that children usually share one haplotype with each parent (Figure 8-9). Odds dictate that children will share one haplotype with half of their siblings and either no haplotypes or both haplotypes with a quarter of their siblings.

	Class II MHC	Class I MHC	CD1
Structure	Two transmembrane chains (α and β)	Single transmembrane chain (α) and β2-microglobulin	Single transmembrane chain (α) and β2-microglobulin
Distribution	B cells, APCs, and some epithelial cells	All nucleated cells and platelets	APCs
Presents	"Exogenous" antigens derived from extracellular organisms	"Endogenous" antigens (8-10 amino acids) derived from intracellular proteins	"Exogenous" lipid antigens derived from extracellular organisms
Reacts with	CD4 on Th cells	CD8 on Tc cells	Unknown

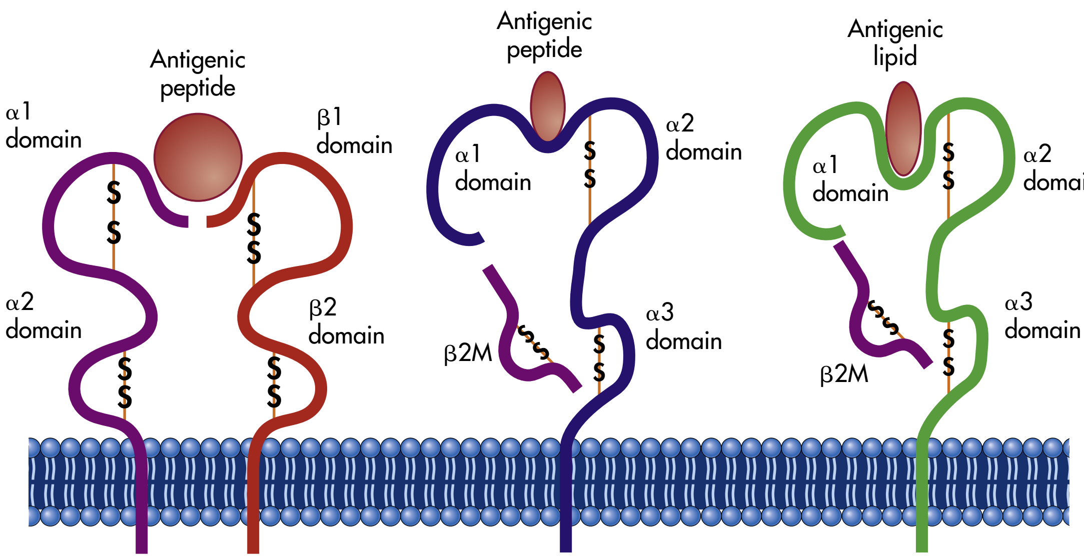

FIGURE 8-8 **Genetics and Structure of Antigen-Presenting Molecules.** Three sets of molecules are primarily responsible for antigen presentation: MHC class I, MHC class II, and CD1. The MHC molecules are encoded from the MHC region on chromosome 6, which contains information for class I and class II molecules, as well as for several other molecules that participate in the innate or immune responses. These include several complement proteins (C′) and cytokines (Cyto), which are referred to as MHC class III molecules. Three principal class I molecules, HLA-A, HLA-B, and HLA-C, are presented here, but this region contains information for the α-chains of several other molecules, including HLA-E, HLA-F, and HLA-G. The MHC class I products complex with β2-microglobulin, which is encoded by a gene on chromosome 15. The MHC class I molecules present small peptide antigens in a pocket formed by the α1 and α2 domains of the α-chain. The conformation of the molecule is stabilized by β2-microglobulin (β2M) as well as by intrachain disulfide bonds (-S-S-). The α- and β-chains of class II molecules are also encoded in this region: HLA-DR, HLA-DP, and HLA-DQ. In some cases, multiple genes for α- and β-chains are available. The MHC class II molecules present peptide antigens in a pocket formed by the α1 domain of the α-chain and the β1 domain of the β-chain. The genes for CD1 molecules are encoded on chromosome 1, which contains genes for five α-chains (CD1A-E), and the α-chains complex with β2-microglobulin to present lipid antigens in a pocket formed by the α1 and α2 domains. All three sets of antigen-presenting molecules are anchored to the plasma membrane by hydrophobic regions on the ends of the α- and β-chains. *MHC,* Major histocompatibility complex.

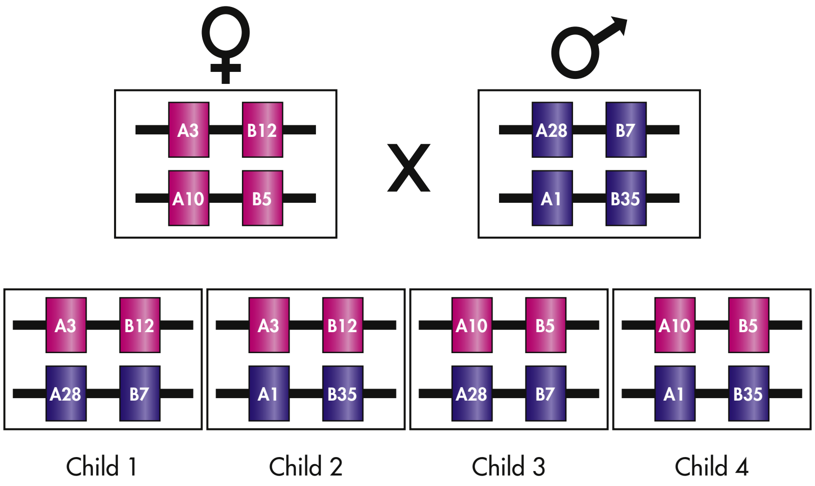

FIGURE 8-9 **Inheritance of HLA.** HLA alleles are inherited in a codominant fashion so that both maternal and paternal antigens are expressed. Specific HLA alleles are commonly given numbers to indicate different antigens. In this example, the mother has linked genes for HLA-A3 and HLA-B12 on one chromosome 6 and genes for HLA-A10 and HLA-B5 on the second chromosome 6. The father has HLA-A28 and HLA-B7 on one chromosome and HLA-A1 and HLA-B35 on the second chromosome. On one particular chromosome, the HLA antigens are firmly linked, with crossovers occurring in only 1% of individuals. The children from this pairing may have one of four possible combinations of maternal and paternal HLA. *HLA,* Human leukocyte antigen.

Thus the chance of finding a match among siblings is much higher (25%) than that from the general population.

It should be noted, however, that although HLA alleles are the primary contributor to rejection of a transplant, a number of other antigens also have a role in determining tissue compatibility. Some of these are encoded on other chromosomes and are inherited independently of HLA antigens. This means that although two people have the same HLA makeup, a graft or transplant still may be rejected because of differences between other antigens. It is preferable to obtain a graft or transplant from a closely related individual, such as a sibling, because the chance of sharing both the same HLA antigens and other undetermined antigenic differences encoded outside the MHC is much greater.

CD1

Another set of antigen-presenting molecules are members of the CD1 group. CD1 molecules have very low genetic polymorphism, a structure similar to MHC class I, and are found primarily on APCs and cells in the thymus. Unlike MHC molecules that present proteins, the CD1 molecules appear to specialize in presenting lipid antigens contained in lipoproteins, glycolipids, and other molecules. These antigens are commonly important factors in infections with bacteria of the *Mycobacterium* spp. (e.g., *Mycobacterium tuberculosis* that causes tuberculosis and *Mycobacterium leprae* that causes leprosy), which have a very large amount of lipid in their cell membranes.

Molecules That Hold Cells Together

The efficient development of an immune response requires several antigen-independent interactions between cells. The interactions between specific cellular receptors and their ligands result in intracellular signaling events that are independent of the TCR or BCR complexes but are necessary complements to the antigen-specific signal. Several of these molecules are listed in Box 8-1.

BOX 8-1 IMPORTANT ADHESION MOLECULE PAIRINGS

Th-cell CD4	⇔	MHC class II on APC
Tc-cell CD8	⇔	MHC class I on APC
Tc-cell CD2	⇔	CD58 (LFA-3) on APC
Tc-cell CD28	⇔	CD80 (B7-1) on APC
Tc-cell LFA-1	⇔	ICAM-1 on APC
Th-cell CD40L (CD154)	⇔	CD40 on B cell
Th-cell CD40L (CD154)	⇔	CD40 on APC

APC, Antigen-presenting cell; *ICAM,* intercellular adhesion molecule; *LFA,* lymphocyte function associated antigen; *MHC,* major histocompatibility complex; *Tc,* cytotoxic cell; *Th,* helper T cell.

Cytokines and Their Receptors

As discussed in Chapter 7, cytokines are low-molecular-weight proteins, or glycoproteins, that function as chemical signals between cells. A large number of cytokines are secreted by APCs and lymphocytes and provide both positive and negative regulation of the immune response. The effects of particular cytokines depend on binding to specific cellular receptors, which are linked to intracellular signaling pathways. The lymphocyte may respond in many ways. One of the most common responses is an increase in the production of proteins, many of which are other cytokines or cytokine receptors. Many cytokines also cause a lymphocyte to proliferate and differentiate. The participation of cytokines is essential to the development of an adequate immune response, and in general, the precise combination of cytokines influences the ultimate response of

TABLE 8-5 KEY CYTOKINES AND RECEPTORS THAT INFLUENCE THE IMMUNE RESPONSE

CYTOKINE	PRIMARY SOURCE	PRIMARY FUNCTION
Interleukin (IL)		
IL-1	APCs	Stimulates T cells to proliferation and differentiation; induces acute-phase proteins in inflammatory response; endogenous pyrogen
IL-2	Th1 cells, NK cells	Stimulates proliferation and differentiation of T cells and NK cells
IL-4	Th2 cells, mast cells	Induces B-cell proliferation and differentiation; up-regulates MHC class II expression; induces class-switch to IgE
IL-5	Th2 cells, mast cells	Induces eosinophil proliferation and differentiation; induces B-cell proliferation and differentiation
IL-6	Th2 cells, APCs	Induces B-cell proliferation and differentiation into plasma cells; induces acute-phase proteins in inflammatory response
IL-7	Thymic epithelial cells, bone marrow stromal cells	Major cytokine for induction of B- and T-cell proliferation and differentiation in central lymphoid organs
IL-8	Macrophages	Chemotactic factor for neutrophils
IL-10	Th cells, B cells	Inhibits cytokine production; activator of B cells
IL-12	B cells, APCs	Induces NK-cell proliferation; increases production of IFN-γ
IL-13	Th2 cells	IL-4–like properties; decreases inflammatory responses
IL-17	Th17 cells	Increases inflammation; increased influx of neutrophils and macrophages; increased epithelial cell chemokine production
IL-22	Th17 cells	Increases inflammation; increased epithelial cell production of antimicrobial peptides
Interferon (IFN)		
IFN-α, IFN-β	Macrophages, some virally infected cells	Antiviral; increases expression of MHC class I; activates NK cells
IFN-γ	Th1 cells, NK cells, Tc cells	Increases expression of MHC class II; activates macrophages and NK cells
Tumor Necrosis Factor (TNF)		
TNF-α (cachectin)	Macrophages	IL-1–like properties; induces cellular proliferation
TNF-β (lymphotoxin)	Tc cells	Kills some cells; increases phagocytosis by macrophages and neutrophils
Transforming Growth Factor (TGF)		
TGF-β	Lymphocytes, macrophages, fibroblasts	Chemotactic for macrophages; increases macrophage IL-1 production; stimulates wound healing

CYTOKINE RECEPTORS	LIGAND	ADDITIONAL INFORMATION
Class I receptor dimers (α- and β-chains)	IL-3, IL-5, IL-6, IL-11, IL-12, IL-13	IL-3 and IL-5 share a common α-chain; IL-6 and IL-11 share a common β-chain
Trimers (α-, β-, and γ-chains)	IL-2, IL-4, IL-7, IL-9, IL-15	All share a common γ-chain
Class II receptors	IFN-α, -β, and -γ	Two chains
TNF receptors	TNF-α, TNF-β, CD40, Fas	Single chain
Immunoglobulin-like receptors	IL-1	Single chain with immunoglobulin-like characteristics

APCs, Antigen-presenting cells; *MHC,* major histocompatibility complex; *NK,* natural killer; *Tc,* cytotoxic cells; *Th,* helper T cells.

a given cell. Specific deficiencies in the immune response that result from genetic mutations that lead to defective cytokine production or defective cytokine receptors are discussed in Chapter 9. Table 8-5 provides information about key cytokines and receptors that are known to influence the immune response.

GENERATION OF CLONAL DIVERSITY

It has been suggested that more than 10^8 different antigenic determinants may be recognized by receptors on an individual's immunocompetent B cells. A similar number may be recognized by T-cell receptors. However, each T or B cell has only a single receptor specificity that recognizes only one antigen, and each is present before that individual is ever exposed to foreign antigen. Thus before the individual is exposed to any foreign antigen, millions of different T- and B-cell antigen receptors must be constructed to recognize *any* potential antigenic determinant.

Several theories were proposed to explain how such a great diversity of recognition could be produced. The process occurs in two phases: the **generation of clonal diversity,** during which all the necessary receptor specificities are produced; and **clonal selection,** during which antigen selects those lymphocytes with compatible receptors, expands their population, and causes differentiation into antibody-secreting plasma cells or mature T cells (Table 8-6).[5,6] The generation of clonal diversity takes place in the **primary (central) lymphoid organs** (i.e., thymus

TABLE 8-6 GENERATION OF CLONAL DIVERSITY VS. CLONAL SELECTION

	GENERATION OF CLONAL DIVERSITY	CLONAL SELECTION
Purpose?	To produce large numbers of T and B lymphocytes with the maximum diversity of antigen receptors	Select, expand, and differentiate clones of T and B cells against a specific antigen
When does it occur?	Primarily in the fetus	Primarily after birth and throughout life
Where does it occur?	Central lymphoid organs: thymus for T cells, bone marrow for B cells	Peripheral lymphoid organs, including lymph nodes, spleen, and other lymphoid tissues
Is foreign antigen involved?	No	Yes; antigen determines which clones of cells will be selected
What hormones/cytokines are involved?	Thymic hormones, IL-7, others	Many cytokines produced by Th cells and APCs
Is tolerance induced?	Central tolerance induced as autoreactive cells are deleted	Peripheral tolerance induced as autoreactive cells are regulated
Final product?	Immunocompetent T and B cells that can react with antigen but have not seen antigen, and migrate to the secondary lymphoid organs	Plasma cells that produce antibody, effector T cells that help (Th), kill targets (Tc), or regulate immune responses (Treg); memory B and T cells

APCs, Antigen-presenting cells; *IL,* interleukin; *Tc,* cytotoxic T cells; *Th,* helper T cells; *Treg,* regulatory T cells.

and bone marrow), is driven by hormones, does not require foreign antigen, and results in the generation of immature but immunocompetent T and B cells with receptors that can recognize virtually any antigenic molecule. Both T and B cells are derived from common precursor cells **(lymphoid stem cells)** that arise either in the liver (in the fetus) or in the bone marrow (of a child or adult). These precursor cells are distinct from the precursor cells that give rise to cells of the innate immune system. The immunocompetent T and B cells migrate from the primary lymphoid organs to **secondary (peripheral) lymphoid organs** (e.g., spleen, lymph nodes, adenoids, tonsils, Peyer patches), where they await antigen. Clonal selection is initiated by antigen and results in a mature and specific immune response against that antigen.

Although generation of clonal diversity primarily occurs in the fetus, it probably continues to a low degree throughout most of adult life. Clonal selection usually begins at birth and proceeds throughout the life of the individual as new antigens are encountered, although it can begin as early as the eighth week of gestation in humans.

As a result of this process, T and B lymphocytes have the capacity to react against virtually any antigen found in nature. This endless array of possible antibodies and TCRs certainly cannot be constructed from the amount of deoxyribonucleic acid (DNA) that is in the nucleus of a human lymphocyte. The enormous repertoire of specificities is instead made possible by rearrangement of existing DNA during T- and B-cell development in the primary lymphoid organs. Loci in the DNA that encode for the variable regions of immunoglobulins and TCRs are recombined in a unique way to generate receptors that collectively can recognize and bind to any possible antigen. The DNA in the nucleus of a developing T and B cell is actually cut and spliced (repaired), a process known as **somatic recombination,** so that after this manipulation, the progeny of a single lymphocyte will synthesize identical immunoglobulins or TCRs. Those variable regions, however, are cut and spliced differently from those of another lymphocyte, making each cell unique and therefore able to react with different antigens. The particular process for B and T cells is discussed next.

T-Cell Maturation

Central Lymphoid Organ

The central lymphoid organ for T-cell development is the thymus, which is an organ located near the heart. Precursor cells (lymphoid stem cells) arise in early embryonic life from the yolk sac and fetal liver and later from the bone marrow. They migrate to the thymus and enter the subcapsular region. As the cells move through the thymic cortex to the medulla, they are instructed by interactions with various thymic cells (epithelial cells, macrophages, and dendritic cells) and thymic hormones to undergo proliferation and progressive development of the characteristics of immunocompetent T cells[7] (Figure 8-10). Changes include development of the T-cell receptor complex and expression of characteristic surface molecules. Many T cells randomly develop TCRs against self-antigens, but are deleted during this process. The final antigen-reactive T cells are released into the blood and take up residence in the secondary lymphoid organs to await antigen.

Production of the T-Cell Receptor

Like antibody, the TCR reacts with antigen (see Figure 8-5). Although the structure of the TCR closely resembles a Fab portion of antibody, the TCR uses different protein chains than are used for antibody. The most common TCR contains α- and β-chains, each of which has a variable region and a constant region. Within each variable region are three CDR regions separated by FR regions.

The great amount of variable region diversity necessary for identifying the huge number of antigens found in nature is produced by random recombination of multiple genes to encode the variable regions of both the α- and β-chains. In the germline genes, the information for the amino acid sequence of the α-chain variable region is found on chromosome 14 in two separated, but closely associated, locations: a set of *V* region genes and a set of *J* region genes (Figure 8-11). The TCR α-chain locus has multiple (at least 50) *V* genes and multiple (at least 50) *J* genes. During somatic recombination in a developing T cell, one of the possible *V* genes is randomly selected and spliced to one of the *J* genes, with the intervening DNA being removed. This DNA rearrangement process is controlled by two enzymes

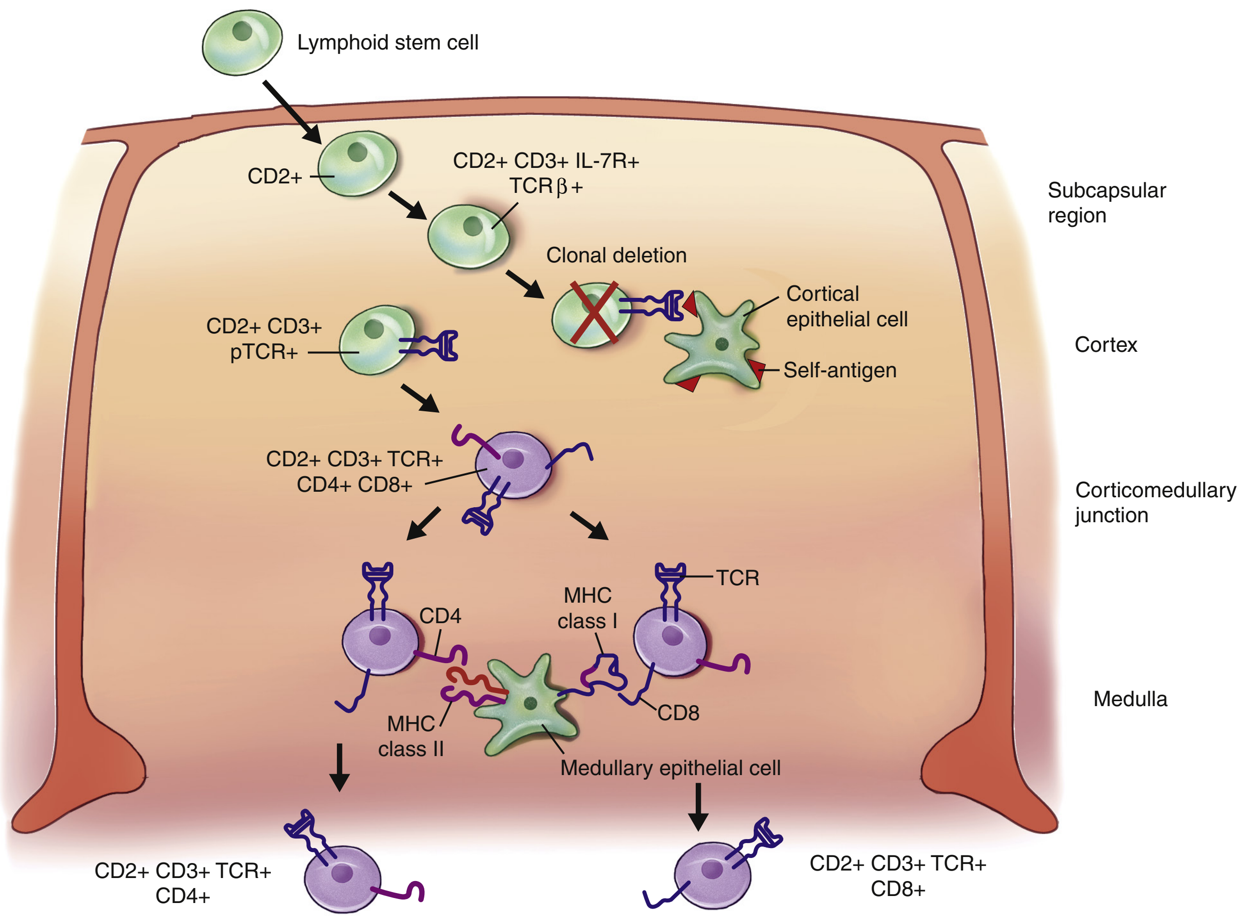

FIGURE 8-10 T-Cell Development in the Thymus. During the generation of clonal diversity in the fetus, lymphoid stem cells undergo several stages of cellular division and differentiation in a central lymphoid organ (the thymus) under the control of hormones but without the influence of foreign antigen. A simplified scheme for that process is presented here. The differentiation process is characterized by the up-regulation of many important surface molecules (only some of which are shown) and the random development of a huge number of different T-cell receptors against all possible antigens that the adult may encounter. The lymphoid stem cell enters the subcapsular region of the thymus, where it begins to undergo differentiation. One of the first surface changes is the appearance of the molecule CD2, which is a marker for all T cells. In the cortex of the thymus, the developing cell encounters epithelial cells that guide most of the early differentiation process. The pre–T cell begins expressing the surface receptor for the cytokine IL-7, which is produced by the epithelial cell along with other thymic hormones to drive the T-cell differentiation process. At this stage the T cell begins constructing the T-cell receptor (TCR) by first rearranging and expressing the TCR β-chain (more detail is provided in Figure 8-11) and expressing CD3 molecules. Although the TCR α-chain has not yet been produced, the β-chain is expressed on the surface as a pre-TCR (pTCR) using a protein that acts as a surrogate for the α-chain. Because of the randomness of the process, some pTCRs are produced with specificities toward self-antigens. Many of these undergo negative selection and are deleted (clonal deletion) by apoptosis induced through interactions with self-antigens presented by the epithelial cells. Survivors of negative selection move toward the thymic cortex and begin expressing the TCR α-chain, the normal TCR, and both CD4 and CD8 on their surfaces. These CD4+, CD8+ "double-positive" cells encounter medullary epithelial cells that express both MHC class I and MHC class II molecules. The phenotype of the developing T cell is positively selected so that interaction between CD4 and MHC class II selects for retention of CD4 expression, whereas interaction between CD8 and MHC class I favors the CD8 phenotype. Thus two populations of "single-positive" immunocompetent T cells leave the thymus: one cell is CD4+, CD8– (destined to be a helper T [Th] cell) and the other is CD4–, CD8+ (destined to be a cytotoxic T [Tc] cell).

produced by genes *RAG-1* and *RAG-2* (recombination activating genes). These enzymes cut double-stranded DNA at specific recognition sites (recombinant signal sequences) and then repair the break, resulting in excision of the DNA between the selected *V* and *J* genes. At transcription, the genetic information for the α-chain variable region is still separated from the gene for the α-chain constant region. This product is transcribed into messenger ribonucleic acid (mRNA) that contains information for the variable region *(VJ)* separated by a span of RNA from the information for the α-chain constant region. An RNA-processing step removes the intervening span, bringing the message for the variable and constant regions together into a final mRNA product that is translated into the intact α-chain protein. The random selection and pairing of 50 *V* and 50 *J*

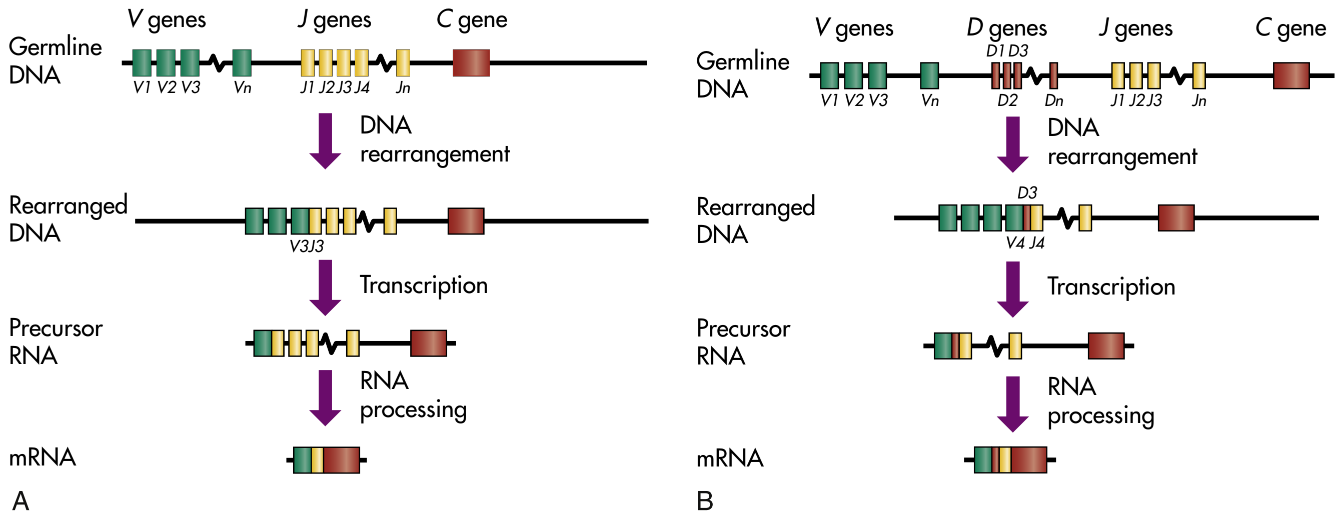

FIGURE 8-11 **DNA Rearrangement of Genes for Antigen-Binding Molecules.** During the generation of clonal diversity, a tremendous number of different antigen-binding molecules are produced. These include the B-cell receptor (BCR), which consists of a membrane-bound antibody molecule, and the T-cell receptor (TCR). The process by which receptor diversity is created is identical for all antigen-binding molecules and is summarized in this figure. Maximum diversity with minimum use of DNA is accomplished by random rearrangement of sets of genes that encode different portions of the variable regions. **A,** The variable regions of the light chain of antibody and the α-chain of the TCR independently rearrange two sets of genes: *V* region genes and *J* region genes. The light chain uses its own set of genes, and the α-chain uses a completely different set. In neither case is the exact number of *V* or *J* region genes known; therefore, in this figure they are numbered from 1 to an unknown value *(n).* In a particular cell's DNA, one *V* gene is randomly selected and moved to a position immediately adjacent to a randomly selected *J* gene. In this example, *V3* and *J3* were selected. The DNA between the selected genes is enzymatically removed and the DNA repaired, so that the rearranged DNA in this example is missing the portion found in the germline DNA between *V3* and *J3.* This product is transcribed into a precursor ribonucleic acid (RNA) that contains information for the rearranged *VJ* pair, a span containing other unselected *J* regions, and information for the appropriate constant region (*C* gene) of the molecule. The RNA between the *VJ* and the *C* regions is not translated; therefore, it is removed by RNA processing to produce a messenger RNA (mRNA) that is translated. **B,** The variable region of the antibody heavy chain and the TCR β-chain results from a similar DNA rearrangement, with the added diversity contributed by a group of *D* region genes. The joining of *D* and *J* occurs first, with the removal of intervening DNA. In this example, *D3* and *J4* were chosen. This is followed by rearrangement of the *V* gene (e.g., *V4*) and formation of a *VDJ* region in the rearranged DNA. The precursor RNA contains information for the *VDJ,* the intervening portion of DNA, and the appropriate constant region. After RNA processing, an mRNA is formed for the intact antibody heavy chain or the TCR β-chain. Once the DNA is rearranged and spliced in a given B or T cell, all of the antigen receptors produced by that cell employ the same *V, D,* and *J* segments and have the same specificity.

genes by a large number of developing T cells can result in more than 2500 possible α-chains.

In a similar fashion, the TCR β-chain locus on chromosome 7 has three sets of genes that rearrange to encode the variable region of that chain: at least 20 *V* genes, 13 *J* genes, and 2 intervening and relatively short *D* genes that add further diversity. Using the RAG-1 and RAG-2 enzymes, a developing T cell randomly selects a set of *V*, *D*, and *J* genes for DNA recombination. The *VDJ* rearranged segment is transcribed with a β-chain constant region, the intervening RNA is removed during processing, and the final mRNA is translated into an intact β-chain.[8]

The α- and β-chains are joined by that cell and inserted into the membrane to make an antigen-specific TCR. The enormous number of possible combinations of α-chain *V* and *J* regions along with the β-chain *V*, *D*, and *J* regions enables the generation of a population of T cells with a large diversity of TCRs (estimated at 1.3×10^5 possible combinations). For both chains, the *V* region genes encode the amino acid sequences that include CDR1 and CDR2 and their appropriate FR regions. The *J* regions contain information for CDR3 and FR4. The TCR β-chain *D* regions encode a short amino acid sequence found in the CDR3 and greatly increases the diversity of the β-chain CDR3. Imprecise joining increases the diversity of the CDR3 regions of both the α- and β-chains even further. For example, the sites of *VJ* and *VDJ* joining may shift slightly resulting in an amino acid being inserted or deleted from the protein.

Although the αβ TCR is the preferred antigen receptor, some T cells use alternative genes: gamma (γ) (chromosome 7) and delta (δ) (chromosome 14, in the middle of α-chain genes). T cells with γδ TCRs appear to migrate to unique areas of the body (the epithelial areas in the skin, reproductive tract, intestine, respiratory tract) and have different and less well understood functions than the T cells with αβ TCRs.

Changes in Characteristic Surface Markers

Differentiation of T cells in the thymus also results in changes in a variety of important surface molecules. As the developing T cells move through the thymic cortex, they initiate the expression of the molecule CD2 on the cell surface. CD2 is a marker

for T cells and is expressed on virtually every subpopulation of cells that have undergone development in the thymus. Within the cortex, the cells begin rearranging the variable region genes necessary for forming a functional T-cell receptor. The T-cell receptor undergoes several stepwise changes until the final αβ TCR is formed. Concurrently, the TCR accessory molecules (collectively called CD3) are expressed. The cell also begins making two important surface proteins, CD4 and CD8, which are concurrently expressed on the developing cell's surface at this stage.[9] These CD4+, CD8+ cells are often called "double-positive" cells. Much of T-cell development is controlled by hormones and cytokines in the thymus, and an early step in maturation is expression of the receptor for interleukin-7 (IL-7R), which is a major cytokine that drives the differentiation process. After entering the medulla of the thymus, the double-positive cells become "single-positive." That is, some of the cells suppress production of the CD8 molecule and remain only CD4+, whereas others suppress CD4 production and remain CD8+.[10] This branch in the differentiation pathway leads to two groups of cells with different functional characteristics: CD4 cells tend to recognize antigen presented by MHC class II molecules and develop into helpers in the later clonal selection process (T-helper cells), whereas CD8 cells recognize antigen presented by MHC class I molecules and become mediators of cell-mediated immunity and kill other cells directly (T-cytotoxic cells).[11]

Central Tolerance

During the random rearrangement of *VJ* and *VDJ* genes to produce the T-cell receptor, some combinations result in specificities that recognize self-antigens. If some of these *autoreactive* T cells were allowed to progress further in development and leave the thymus, a severe immunologic reaction against the individual's own tissues could result. One stage at which tolerance for self-antigens is maintained is the deletion of autoreactive T cells in the thymus, which is referred to as central tolerance.

A variety of self-antigens are expressed by thymic cells. Many thymic cells express MHC class I or MHC class II molecules. During the T-cell's double-positive stage, if a TCR strongly reacts with MHC class I or class II, the T cell will undergo apoptosis, referred to as *clonal deletion*. A large spectrum of other self-antigens is expressed on the surface of thymic macrophages, dendritic cells, and especially epithelial cells.[12] If a developing T-cell's TCR binds strongly with a self-antigen, it is deleted. Although this process of *negative selection* induces more than 95% of T cells to undergo apoptosis in the thymus, a limited number of autoreactive clones persist and must be controlled by other means in the peripheral lymphoid organs (**peripheral tolerance).**

The destiny of the double-positive cells with TCRs specific for foreign antigens (which are not expressed in the thymus) is determined by their interaction in the thymus with MHC antigens. If their surface CD4 molecules bind to MHC class II molecules on the thymic cells, the T cell will become CD4 single-positive. However, if their surface CD8 reacts with MHC class I molecules, the cells will become CD8 single-positive. This *positive selection* process results in about 60% of immunocompetent T cells being CD4+ and 40% being CD8+ when they leave the thymus.[13]

B-Cell Maturation

Central Lymphoid Organ

Although the thymus is the central lymphoid organ for T-cell development, humans do not appear to have a discrete organ for B-cell development. In chickens, B lymphocytes undergo differentiation in an organ called the *bursa of Fabricius.* In humans, portions of the bone marrow function as a bursal-equivalent tissue for B-cell development.[14]

Regardless of the lack of a discrete organ, B-cell differentiation undergoes a very similar process to that described above for T cells.[15] Lymphoid stem cells in the bone marrow interact with stromal cells through a variety of intercellular adhesion molecules (Figure 8-12). As the stem cell begins to mature, it progressively develops a variety of necessary surface markers, the earliest being CD45R and the IL-7 receptor. IL-7, produced by the stromal cells, is critical in driving the further differentiation and proliferation of the B cell. The next stage in development is formation of the B-cell receptor.

Production of the B-Cell Receptor

The BCR is an antibody that is anchored to the plasma membrane. The process by which BCR diversity is generated is virtually identical to the process in T cells and also requires the genetic rearrangement of *V, D,* and *J* genes. The segments of DNA that encode either kappa (κ) (chromosome 2) or lambda (λ) (chromosome 22) light chains contain about 70 *V* and 5 *J* segments, whereas the heavy-chain locus on chromosome 14 contains about 80 *V,* 30 *D,* and 6 *J* regions. The locus for the antibody heavy chain also contains multiple sequential regions for different constant regions, with the gene for the mu (μ) constant region being closest to the *VDJ* region, and the delta (δ) constant region gene being next in sequence (Figure 8-13). These are followed by the constant region genes for other classes and subclasses. In the developing B cell, the initial RNA transcript contains information for the *VDJ* recombination, the μ constant region, and the δ constant region. Transcription is signaled to stop immediately after the δ constant region. During the following RNA processing step to form a final mRNA product, the cell can alternatively process some mRNAs to retain the μ constant region only or process other mRNA molecules to remove the μ constant region and retain the δ constant region. Thus one cell can use multiple mRNA molecules and alternative RNA processing to simultaneously produce two different heavy chains, μ and δ, both of which have the same variable region.

The developing B cell rearranges and expresses the heavy chain, which is followed by the rearrangement of either the κ or the λ light chain so that only one type is produced. The light chains are assembled with two μ heavy chains to form a monomeric IgM antibody or with two δ-chains to form an IgD antibody. Because each heavy chain used the same *VDJ* rearrangement and the same light chain, the variable regions and therefore the specificities of the IgM and IgD are identical. At this stage of B-cell development, both antibodies have hydrophobic, or sticky, "tails" that result in insertion into the plasma

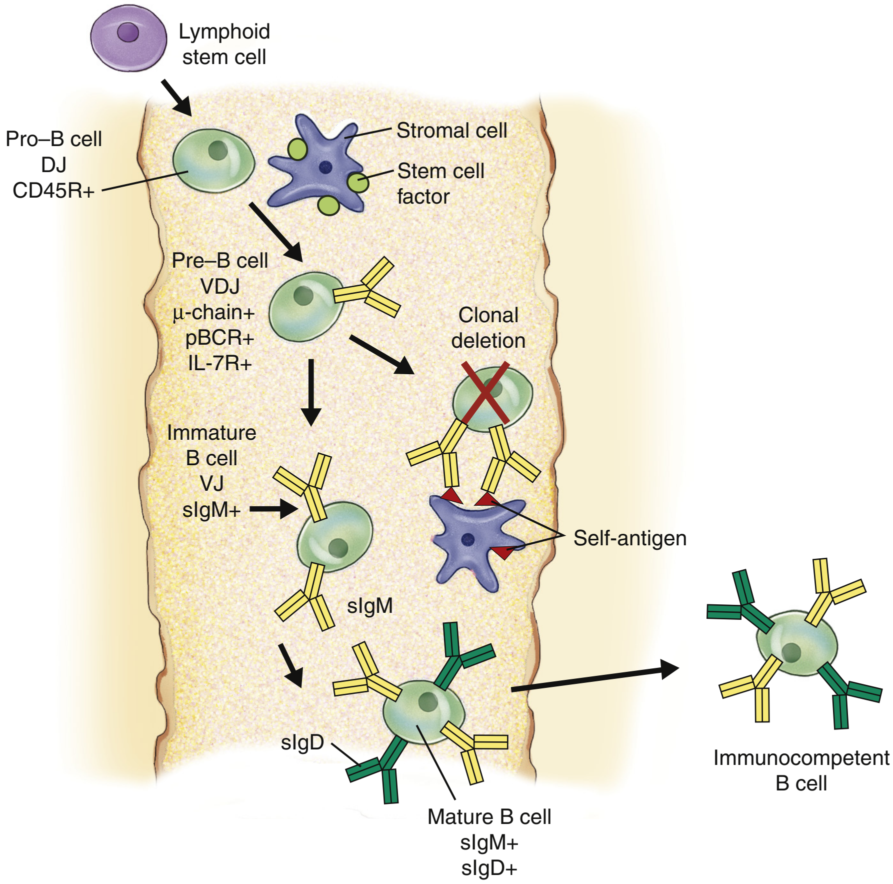

FIGURE 8-12 **B-Cell Development in the Bone Marrow.** During the generation of clonal diversity, lymphoid stem cells enter portions of the bone marrow that serve as the central lymph organ for B-cell development. Interactions with a series of bone marrow stromal cells guide the proliferation and differentiation process through direct cell-to-cell contact and the production of cytokines and hormones by the stromal cells, but without the presence of foreign antigen. A simplified scheme for that process is presented here. As with T-cell development, the differentiation process of B cells is characterized by the up-regulation of many important surface molecules (only some of which are shown) and the random development of a huge number of different B-cell receptors. The early B cell (pro–B cell) binds to a membrane-bound cytokine (stem cell factor) on the stromal cell and initiates expression of the surface molecule CD45R and begins to rearrange the *DJ* regions of the antibody heavy-chain gene. As the cell progresses to the pre–B-cell stage, it concludes DNA rearrangement of the heavy chain *(VDJ)* and begins expressing cytoplasmic mu (μ) heavy chain. The μ- chain is incorporated into a pre–B-cell receptor (pBCR) using a surrogate protein in place of the light chain. The cell also up-regulates the IL-7 receptor (IL-7R), which interacts with IL-7 produced by the stromal cells to drive the remaining steps in differentiation. Some pBCRs have specificities toward self-antigen. Many of these encounter self-antigen expressed on the stromal cells and undergo negative selection (clonal deletion). The surviving cells (immature B cells) rearrange the light-chain DNA *(VJ)* and express a BCR consisting of light chain and the μ-heavy chain (surface IgM [sIgM]). In the mature B cell, changes in processing of the heavy-chain precursor RNA result in co-expression of sIgM and IgD (sIgD) (see Figure 8-13 for more details).

membrane and the co-expression of IgM and IgD receptors on the cell surface.

Changes in Characteristic Surface Markers

As with T cells, B-cell differentiation is also characterized by the development of a variety of important surface molecules. These include CD21 (a complement receptor) and CD40 (adhesion molecule required for later interactions with Th).

Central Tolerance

During the very earliest stages of formation of the BCR in the bone marrow, a large number of autoreactive B cells are eliminated if exposed to self-antigen.[16] It is estimated that more than 90% of developing B cells are induced to undergo apoptosis.

INDUCTION OF AN IMMUNE RESPONSE: CLONAL SELECTION

As described in the previous chapter, successful invasion by a pathogen will initially elicit an inflammatory response as a host attempts to destroy and clear the invading microorganism. In addition to carrying out their roles as inflammatory effector cells, some of the cells involved in innate immunity are responsible for communicating with immature B and T lymphocytes to initiate specific and longer-acting acquired immunity. This

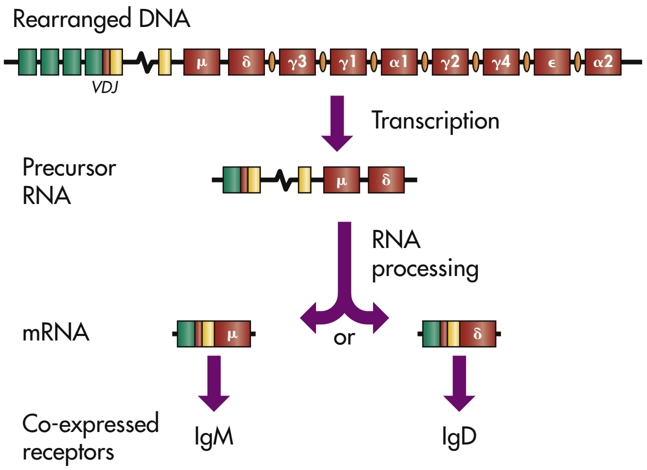

FIGURE 8-13 Genetics of the B-Cell Receptor. Most mature immunocompetent B cells express both surface IgM and IgD as the B-cell receptor. In the germline DNA, the heavy-chain gene complex consists of a series of *V, D, J,* and constant region genes. In humans, each class and subclass of antibody has a unique constant region gene arranged in the indicated order. Switch regions occur preceding every constant region gene, except mu (μ) (IgM) and delta (δ) (IgD). After successful DNA rearrangement of the *VDJ* regions, a ribonucleic acid (RNA) molecule is transcribed that contains the information from the *VDJ,* intervening DNA, the μ constant region, and the δ constant region. Precursor RNA molecules are alternatively processed to produce messenger RNAs (mRNAs) containing either μ or δ. Initially, RNA processing favors the μ chain and production of surface IgM (see Figure 8-12), but as the B cell matures, both mRNA molecules are produced.

intercellular communication occurs via direct cellular contact in peripheral lymphoid tissues and is essential for the specificity of the adaptive immune response.

Secondary Lymphoid Organs

The secondary lymphoid organs include the spleen, lymph nodes, adenoids, tonsils, Peyer patches (intestines), and the appendix (see Figure 8-3). Immunocompetent lymphocytes enter the secondary lymphoid organs through the blood and enter specialized small veins, called **high endothelial venules (HEVs),** where they bind to the endothelium through a family of adhesion molecules. The lymphocytes migrate from the vessels into the lymphoid tissues, which contain B- and T-cell–rich areas. B lymphocytes that encounter antigen in the secondary lymph organs usually undergo a process of differentiation and proliferation that results in the formation of specialized germinal centers in these organs (Figure 8-14).[17]

Antigen Processing and Presentation

Most antigens do not react directly with T or B cells, but require processing and presentation in the appropriate fashion. This is the duty of APCs.

Pathogens that penetrate the external barriers and enter the tissues or bloodstream encounter a variety of phagocytic cells and are therefore likely to be ingested and destroyed. If the infectious agent is in the tissues, they may elicit an inflammatory response that results in the infiltration of macrophages

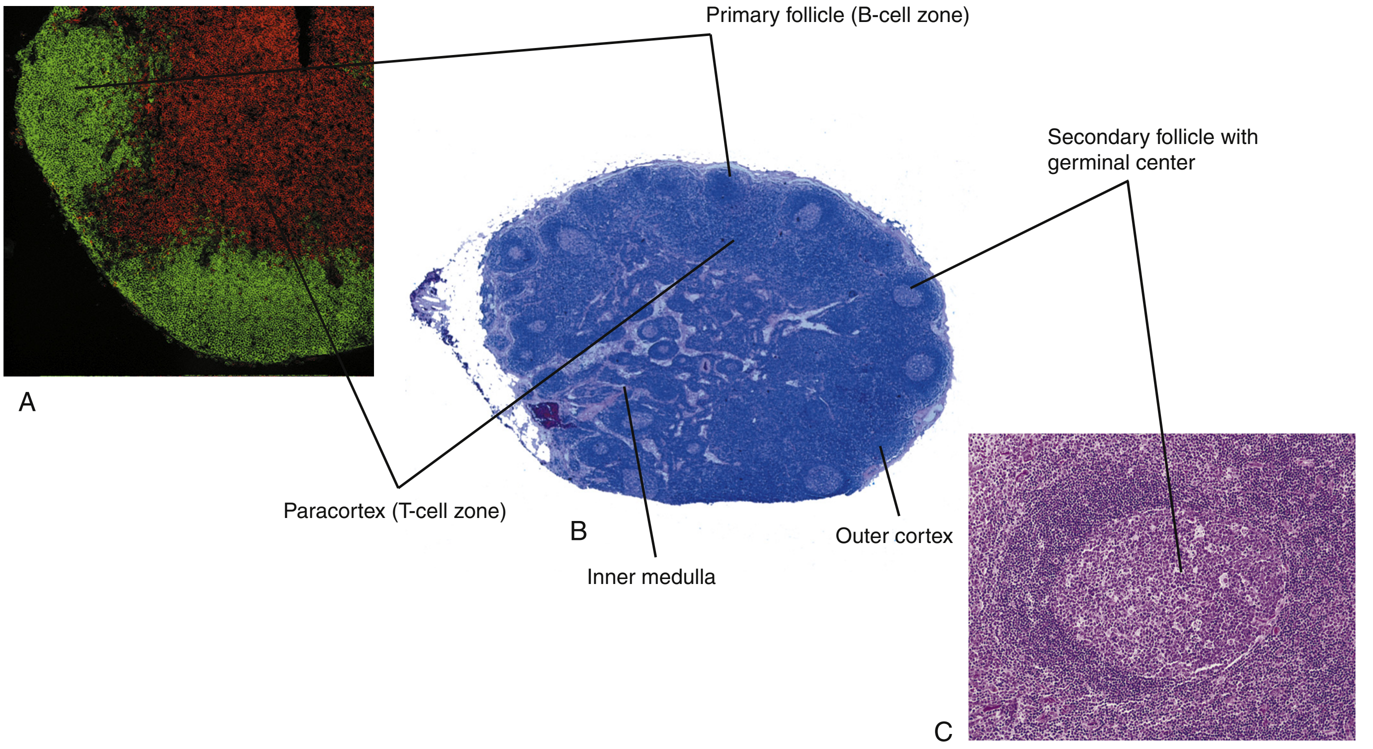

FIGURE 8-14 Histology of a Secondary Lymphoid Organ. **A,** The lymph node contains areas (primary follicles) that are rich in immunocompetent B cells *(stained green),* and T cells *(stained red)* in the paracortex. **B,** A lymph node is organized into an outer cortex and an inner medulla. **C,** In response to antigen, B cells undergo proliferation, resulting in the formation of secondary follicles with germinal centers. (Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

into the site. Additionally, the infectious agent or fragments of the microorganism may be removed by the lymphatics, which drain to the lymph nodes. The lymph nodes are extremely rich in dendritic cells and macrophages, which phagocytose the material and function as APCs for T and B lymphocytes in the lymph nodes. Pathogens entering through the bloodstream may be removed by phagocytic cells in the spleen and other lymphoid tissues. In either case, the phagocytic cells that digest invading pathogens are also responsible for processing antigens from the pathogen and displaying or presenting those antigens on the phagocyte's surface to neighboring lymphocytes in order to initiate the adaptive immune response against that specific pathogen.

Many cells have the capacity to present antigen to some degree, but dendritic cells, macrophages, and B lymphocytes are so efficient at antigen presentation that they are considered "professional" APCs. Each of these three APCs is responsible for the presentation of antigens of different types and from different sources. B cells present antigen to Th cells that facilitate development of the humoral immune response. Macrophages are very effective in presenting antigen to memory Th cells in order to initiate a rapid response to antigens (i.e., secondary immune response). The dendritic cells are perhaps the most effective in presenting antigen to naïve immunocompetent Th cells. Dendritic cells develop from bone marrow precursor cells, either of myeloid or of lymphoid lineage (at least two populations of dendritic cells have been described). They migrate to the peripheral tissues (e.g., skin, intestinal tract) and to the secondary lymphoid organs. Immature dendritic cells at a site of inflammation function as phagocytes, and the process of phagocytosis can initiate differentiation and directed migration to the secondary lymphoid organs, particularly the lymph nodes (Figure 8-15).[18] Thus dendritic cells can carry processed antigen from a site of inflammation to the T-cell–rich areas of the lymph nodes.

Both antigen processing and presentation are necessary for an adaptive immune response to occur. Although B and T

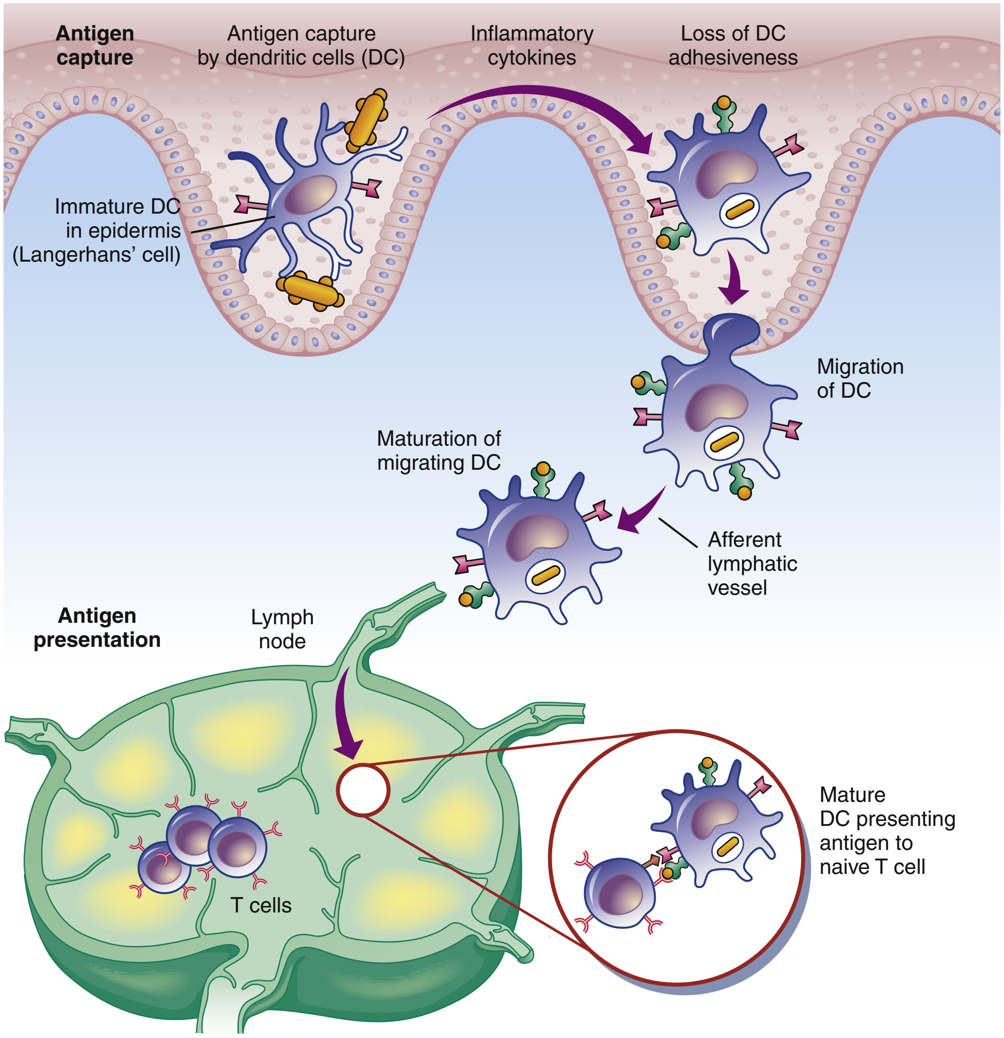

FIGURE 8-15 **The Role of the Dendritic Cell in Capturing Antigen.** Immature dendritic cells in the tissues encounter and phagocytose antigen, which results in the production of inflammatory cytokines and a loss of adhesive interactions with neighboring cells. The maturing dendritic cell migrates through the lymphatic vessels to a regional lymph node, where it presents the antigen to immunocompetent T cells to initiate the clonal selection process. (Redrawn from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

lymphocytes are immunocompetent before they have "seen" an antigen on the surface of an APC, they are considered "naive" until they have actually done so. The processing and presentation of antigens to naïve lymphocytes result in activation of an acquired immune response only if (1) the antigen is of the appropriate type; (2) the lymphocytes are prepared to recognize the presented antigen; and (3) the antigen is presented appropriately.

Pathways of Antigen Processing

In general, the immune system responds to two types of antigens: exogenous and endogenous. Using infection as a model, exogenous antigens are carried on microorganisms that are trapped and killed by phagocytic cells; therefore, they come from outside the cell. Endogenous antigens are synthesized within a cell. These include viral antigens because viruses infect cells and use the normal cellular protein-synthesizing machinery to translate the viral genes into viral proteins. Endogenous antigens also may include those uniquely produced by cancerous cells. When many cells undergo malignant change, they begin producing unique proteins that are specific to cancer cells and are presented as foreign antigens on the cell surface.

Exogenous and endogenous antigens are preferentially presented by different classes of MHC molecules: class I MHC molecules generally present endogenous antigens, and class II molecules prefer exogenous antigens (Figure 8-16).[19] Because class I MHC molecules are expressed on all cells, except red blood cells, any change in that cell attributable to viral infection or malignancy may result in foreign antigen being presented by MHC class I on that cell's surface. Class II MHC molecules are co-expressed with MHC class I molecules on a more limited number of cells that have APC function, including

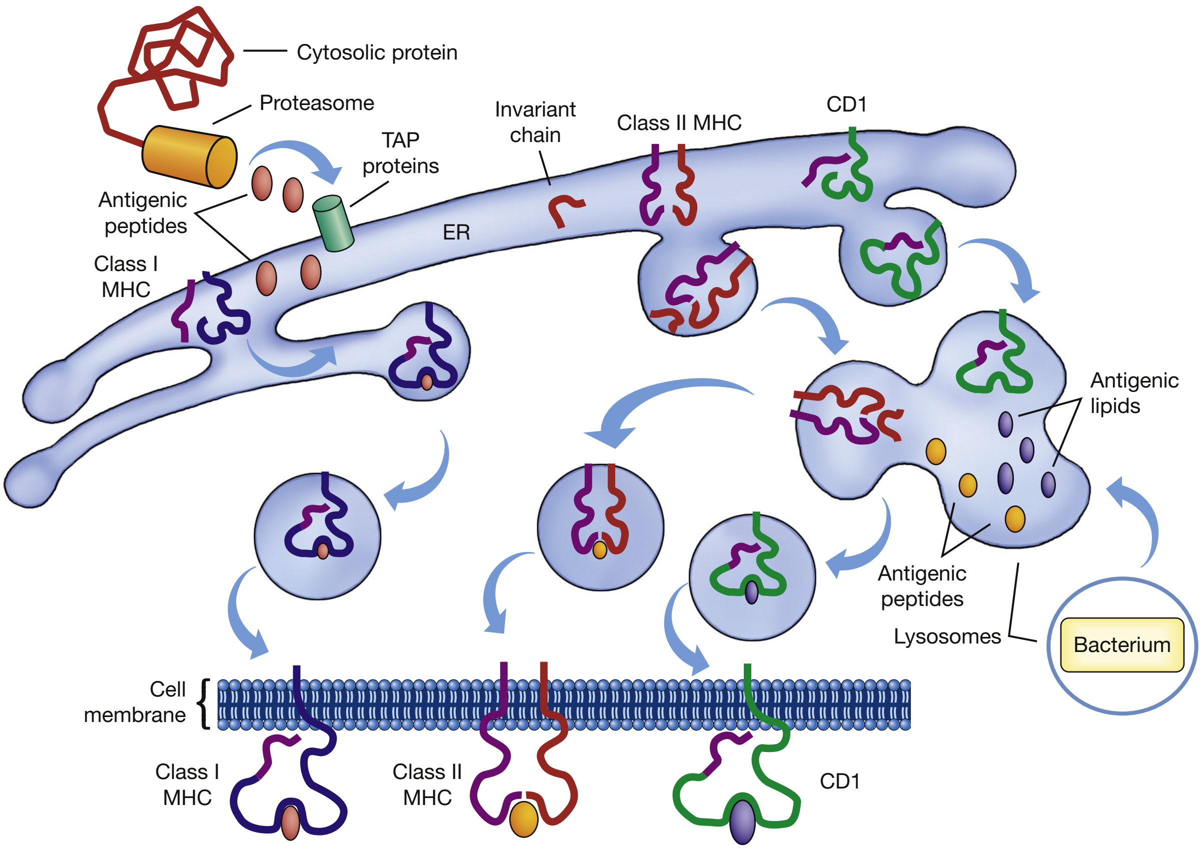

FIGURE 8-16 **Antigen Processing.** Antigen processing and presentation are required for initiation of most immune responses. Foreign antigen may be either endogenous (cytosolic protein) or exogenous (e.g., bacterium). Endogenous antigenic determinants (antigenic peptides) are produced by cellular proteasomes and transported by TAP proteins into the endoplasmic reticulum (ER) where the MHC and CD1 molecules are being assembled. In the ER, antigenic peptides bind to the α-chains of the MHC class I molecule, and the complex is transported to the cell surface. In the ER, the α- and β-chains of the MHC class II molecules are also being assembled, but the antigen-binding site is blocked by a small molecule (invariant chain) to prevent interactions with endogenous antigenic peptides. The MHC class II–invariant chain complex is transported to lysosomes, where exogenous antigenic fragments have been generated as a result of phagocytosis. In the lysosomes the invariant chain is digested and replaced by exogenous antigenic peptides, after which the MHC class II–antigen complex is inserted into the cell membrane. CD1 is also assembled in the ER, but its antigen-binding site is specific for lipid antigenic determinants and does not bind endogenous antigenic peptides. The CD1 molecule is transported to the lysosomes and may encounter and bind antigenic lipids produced by phagocytic digestion of engulfed bacteria. The CD1-antigen complex is transported to the cell membrane and presents lipid antigens. *MHC,* Major histocompatibility complex; *TAP,* transporter associated with antigen processing.

macrophages, dendritic cells, B lymphocytes, activated T lymphocytes, and some endothelial cells.

Thus, the term **antigen processing** relates to the process by which exogenous and endogenous antigens are linked with the appropriate MHC molecules. Endogenous antigens are usually components of proteins synthesized in the cytosol. They are degraded in the cytosol by proteasomes into small peptides and transported by TAP (transporter associated with antigen processing) proteins (TAP-1 and TAP-2) into the endoplasmic reticulum, where MHC class I and class II molecules are assembled.[20] The class I MHC molecules have open antigen-binding sites so that antigen, the class I MHC α-chain, and a β2-microglobulin molecule form a stable complex that is transported through the Golgi apparatus to the plasma membrane. The antigenic peptides presented by class I MHC molecules are usually very small, 8 to 10 amino acids in length.

MHC class II molecules are also assembled in the endoplasmic reticulum but do not bind with endogenous antigen because the antigen-binding site is blocked by a small protein called **invariant chain.** Exogenous antigens are internalized by phagocytosis and small antigenic molecules produced by digestion in the lysosomes. The MHC class II complexes of the class II α- and β-chains, with invariant chain, are transported to the lysosomes containing exogenous antigens. In the lysosomal environment, the invariant chain is digested and replaced by antigenic molecules that are usually slightly larger (in excess of 12 amino acids in length) than those presented by MHC class I molecules.

CD1 presents a variety of lipid-containing antigens that are usually derived from phagocytosis and digestion of infectious microorganisms with very high lipid content in their cell membranes. Therefore, CD1 complexes with antigen in the lysosomes, in a fashion similar to MHC class II. The “pocket” that holds antigen for presentation by CD1 is generally more narrow and deeper than that described for MHC molecules, and it is lined with many hydrophobic amino acids that interact with lipid.

T-Helper Lymphocytes

Regardless of whether an antigen primarily induces a cellular or humoral immune response, a subpopulation of T lymphocytes, **T-helper cells (Th cells),** is usually necessary for the process. As indicated by the name, this group of T cells *helps* the antigen-driven maturation of both B and T cells. They perform this task by facilitating and magnifying the interaction between APCs and the immunocompetent lymphocytes. This extremely important role involves three distinct steps: (1) the Th cell directly interacts with the APC through a variety of antigen-specific and antigen-independent receptors; (2) the Th cell undergoes a differentiation process during which a variety of cytokine genes are activated; and (3) depending on the pattern of cytokines expressed, the mature Th cell interacts with either immunocompetent B or T cells to enhance their response to antigen, which results in differentiation into either plasma cells or effector T cells, such as T-cytotoxic cells. Th cells are critical to most immune responses, and a variety of major Th-cell defects that lead to severely diminished immune responses are discussed in later chapters.

APC-Th Cooperation

Cells that are destined to become Th cells emerge from the thymus with characteristic cell surface markers. They have a functional αβ TCR complex and express the surface molecule CD4 and lack CD8. These are generally referred to as precursor Th cells, or sometimes Thp cells (Figure 8-17). As described previously, the TCR recognizes antigen and the CD4 molecule confines antigen presentation to MHC class II molecules; thus CD4+ cells are *class II restricted.* In order to undergo maturation, the Th cell must receive three independent signals: (1) antigen binding through the combined interaction of the TCR complex and CD4, (2) co-stimulatory signals through a variety of intercellular adhesion molecules, and (3) activation of specific cytokine receptors. If the appropriate signaling pathways are activated, the cell will differentiate through multiple intermediate stages into functional Th cells.

The complex of an antigenic peptide presented by an MHC class II molecule is recognized by multiple molecules on the Th-cell surface. The TCR binds directly to the antigen, whereas CD4 independently binds to a different site on the MHC class II β-chain. This co-recognition of the MHC-antigen complex by the TCR and CD4 brings CD4 into proximity with the CD3 components of the TCR complex, which initiates a series of enzymatic interactions among other molecules associated with the cytoplasmic portions of CD3 and CD4, such as the protein kinases $p56^{lck}$ and ZAP70. These molecules activate a signaling pathway from the TCR to the Th-cell nucleus.

The antigenic signal alone is inadequate and may even inactivate the Th cell if co-stimulatory signals are not present.[21] Co-stimulatory molecules are necessary for proper differentiation to occur. A variety of molecular interactions have been described, but the most critical appears to involve B7 on the APC and CD28 on the Th cell. Other interactions occur between CD48 on the APC and CD2 on the Th cell and between a variety of other adhesion molecules. In each case, the Th-cell molecule sends an activation signal to the nucleus. An additional signal is provided by cytokine. At this early stage of Th-cell differentiation, IL-1 secreted by the APC provides this signal through interaction with the IL-1 receptor on the Th cell.[22]

The initial differentiation response by the Th cell includes the production of the cytokine IL-2 and up-regulation of IL-2 receptors. IL-2 is secreted and acts in an autocrine (self-stimulating) fashion to induce further maturation and proliferation of the Th cell. Without IL-2 production, the Th cell cannot efficiently mature into a functional helper cell.[23] At this point, Th cells undergo one of several different differentiation pathways into Th subsets.

Th Subsets

The most clearly characterized Th-cell subsets are **Th1** and **Th2 cells,** and the newly described **Th17 cells** (see Figure 8-17). These subsets have different functions: Th1 cells help develop cellular immunity, Th2 cells help develop humoral immunity, and Th17 cells increase the inflammatory response. A fourth

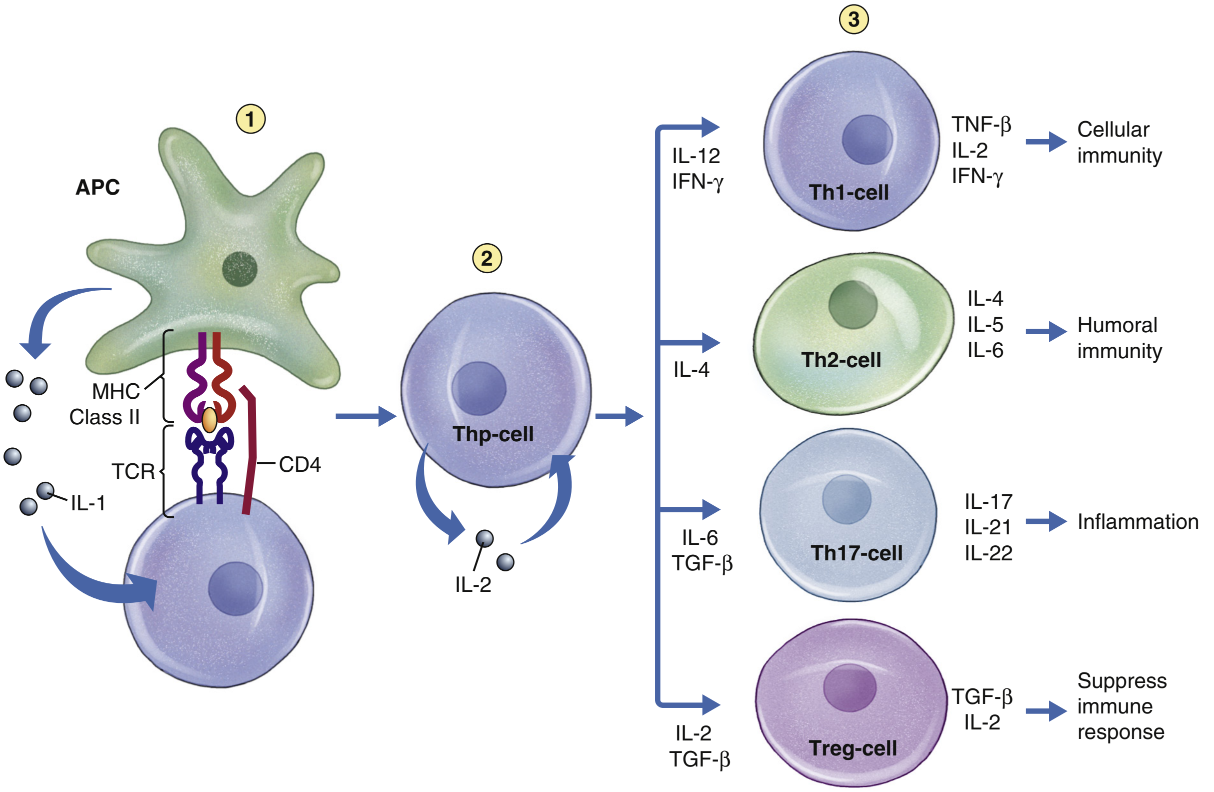

FIGURE 8-17 **Development of T-Cell Subsets.** The most important step in clonal selection is the production of populations of helper T (Th) cells (Th1, Th2, and Th17) and regulatory T (Treg) cells that are necessary for the development of cellular and humoral immune responses. In this model, APCs (probably multiple populations) may influence whether a precursor Th cell (Thp cell) will differentiate into a Th1, Th2, Th17, or Treg cell. Differentiation of the Thp cell is initiated by three signaling events. **(1)** The antigen signal is produced by the interaction of the T-cell receptor (TCR) and CD4 with antigen presented by MHC class II molecules. A set of co-stimulatory signals is produced from interactions between adhesion molecules (e.g., CD80 and CD28) (not shown). A third signal is produced by the interactions of cytokines (particularly interleukin-1 [IL-1]) with appropriate cytokine receptors (IL-1R) on the Thp cell. **(2)** The Thp cell up-regulates IL-2 production and expression of the IL-2 receptor (IL-2R), which act in an autocrine fashion to accelerate Thp-cell differentiation and proliferation. **(3)** Commitment to a particular phenotype results from the relative concentrations of other cytokines. IL-12 and IFN-γ produced by some populations of APCs favor differentiation into the Th1-cell phenotype; IL-4, which is produced by a variety of cells, favors differentiation into the Th2-cell phenotype; IL-6 and TGF-β (T-cell growth factor) facilitate differentiation into Th17 cells; IL-2 and TGF-β induce differentiation into Treg cells. The Th1 cell is characterized by the production of cytokines that assist in the differentiation of cytotoxic T (Tc) cells, leading to cellular immunity, whereas the Th2 cell produces cytokines that favor B-cell differentiation and humoral immunity. Th1 and Th2 cells affect each other through the production of inhibitory cytokines: IFN-γ will inhibit the development of Th2 cells, and IL-4 will inhibit the development of Th1 cells. Th17 cells produce cytokines that affect phagocytes and increase inflammation. Treg cells produce immunosuppressive cytokines that prevent the immune response from being excessive. *APC,* Antigen-presenting cell; *IFN,* interferon; *MHC,* major histocompatibility complex; *TGF,* transforming growth factor.

subset, Treg cells, is discussed later in this chapter. The Th subsets differ considerably in the spectrum of cytokines produced by each, as well as the expression of surface cytokine receptors and intercellular adhesion molecules. Th1 cells produce IL-2, tumor necrosis factor-beta (TNF-β), and interferon-gamma (IFN-γ);[24] Th2 cells produce IL-4, IL-5, IL-6, and IL-13,[25] and Th17 cells produce IL-17, IL-21, and IL-22.[26] As will be seen in the next portions of this chapter, the Th1 cytokines affect Tc-cell development, and the Th2 cytokines are needed for B-cell maturation, including class-switch. Th17-cell cytokines affect inflammatory responses, particularly infiltration of neutrophils and macrophages and production of antimicrobial proteins and chemokines by epithelial cells. Members of the IL-17 cytokine family induce epithelial cell chemokines and neutrophil infiltration, and IL-22 more specifically affects epithelial cell antimicrobial protein production.[27] Thus Th17 cells control many aspects of inflammation, including chronic inflammation.[28] Th1, Th2, and Th17 cells also have different cytokine receptors, so that IFN-γ produced by Th1 cells will bind to receptors on Th2 and Th17 cells and suppress their function. Likewise, Th2 cells produce IL-4, which suppresses Th1 and Th17 cells through their IL-4 receptors. Thus in some instances the immune response favors antibody formation, with suppression of a cell-mediated response, whereas in other instances the opposite is true. For example, antigens derived from viral or bacterial pathogens and those derived from cancer cells are hypothesized to induce a

greater number of Th1 cells relative to Th2 cells, whereas antigens derived from multicellular parasites and allergens are hypothesized to result in production of more Th2 cells. Many antigens (e.g., tetanus vaccine), however, produce excellent humoral and cell-mediated responses simultaneously.

How a Th cell is guided into becoming a Th1, Th2, or Th17 cell is not fully known. Some evidence indicates that different subpopulations of APCs influence the choice by secreting different profiles of cytokines that may favor one route of differentiation over another (see Figure 8-17).

B-Cell Activation: The Humoral Immune Response

When an immunocompetent B cell encounters an antigen for the first time, only those cells with specific BCRs complementary to that antigen's determinant sites are stimulated to proliferate and differentiate (clonal selection), resulting in multiple copies of that particular B cell. The differentiated B cell becomes a **plasma cell** and can be found in the blood, secondary lymphoid organs (primarily spleen and lymph nodes), and some inflammatory sites. Each plasma cell is a factory for antibody production and is dedicated to the secretion of a single class or subclass of antibody with one variable region and therefore specificity against one antigenic determinant.

Primary and Secondary Immune Responses

The immune response to antigenic challenge has classically been divided into two phases—the primary and secondary responses—that can be most easily demonstrated by serologic tests that measure plasma concentrations of antibody over time (Figure 8-18). On initial exposure to most antigens, there is a latent period, or lag phase, during which B-cell differentiation and proliferation occur. After approximately 5 to 7 days, IgM antibody specific for that antigen can be detected in the circulation. The lag phase is a result of the time necessary for clonal selection, including processing and presentation of antigens, induction of Th cells, interactions between immunocompetent B cells and Th cells, and maturation and proliferation of the B cells into plasma cells and memory cells.

This is the initial response, or **primary immune response.** Typically, IgM will be produced first, followed by IgG against the same antigen. The quantity of IgG produced may be about equal to or less than the amount of IgM production. If no further exposure to the antigen occurs, the circulating antibody is catabolized (broken down) and measurable quantities fall. The individual's immune system, however, has been primed. A second challenge by the same antigen results in the **secondary (anamnestic) immune response,** which is characterized by the more rapid production of a larger amount of antibody than that produced by the primary response. The rapidity of the secondary immune response is the result of the presence of memory cells that do not require further differentiation. IgM may be transiently produced in the secondary response and the quantity may be about the same as that produced in the primary response. IgG production is increased considerably, making it the predominant antibody class of the secondary response. It is often present in concentrations several times larger than those of IgM, and levels of circulating IgG specific for that antigen may remain elevated for an extended period of time. If the antigenic challenge is in the form of a vaccine or occurs through natural infection, the level of protective IgG may remain elevated for decades.

The existence of a prolonged and protective secondary immune response explains how vaccinations provide protection against certain pathogenic microorganisms. Edward Jenner, an English physician of the late eighteenth century, performed the first well-documented vaccine trial.[29,30] Although some of the stories about Jenner's experiments are fanciful, it is known that Jenner recognized that milkmaids were protected from the deadly smallpox virus if they had previously developed cowpox, a bovine equivalent of smallpox that causes only mild disease

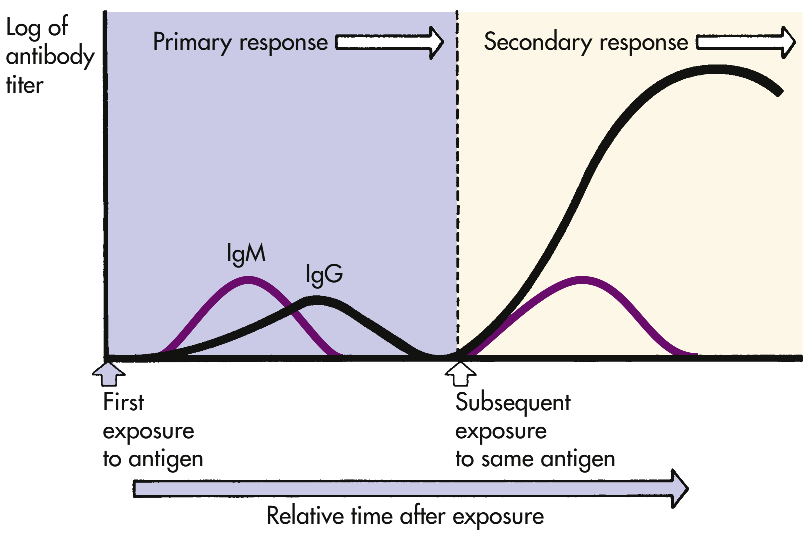

FIGURE 8-18 Primary and Secondary Immune Responses. Antigen responses are dominated by two classes of immunoglobulins, IgM and IgG. IgM predominates on initial exposure to the antigen in the primary response, with IgG appearing later. After the host's immune system is primed, another challenge by the same antigen induces the secondary response in which some IgM and larger amounts of IgG are produced.

in humans. Jenner took material from a cowpox pustule on the hand of an infected milkmaid and injected it into the arm of an 8-year-old boy. After the boy's initial inflammatory reaction to the injection subsided, Jenner injected the boy again, this time with material from a smallpox pustule. Fortunately, the experiment was a success because Jenner is reported to have reinjected smallpox virus into the boy at least 20 times without the child becoming ill. In Jenner's experiment, the antigens on the cowpox virus and the smallpox virus were sufficiently similar that the cowpox antigen functioned as an altered or attenuated smallpox antigen. The antibodies and lymphocytes that recognized and destroyed cowpox also were able to recognize the smallpox virus, thereby protecting the immunized child against smallpox. In 1798, Jenner used the term *vaccination* (*vacca* = cow) to describe his technique.

Cellular Interactions

As with most aspects of immunity, a sequence of cellular interactions is required to produce an effective antibody response (Figure 8-19). The immunocompetent B cell is also an APC and expresses surface IgM and IgD BCRs. Unlike the T-cell receptor that can only "see" processed and presented antigen, the BCR can react with soluble antigen. Antigen binding to the BCR complex activates intracellular kinases, in a fashion similar to the TCR receptor complex. In many instances, circulating antigen, either on macromolecules or on the surface of a pathogen, will have activated the complement system through the alternative or lectin pathways. Thus complement receptors on the B cell, such as CD19 and CD21, act as co-receptors to bind antigen.[31] As a result of signaling from the BCR complex and other surface co-receptors, the antigen-bearing macromolecule internalizes, degrades in the lysosomes, and complexes with MHC class II molecules for presentation on the cell surface, where it is recognized by a Th2 cell through the TCR and CD4. The intercellular bridge created through antigen induces the Th2 cell to up-regulate additional surface receptors and secrete cytokines. Direct interaction between CD40 on the B-cell surface and the CD40 ligand (CD40L, also called *CD154*) on the Th2 cell, as well as the interaction of B7 on the B cell and CD28 on the Th cell, and exposure of the B cell to Th2-cell cytokines (particularly IL-4) induce proliferation of the B cell and maturation into a plasma cell.[32] A major component of maturation is class-switch.

Class-Switch

The immunocompetent B cell uses IgM and IgD as receptors. During the clonal selection process, however, each B cell has the option of changing the class of antibody to a secreted form of one of the four IgG subclasses, one of the two IgA subclasses, or IgE, or continuing to produce IgM but changing to a secreted form, usually a pentamer. This process is called **class-** or **isotype-switch.** During this process the variable region of the antibody heavy chain is conserved, and the light chain remains

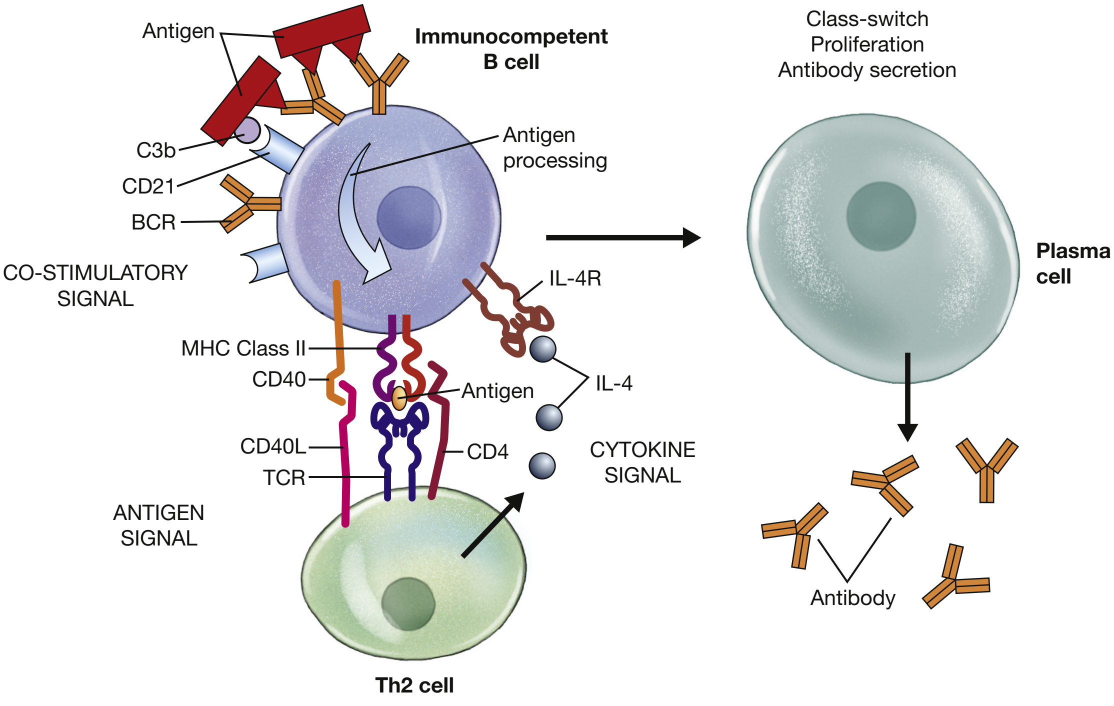

FIGURE 8-19 B-Cell Clonal Selection. Immunocompetent B cells undergo proliferation and differentiation into antibody-secreting plasma cells. Three signals are necessary. The antigen signal is provided by the B cell itself. A B cell can recognize soluble antigen directly through the B-cell receptor and co-receptors, such as complement receptors (CD21), which usually involve accessory molecules such as CD19 (not shown). Antigen is internalized and processed for presentation by MHC class II molecules, which interact with the T-cell receptor (TCR) and CD4 on Th2 cells. Co-stimulatory signals are provided through adhesion molecules, particularly CD40 and CD40L (CD154). The cytokine signal is provided by Th2 cytokines (particularly IL-4) binding to appropriate cytokine receptors (IL-4R) on the B cell. Additional cytokines influence switch to particular classes or subclasses of antibody. *MHC,* Major histocompatibility complex.

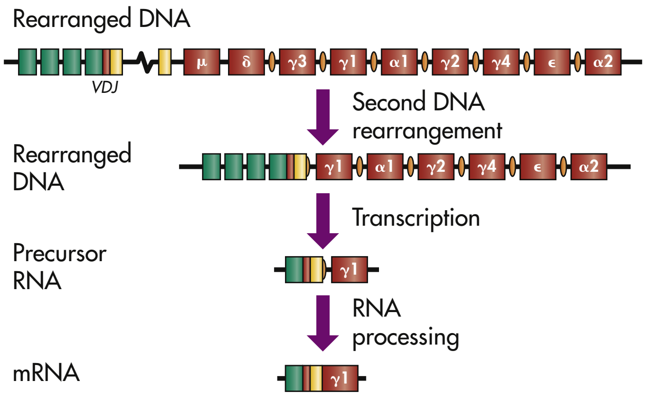

FIGURE 8-20 Genetics of Class-Switch. During clonal selection, most B cells switch from expression of surface IgM and IgD to a different class or subclass of antibody. A first set of DNA rearrangements during the generation of clonal diversity resulted in formation of the *VDJ* region. The class-switch process involves a second DNA rearrangement during which the *VDJ* region is moved to a switch region *(orange ovals)* immediately preceding the new class/subclass of antibody. In this example, the B cell undergoes class-switch to a γ1 heavy chain and secretion of an IgG1 antibody. The intervening DNA between the *VDJ* and the selected switch region is excised, and the DNA is repaired (DNA after second rearrangement) and transcribed into a precursor ribonucleic acid (RNA). The RNA is processed to a messenger RNA (mRNA) with information for the new heavy chain.

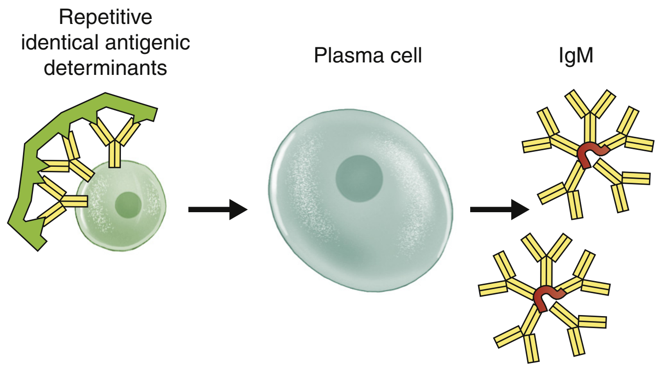

FIGURE 8-21 Activation of a B Cell by a T-Cell–Independent Antigen. Molecules containing repeating identical antigenic determinants may interact simultaneously with several receptors on the surface of the B cell and induce the proliferation and production of immunoglobulins, mainly IgM.

unchanged from that used in the BCR; therefore, the antigenic specificity also remains unchanged.

The mechanism of class-switch involves another DNA rearrangement, during which the *VDJ* region encoding the heavy-chain's variable region is moved to another site on the DNA that is adjacent to the gene for a different constant region under the control of activation-induced cytidine deaminase (AICD) (Figure 8-20). The DNA is cut and mended with removal of the DNA that was between the *VDJ* site and the new constant region. Specific recognition sites (switch regions) precede each constant region gene, and the particular constant region chosen for class-switch appears to be, at least partially, under the control of specific Th2 cytokines. For instance, IL-4 and IL-13 appear to preferentially stimulate switch to IgE, and transforming growth factor-beta (TGF-β) and IL-5 appear to play major roles in class-switch to IgA.

A few antigens can bypass the need for Th cells and can directly stimulate B-cell maturation and proliferation. These are called *T-independent antigens* (Figure 8-21). They are mostly bacterial products that are large and are likely to have repeating antigenic determinants (multiple identical antigenic determinant sites) that bind and cross-link several B-cell receptors. The accumulated intracellular signal is adequate to induce differentiation to a plasma cell but is not adequate to induce class-switch. The CD40-CD40L interaction is a necessary component of the signal that leads to class-switch. Therefore, T-independent antigens usually induce a relatively pure IgM primary and secondary immune response.

Cellular Differentiation

During the clonal selection process, B cells differentiate into antibody-producing plasma cells and into a set of long-lived memory cells. During the differentiation of B cells into plasma cells, the CDR portions of the antibody variable region are prone to somatic point mutations that lead to changes in single amino acids. Some of these changes produce better antibodies that bind more strongly (higher affinity) to the antigen. The presence of antigen creates a positive selective pressure toward the developing B cells that express the higher-affinity antibody, which results in a process called *affinity maturation,* in which the quality of the circulating antibody improves over time. Plasma cells may migrate to special regions of the spleen, lymph nodes, and mucosal-associated lymphoid tissues that support the plasma cell's long-term survival and function so that an adequate level of protective antibody is available in the circulation for decades after vaccination or resolution of infection.[33]

The memory cells remain inactive until subsequent exposure to the same antigen.[34] On reexposure, these memory cells do not require much further differentiation and will therefore differentiate rapidly into new plasma cells.

T-Cell Activation: The Cellular Immune Response

Activation of the cell-mediated arm of the immune response begins with the binding of antigen to specific T-cell receptors. Through a variety of intercellular collaborations that are mediated by specific cellular receptors and cytokines, the naïve T cell proliferates and differentiates into a functional (effector) T cell. The two main effector functions of activated T cells are (1) direct killing of foreign and/or abnormal cells and (2) assistance and/or activation of other cells, such as macrophages. The first function is carried out by a subclass of T cells, termed T-cytotoxic lymphocytes (Tc cells, or CTLs). Activation of macrophages is performed by a special subset of Th cells. Additional T cells develop into cells that regulate the immune response in order to avoid inadvertently attacking self-antigens or to avoid overactivation of the immune response. This mixed population of cells is termed **T-regulatory (Treg) cells.** Finally, **T-memory cells** are also produced to help induce secondary cell-mediated immune responses.[35]

Cellular Interactions

During the clonal selection phase of the cell-mediated immune response, immunocompetent T cells in the peripheral lymphoid

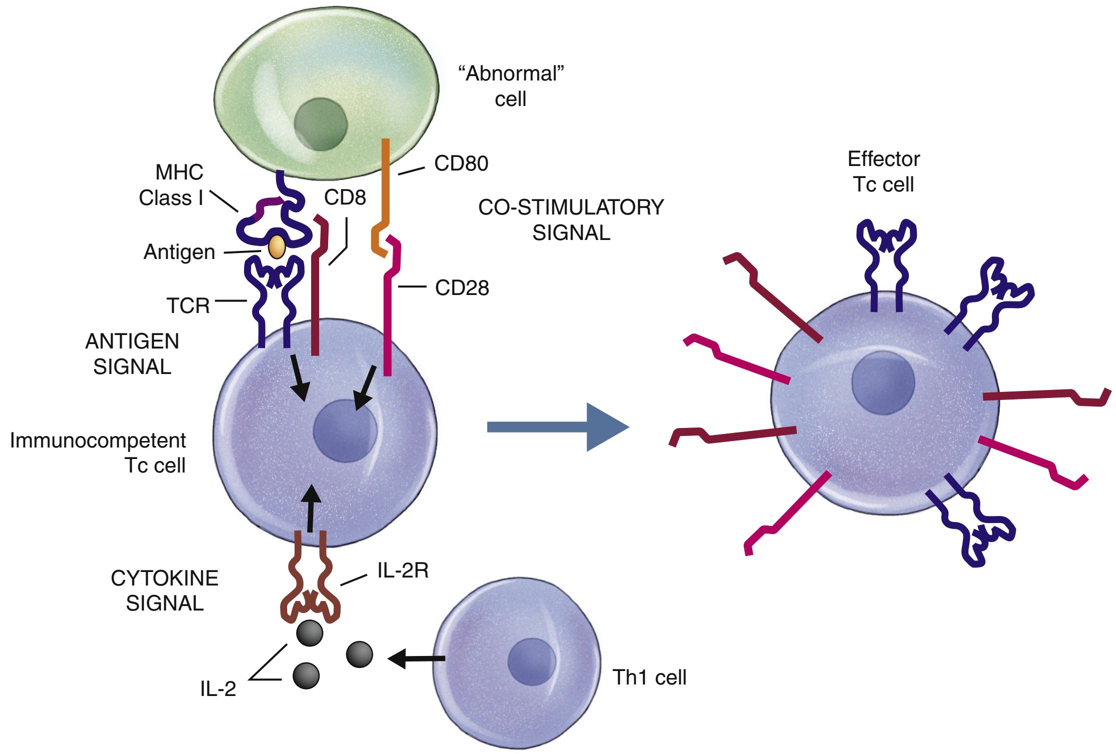

FIGURE 8-22 **Tc-Cell Clonal Selection.** The development of effector cytotoxic T (Tc) cells during clonal selection results from three cooperative signaling events provided by antigen, co-stimulatory adhesion molecules, and cytokines. The immunocompetent Tc cell "sees" antigen presented by MHC class I molecules on the surface of a virally infected or cancerous "abnormal" cell. The antigen–MHC class I complex is recognized simultaneously by the T-cell receptor (TCR), which binds to antigen, and CD8, which binds to the MHC class I molecule. The proximity of signaling molecules associated with the cytoplasmic portions of CD8 and the TCR result in intracellular signaling. A separate signal results from the interaction of several groups of adhesion molecules (e.g., CD80 and CD28 in this example). The third signal is provided by the interaction of cytokine, particularly IL-2 from Th1 cells, and the appropriate receptor. *MHC,* Major histocompatibility complex.

organs must recognize antigen that has been processed and presented by MHC class I molecules (Figure 8-22). The antigen is usually an endogenous antigen expressed on the surface of cells infected with a virus or cells that have become malignant. The T cells have a functional αβ TCR complex and express the surface molecule CD8, rather than CD4. The presence of the CD8 molecule confines antigen recognition to MHC class I molecules; therefore, CD8+ T cells are *class I restricted*. The TCR binds directly to the antigenic peptide, whereas CD8 independently binds to a different site on the MHC class I α-chain. This co-recognition of the MHC-antigen complex by the TCR and CD8 brings CD8 into proximity with the CD3 components of the TCR complex, which initiates a series of enzymatic interactions among other molecules associated with the cytoplasmic portions of CD3 and CD4, as was described for Th-cell activation. These molecules activate a signaling pathway from the TCR to the T-cell nucleus.

To undergo maturation, the T cell must receive independent signals from a variety of co-stimulatory intercellular adhesion molecules and specific cytokine receptors. If the appropriate signaling pathways are activated, the cell will proliferate and differentiate through multiple intermediate stages into functional Tc cells. The co-stimulatory signals for Tc-cell maturation are virtually the same as has been described for Th-cell maturation: B7 on the cell-presenting antigen and CD28 on the T cell, CD48 on the antigen-presenting cell and CD2 on the T cell, and a variety of other adhesion molecules. Development of Tc cells also requires cytokines, especially IL-2, produced by the Th1 cell.

Cellular Differentiation

The result of these cellular interactions is the production of active Tc cells with the capacity to identify antigens on the surface of infected or malignant cells and then to destroy those cells. As with B cells, some of the T cells that become activated in response to antigen presentation will not become effectors that destroy infected targets, but instead develop into a population of T-memory cells. These cells have the capacity to rapidly respond to further exposure to the same antigen.

Superantigens

A group of molecules has the ability to bind the variable portion of the TCR β-chain outside of its normal antigen-specific binding site, as well as the α-chain of MHC class II molecules outside of their antigen-presentation sites (Figure 8-23). Thus these molecules are not digested and processed by an APC to be presented to an immune cell. This binding results in adherence of the TCR and MHC class II molecules, independent of antigen recognition, and provides an activation signal for Th-cell

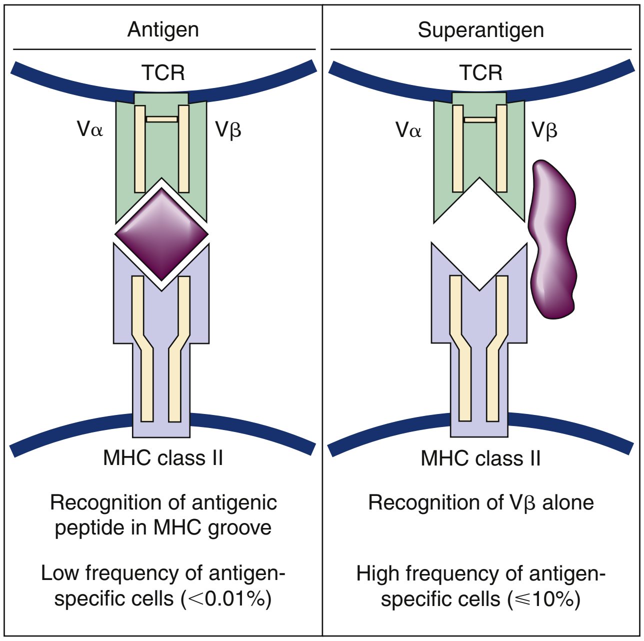

FIGURE 8-23 **Superantigens.** The T-cell receptor (TCR) and an MHC class II molecule normally simultaneously interact with a processed antigen to induce T-cell differentiation. Superantigens, such as some bacterial toxins, bind directly to the TCR and the MHC class II molecules. Superantigens activate Th cells independently of TCR antigen specificity. *MHC,* Major histocompatibility complex; *V,* variable; *Vα,* variable region of the α-chain; *Vβ,* variable region of the β-chain.

activation and proliferation. The normal antigen-specific recognition between Th cells and APCs results in activation of relatively few cells: only those cells with specific TCRs against that antigen. The type of binding described here results in activation of large populations of T lymphocytes, regardless of antigen specificity. Thus these molecules have been referred to as **superantigens (SAGs).**

SAGs induce an excessive production of cytokines, including IL-2, IFN-γ, and TNF-α. The overproduction of inflammatory cytokines results in symptoms of a systemic inflammatory reaction, including fever, low blood pressure, and, potentially, fatal shock. Some examples of SAGs are the bacterial toxins produced by *Staphylococcus aureus* and *Streptococcus pyogenes* (including the superantigens that cause toxic shock syndrome and food poisoning).[36] Some viruses are also able to produce superantigens, although the exact nature of these antigens is unclear.

EFFECTOR MECHANISMS

Antibody Function

Protection Against Infection

The chief function of circulating antibodies is to protect the host from infection. Protection can be afforded by antibody in several ways, either directly or indirectly (Figure 8-24). Directly, antibody can cause **neutralization** (inactivating or blocking the binding of an antigen to a receptor), **agglutination** (clumping insoluble particles that are in suspension), or **precipitation**

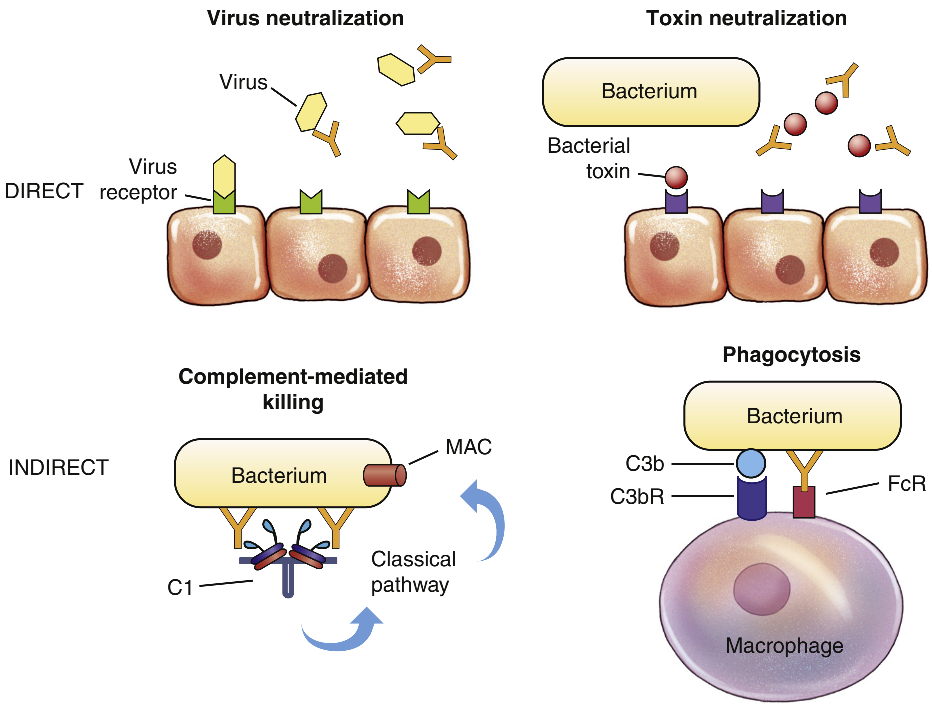

FIGURE 8-24 **Direct and Indirect Functions of Antibody.** Protective activities of antibodies can be direct (through the action of antibody alone) or indirect (requiring activation of other components of the innate immune response, usually through the Fc region). Direct means include neutralization of viruses or bacterial toxins before they bind to receptors on the surface of the host's cells. Indirect means include activation of the classical complement pathway through C1, resulting in formation of the membrane attack complex (MAC), or by increased phagocytosis of bacteria opsonized with antibody and complement components bound to appropriate surface receptors (FcR and C3bR).

(making a soluble antigen into an insoluble precipitate) of infectious agents or their toxic products. Indirectly, antibodies activate several components of innate immunity, including complement and phagocytes.

Direct Effects. To cause infection, many pathogens must attach to specific receptors on the host's cells. For instance, viruses that cause the common cold or the influenza virus must attach to specific receptors on epithelial cells. Some bacteria, such as *Neisseria gonorrhoeae* that causes gonorrhea, must attach to specific sites on epithelial cells. Antibodies may protect the host against infection by covering the portions of the microorganism that it needs to bind to the host cell. Neutralization, or prevention of attachment to the host cell, thereby prevents infection of the host.

Protection against many viral infections can be elicited effectively by vaccination with inactivated or **attenuated** (weakened) **viruses** to induce neutralizing antibody production at the site of typical viral entrance into the body. A good indication of the degree of protection against viral infection is the level of circulating antibodies found in the blood. The level of circulating antibodies is referred to as an **antibody titer.** However, many viruses (e.g., measles, herpes) are inaccessible to antibodies after initial infection because they do not circulate in the bloodstream but instead remain inside infected cells, spreading by direct cell-to-cell contact. Neutralizing antibodies against this type of virus are most effective in preventing the initial infection. Other viruses, such as polio and influenza, spread through the blood, are more susceptible to the effects of circulating antibodies, and can be controlled by antibodies even after the initial infection.

The symptoms of some infectious diseases result directly from toxins produced by infecting bacteria. For instance, the symptoms of tetanus or diphtheria are mediated by specific toxins. To cause disease, most toxins must bind to surface molecules on the individual's cells. Protective antibodies can bind to the toxins, prevent their interaction with cells, and neutralize their biologic effects. Detection of the presence of an antibody response against a specific toxin (antibodies referred to as *antitoxins*) can aid in the diagnosis of diseases. For example, group A streptococcal bacteria produce a toxin, streptolysin O, that destroys cells, particularly erythrocytes and leukocytes. The infected individual produces an antibody that can neutralize this toxin (antistreptolysin O) and also be detected in laboratory tests as a useful diagnostic tool for group A streptococcal infections. Antibodies that neutralize bacterial toxins can be induced to confer immunity against bacterial pathogens by means of immunization. To prevent harming the recipient of immunization, bacterial toxins are chemically inactivated to destroy their harmful properties but still retain immunogenicity. These are referred to as *toxoids*. Examples of bacterial pathogens for which immunization with toxoids can provide immunologic protection include those that cause diphtheria and tetanus.

Indirect Effects. Antibody can be protective by interacting with or activating components of nonspecific inflammation. Indirect effects are mediated by the Fc portion of the antibody molecule and include opsonic activity resulting in enhanced phagocytosis and activation of the complement system that may lead to complement-mediated destruction of the pathogen or increased opsonic activity through deposition of C3b.

In their role as **opsonins,** antibody and C3b make the pathogen more susceptible to phagocytosis through binding to Fc or C3b receptors on the phagocyte's surface. **Opsonization** is often necessary for efficient bacterial clearance because many bacteria have an outer capsule that deters recognition by phagocytes unless it is coated with an antibody or complement protein. Bacterial surface molecules are usually complex and have multiple accessible antigenic determinants, enabling them to bind several different antibodies simultaneously. When an antigen reacts with the Fab regions of antibody, the Fc portion of that antibody is recognized and binds to Fc receptors on the surfaces of inflammatory cells. Engagement of Fc receptors results in their activation, making phagocytosis of the opsonized bacterium more efficient.

Secretory Immune Response

The immune response that protects the entire body is produced by the **systemic immune system.** A distinct set of lymphoid tissues makes up another, partially independent, immune system at the external surfaces of the body. This system is called the **secretory (mucosal) immune system** (Figure 8-25). Most humoral immune responses occur when antibodies or B cells encounter antigens in the blood, but sometimes this encounter occurs in other body fluids. Antibodies are present in bodily secretions such as tears, sweat, saliva, mucus, and breast milk, where they can protect the body against antigens that have not yet penetrated the skin or mucous membranes.

Antibodies in secretions are produced by plasma cells of the secretory (mucosal) immune system. The B cells of these two systems follow a different pattern of migration after they leave the bone marrow.[37] B lymphocytes of the systemic immune system travel through the spleen and most lymph nodes, whereas those of the secretory immune system travel through a different group of lymphoid tissues including the lacrimal and salivary glands and the lymphoid tissues of the breasts, bronchi, intestines, and genitourinary tract. Immunoglobulins that are secreted at these sites are called **secretory immunoglobulins** and act locally rather than systemically.

Local protection is necessary to combat antigens (chiefly infectious microorganisms) that are inhaled, swallowed, or otherwise come into contact with external body surfaces. Once they have taken up residence in the external layers of the body, harmful microorganisms can cause local disease or possibly penetrate the barriers described in Chapter 7 to cause systemic disease. Alternatively, the microorganisms may fail to cause disease in the individual, either because the microorganisms are passed out of the body without any ill effects or because the infection is thwarted by the systemic immune system. In the latter case the individual may continue to "carry" the infectious agent in the mucosal areas, thereby enabling its spread to other individuals. The major function of the secretory immune system is to halt viral and bacterial invasion before local or systemic disease can develop and to prevent a carrier state that may result in spread of the infection to others.

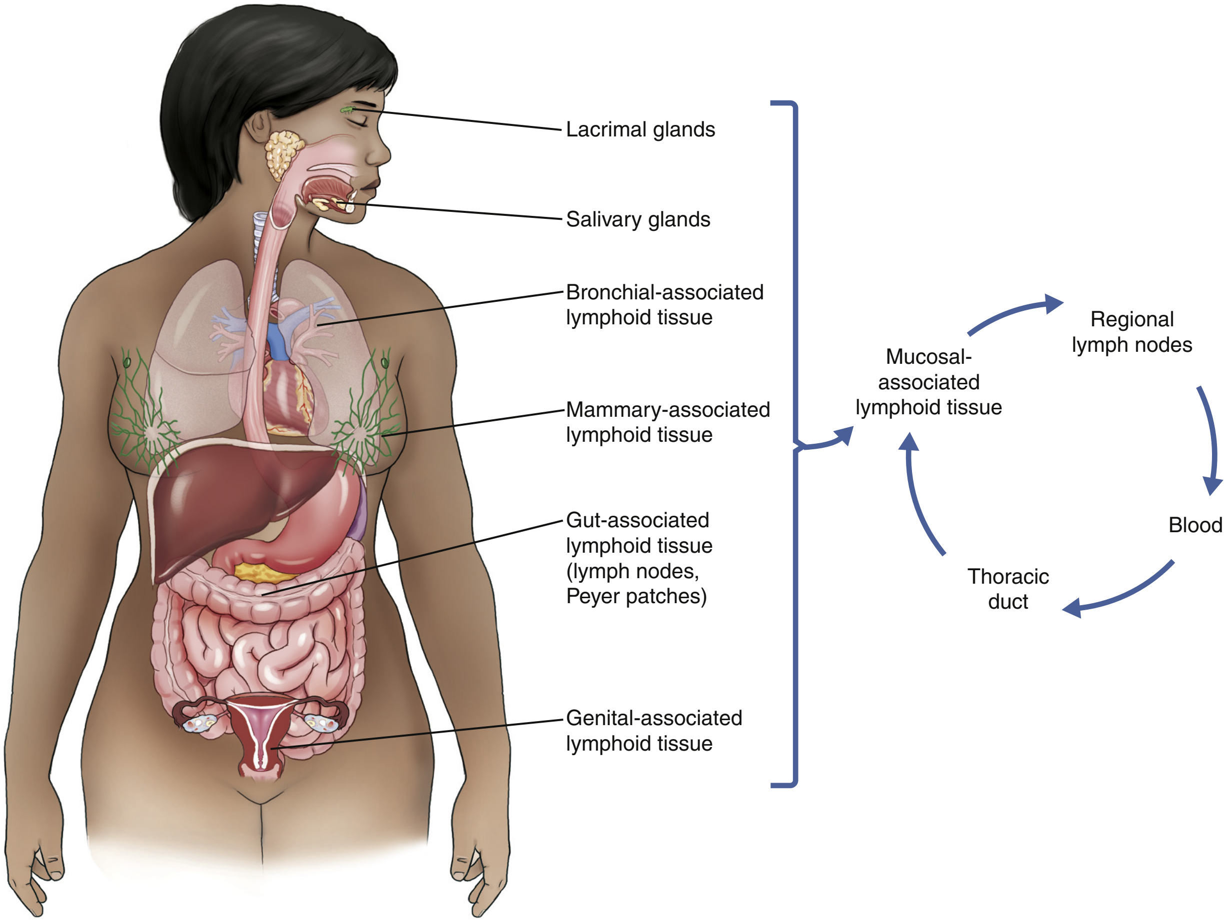

FIGURE 8-25 Secretory Immune System. Lymphocytes from the mucosal-associated lymphoid tissues circulate throughout the body in a pattern separate from other lymphocytes. For example, lymphocytes from the gut-associated lymphoid tissue circulate through the regional lymph nodes, the thoracic duct, and the blood and return to other mucosal-associated lymphoid tissues rather than to lymphoid tissue of the systemic immune system.

IgA is the dominant secretory immunoglobulin, although IgM and IgG also are present in secretions.[38] The primary role of IgA is to prevent the attachment and invasion of pathogens through mucosal membranes, such as those of the gastrointestinal, pulmonary, and genitourinary tracts.[39] To induce protective immunity against some pathogens that enter through these routes, local immunization seems to be preferable to inducing only systemic immunity. For instance, two different vaccines have been used against polio. The Sabin vaccine was administered orally as an attenuated (i.e., inactivated so as to render relatively harmless) live virus. This route caused a transient, limited infection and induced effective systemic immunity and secretory immunity, preventing both the disease and the establishment of a carrier state. The Salk vaccine, on the other hand, consisted of killed viruses that were administered intradermally. It induced adequate systemic protection but did not generally prevent an intestinal carrier state.

Because B lymphocytes of the secretory/mucosal immune system travel through breast-associated lymphoid tissue, most antigens to which the mother has been exposed gastrointestinally (e.g., poliovirus) induce secretion of specific IgAs, IgMs, and IgGs into the breast milk. Antibodies in the milk may provide protection against these infectious disease agents to the nursing newborn. Although colostral antibodies (i.e., found in colostrum of breast milk) provide the newborn with passive immunity against gastrointestinal infections, they do not provide systemic immunity because they do not cross the newborn's gut into the bloodstream after the first 24 hours of life. Passive systemic immunity is provided by maternal antibodies that passed across the placenta into the fetus before birth.

The mechanisms and functions of antigen-antibody binding are the same in the secretory immune system as they are in the systemic immune systems; that is, binding neutralizes or opsonizes the antigen, preventing it from harming the host. The major differences between the two systems include (1) the order of utilization—the secretory immune response is part of the body's first-line defense, whereas the systemic response is the body's final defense; (2) the lymphocytes of each system follow different paths of migration and pass through different secondary lymphoid tissues; and (3) the secretory response occurs locally and externally (in body secretions), whereas the systemic response occurs systemically and internally (in blood and tissues).

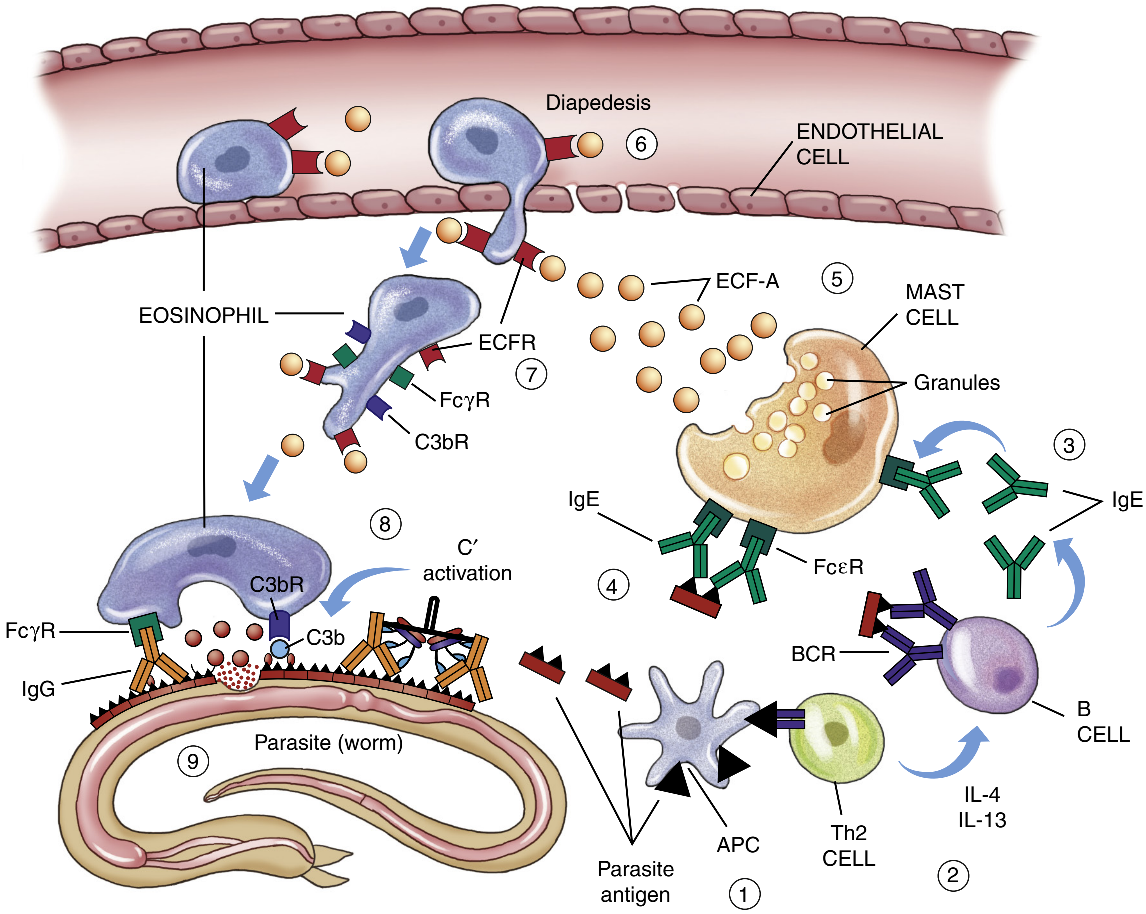

FIGURE 8-26 IgE Function. Soluble antigens from a parasitic infection are processed by local antigen-presenting cells (APCs) and presented to Th2 cells **(1),** which respond by producing cytokines that favor class-switch to IgE production **(2).** B cells bind soluble parasite antigen, and some switch to producing IgG, whereas others switch to IgE. The secreted IgE molecules bind to IgE-specific receptors (FcεR) on the mast cell surface **(3).** Additional soluble parasite antigen cross-links IgE-FcεR complexes on the mast cell surface **(4),** leading to mast cell degranulation and release of many proinflammatory products, including eosinophil chemotactic factor of anaphylaxis (ECF-A) **(5).** Eosinophils have receptors for ECF-A (ECFR) and are stimulated to increase adherence to the vessel walls and initiate diapedesis **(6)** and invasion of the surrounding tissue. The eosinophil also responds by increasing the density of surface receptors for IgG (FcγR) and complement component C3b (C3bR) **(7).** IgG had previously attached to the antigens on the parasite's surface and activated the complement cascade (C′ activation) in a failed attempt to damage the parasite. The eosinophil attaches to the parasite's surface through Fc and C3b receptors **(8).** Once bound to the parasite, the eosinophil releases its lysosomal enzymes onto the parasite, damaging its outer membrane **(9).**

IgE

IgE is a special class of antibody that is designed to help protect the individual from infection with large parasitic worms. However, when IgE is produced against relatively innocuous environmental antigens, it is also the primary cause of common allergies (e.g., hay fever, dust allergies, bee stings). The role of IgE in allergies is discussed in Chapter 9.

Large multicellular parasites usually invade mucosal tissues (Figure 8-26). In response to parasitic antigens, a variety of different antibody classes are produced with many B cells class-switching to IgE-secreting plasma cells under the direction of Th2 cells primarily producing IL-4 and IL-13.[40] IgG, IgM, and IgA bind to the surface of parasites, activate complement, generate chemotactic factors for neutrophils and macrophages, and serve as opsonins for those phagocytic cells. The influx of neutrophils and macrophages progressively leads to development of a granulomatous response around the parasite. Unique to parasitic infections, the eosinophil is a primary cell in the granuloma. The influx of eosinophils results from IgE-triggered mast cell degranulation. Mast cells in the tissues have very high affinity Fc receptors for IgE, which rapidly bind IgE to the mast cell surface.[41] Soluble macromolecules with multiple antigenic determinants are released from the parasite, react with the IgE-Fc receptors, and initiate mast cell degranulation (see Chapter 7). Eosinophil chemotactic factor of anaphylaxis (ECF-A) is released from mast cell granules and attracts eosinophils to the site of infection, as well as up-regulates surface receptors for IgG and complement component C3b. Eosinophil attachment to the parasite results in degranulation, releasing a variety of very toxic proteins that are at unusually high concentrations in eosinophilic granules, *major basic protein* (binds to heparin sulfate proteoglycans), *eosinophil cationic protein* (a member of the RNase

A family), and others. These can cause extensive damage to the parasite if an adequate number of eosinophils are involved.

T-Lymphocyte Function

Killing Abnormal Cells

T-Cytotoxic Lymphocytes. **T-cytotoxic lymphocytes (Tc cells)** are responsible for the cell-mediated destruction of such targets as tumor cells or cells infected with viruses. To perform this function, the Tc cell must directly adhere to the target cell through antigen presentation in association with MHC class I molecules and appropriate adhesion molecules (Figure 8-27). Most Tc-cell killing requires the αβ TCR complex and CD8 and is therefore *class I restricted.* Because of the cellular distribution of MHC class I molecules, Tc cells can recognize antigen on the surface of almost any type of cell that has been infected by a virus or has become cancerous.

After attachment to a target cell, killing can occur by at least two different mechanisms that induce apoptosis: through the actions of perforin and granzyme or by direct receptor interactions. Perforins and granzymes are contained in the Tc-cell lysosomal granules, which are released onto the surface of the target cell. Perforin acts in a fashion similar to C9 of the complement

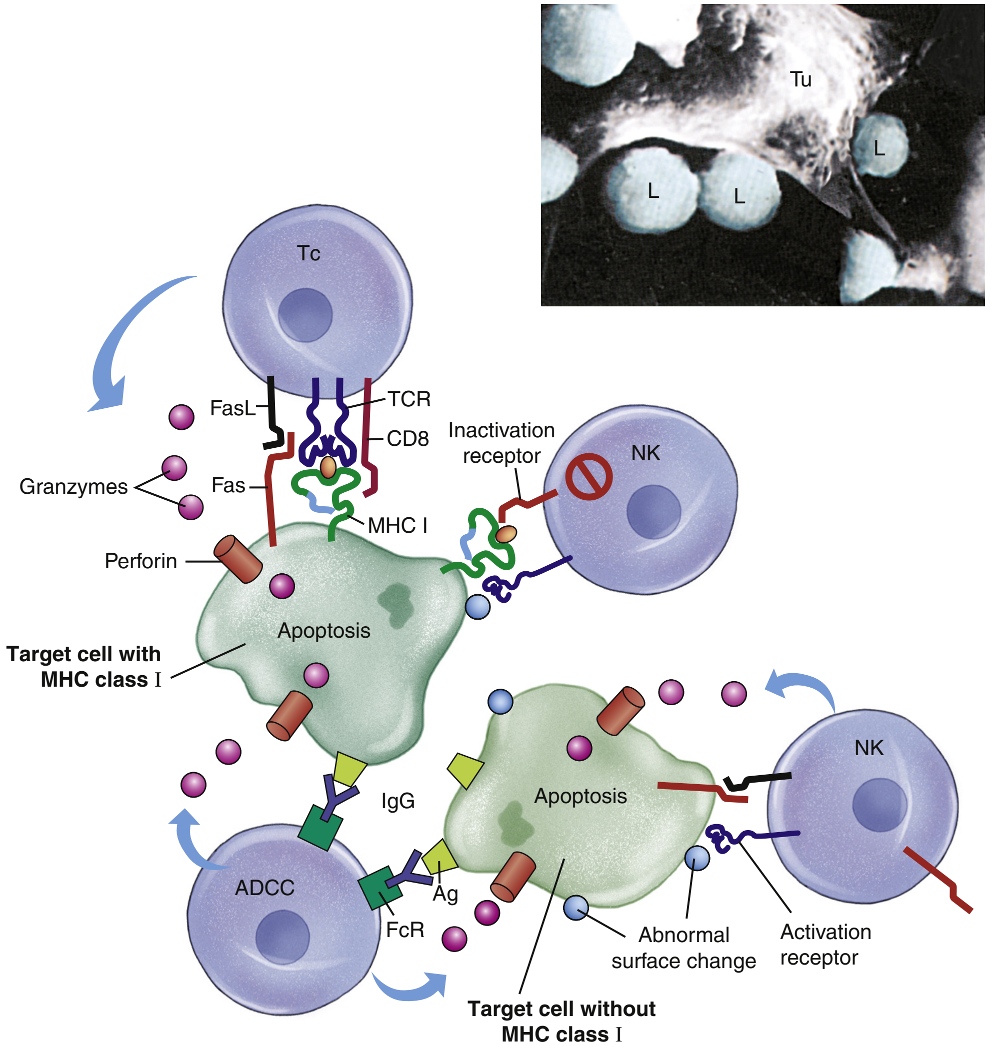

FIGURE 8-27 **Cell Killing Mechanisms.** Several cells have the capacity to kill abnormal (e.g., virally infected, cancerous) target cells. Cytotoxic T (Tc) cells recognized endogenous antigen presented by MHC class I molecules *(cell on upper left).* The intercellular interaction is enhanced through a variety of co-stimulatory adhesion molecules (not shown). The Tc cell mobilizes multiple killing mechanisms that induce apoptosis of the target cell, including the secretion of perforin that creates pores for the entrance of granzymes into the target cell and stimulation of Fas molecules on the target cell surface by Fas ligand (FasL) on the Tc cell. Natural killer (NK) cells *(cells on right)* use the same mechanisms to kill target cells through activation receptors that recognize "abnormal surface changes." NK cells specifically kill targets that have down-regulated expression of surface MHC class I molecules. Targets expressing MHC class I molecules inactivate NK cells through a variety of inactivation receptors *(cell on upper right).* Several cells, including macrophages and NK cells, can kill by antibody-dependent cellular cytotoxicity (ADCC). IgG antibody binds to foreign antigen on the target cell. Cells involved in ADCC *(cell on lower left)* bind IgG through Fc receptors (FcRs) and initiate killing. The insert is a scanning electron microscopic view of Tc cells *(L)* attacking a much larger tumor cell *(Tu). MHC,* Major histocompatibility complex. (Insert from Abbas A, Lichtman A: *Cellular and molecular immunology,* ed 5, Philadelphia, 2003, Saunders.)

cascade and penetrates, polymerizes, and forms pores in the target cell's plasma membrane. The granzymes enter the target cell through the perforin-lined pores and activate cellular enzymes (caspases) that are involved in apoptosis, resulting in death of the target. Additionally, target cell apoptosis can be induced directly through the stimulation of specific receptors on the cell surface. For instance, Tc cells express a surface molecule called *Fas ligand,* which is very similar to TNF-α and reacts with a protein called *Fas* (CD95) on the target cell surface. Activation of Fas signals the target cell to undergo apoptosis.

Other Cells That Kill Abnormal Cells. A variety of other cells kill targets in a fashion similar to Tc lymphocytes. Prominent among these cells are natural killer (NK) cells (see Chapter 7). In many ways, NK cells complement the effects of Tc cells. In some instances, a virally infected or cancerous cell will "protect" itself by down-regulating MHC class I molecule expression. Without surface MHC class I molecules, a cell becomes resistant to Tc-cell recognition and killing. NK cells are a special group of lymphoid cells that are similar to T cells but do not undergo maturation in the thymus and lack antigen-specific receptors. Instead, they express Fc receptors (CD16) for IgG and a variety of NK-specific cell surface receptors (similar to pattern recognition receptors, see Chapter 7) that identify protein changes on the surface of cells that have been infected or are in other ways abnormal.[42] After attachment, the NK cell kills its target in a manner similar to that of Tc cells. However, NK cells also express another set of receptors, inhibitory receptors, which bind to MHC class I molecules.[43] If the target cell continues to express MHC class I, the NK cell will bind to the class I molecule, and an inhibitory signal will result. Thus NK cells do not inadvertently kill MHC class I–bearing cells. If these cells are infected or malignant, yet still express MHC class I, they remain sensitive to Tc-cell killing. Thus Tc cells kill abnormal cells that continue to express MHC class I, whereas NK cells kill abnormal cells that have suppressed MHC class I expression.

NK cells, as well as some macrophages, can specifically kill targets through use of antibody. These cells express Fc receptors on their surface. If a pathogen or abnormal cell expresses a foreign antigen that elicits IgG antibody, which binds to the antigen, the NK cell can attach to the IgG through Fc receptors and activate its normal killing mechanisms. This is referred to as **antibody-dependent cell-mediated cytotoxicity (ADCC)** (see Figure 8-27).

Another population of NK-like cells has been identified, NK-T cells.[44] NK-T cells are produced in the thymus and more closely resemble Tc cells. However, they express TCRs that have very limited variability and recognize antigens presented by CD1.

T Cells That Activate Macrophages

Under conditions of chronic inflammation, T cells produce cytokines that activate macrophages (see Chapter 7). Macrophage activation is usually accomplished by Th1 cells that recognize antigen and produce cytokines (particularly IFN-γ) that, in cooperation with microbial products (e.g., LPS), stimulate the macrophage to become a more efficient phagocyte and increase production of proteolytic enzymes and other antimicrobial substances (Figure 8-28). IFN-γ–induced macrophage activation is also achieved by NK cells and CD8+ T-cytotoxic

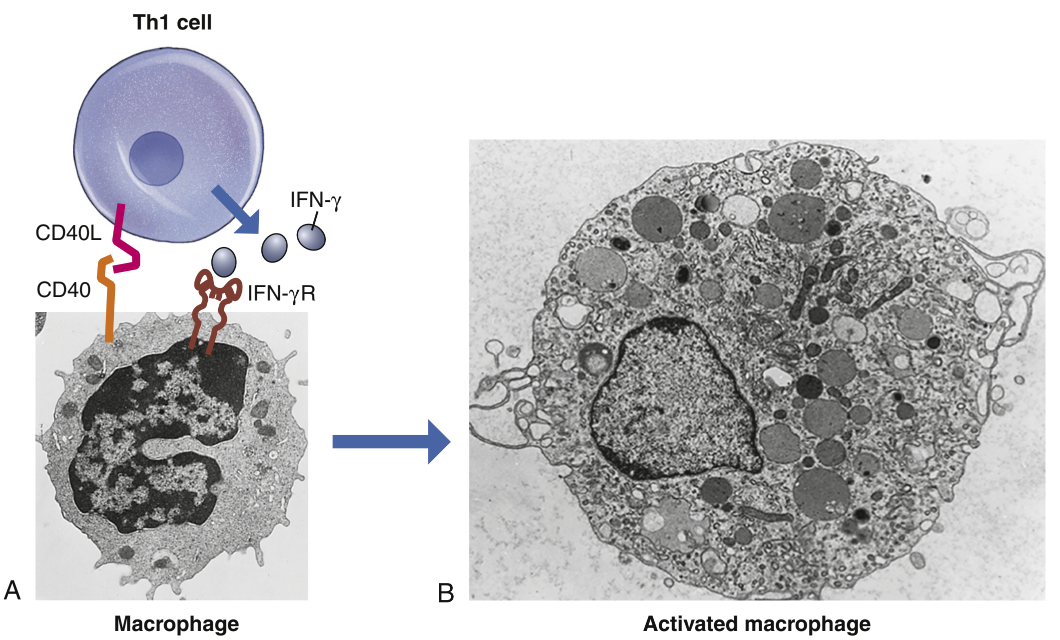

FIGURE 8-28 Activation of a Macrophage by a T Cell. A population of T cells that helps immune and inflammatory responses (helper T cells or Th1 cells) produces cytokines that activate macrophages. Optimal macrophage activation also requires close contact among the cells, which is mediated by a variety of adhesion molecules expressed on the surface of each cell (CD40L and CD40 shown here). *CD40L,* CD40 ligand; *IFN-γ*, interferon-gamma; *IFN-γR,* receptor for interferon gamma. (Micrograph in **A** courtesy Dr. Noel Weidner, Department of Pathology, University of California, San Diego. **B** from Fawcett DW: *Bloom and Fawcett: a textbook of histology,* ed 12, New York, 1994, Chapman & Hall. With kind permission of Springer Science and Business Media.)

cells. Additional signals (e.g., the CXC chemokine macrophage migration inhibitory factor) retain macrophages at inflammatory sites and increase intercellular adhesion between the Th1 cell (CD40L) and the macrophage (CD40).

T-Regulatory Lymphocytes

One form of peripheral tolerance to self-antigens occurs in Treg cells, a subpopulation of CD4+ T cells (see Figure 8-17).[45] As with Th cells, Treg cells are activated by antigen presented in the context of class II MHC and differentiation under the control of specific cytokines, primarily TGF-β and IL-2, during which they express CD25 (the α-chain of the IL-2 receptor) and are frequently designated CD4+, CD25+ Treg cells.[46] The role of Treg cells is to control or limit the immune response to protect the host's own tissues against autoimmune reactions. Treg cells produce very high levels of TGF-β and IL-10, an immunosuppressive cytokine, which generally decrease Th1 and Th2 activity and suppress antigen recognition and Th-cell proliferation. The role of Treg cells and other regulatory cells (e.g., CD25 cells, CD8+ regulatory cells, and Breg cells) is under intense investigation to determine the degree of their heterogeneity of derivation, function, and specificity.

FETAL AND NEONATAL IMMUNE FUNCTION

The normal human infant is immunologically immature at birth. Although cell-mediated immunologic capabilities begin developing early in gestation and probably are completely functional at birth, antibody production is clearly deficient. In the last trimester, the fetus appears capable of producing a primary immune response (almost entirely IgM) to antigenic challenge in utero but is unable to produce a significant IgG response. Although some IgA can be detected, the capacity to produce IgA is underdeveloped.

To protect the child against infectious agents both in utero and during the first few postnatal months, a system of active transport facilitates the passage of maternal antibodies into the fetal circulation (Figure 8-29). In the placenta, maternal and fetal blood is separated by a layer of specialized cells termed *trophoblasts*. Immunoglobulins are too large to diffuse across this cellular layer so the trophoblastic cells actively transport immunoglobulins from the maternal to the fetal circulation. Active transport of maternal IgG is mediated by surface receptors that are specific for the Fc portion of free IgG but not for IgM, IgE, or IgA. Active transport sometimes results in higher antibody titers in umbilical cord blood than in maternal blood. (Active transport mechanisms are discussed in Chapter 1.)

At birth, total IgG levels in the umbilical cord are near adult levels (Figure 8-30). When the source of maternal antibodies is severed at birth, antibody titers in the newborn begin to drop as maternal antibody is catabolized. Thus antibody titers drop rapidly as the neonate's production of IgG is beginning to rise. The rate of catabolism is usually more rapid than the rate of production so that the total immunoglobulin levels reach a minimum at 5 to 6 months in the normal child, occasionally causing transient hypogammaglobulinemia (insufficient quantities of circulating immunoglobulins). Many normal infants experience recurrent mild respiratory tract infections at this age.

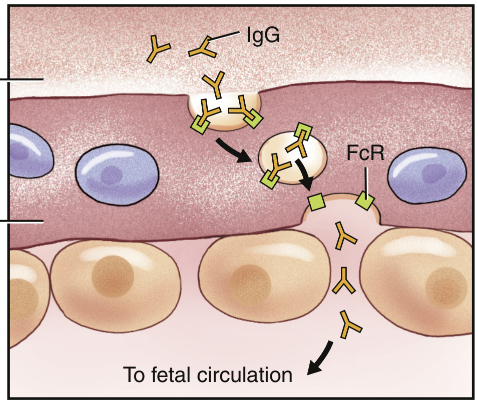

FIGURE 8-29 Transport of IgG Across the Syncytiotrophoblast. The human placenta is covered with a specialized multinucleated cell, the syncytiotrophoblast. Transport of maternal IgG across the syncytiotrophoblast and into the fetal circulation is an active process. Maternal IgG binds to Fc receptors on the surface of the syncytiotrophoblast and is internalized by the process of endocytosis. Receptors on the syncytiotrophoblast are specific for the Fc portion of IgG and do not bind other classes of immunoglobulins. Interaction of IgG with Fc receptors protects the antibody from lysosomal digestion during transport of the vacuole across the cell (i.e., transcytosis). On the fetal side of the syncytiotrophoblast, IgG is released by exocytosis (see Chapter 1).

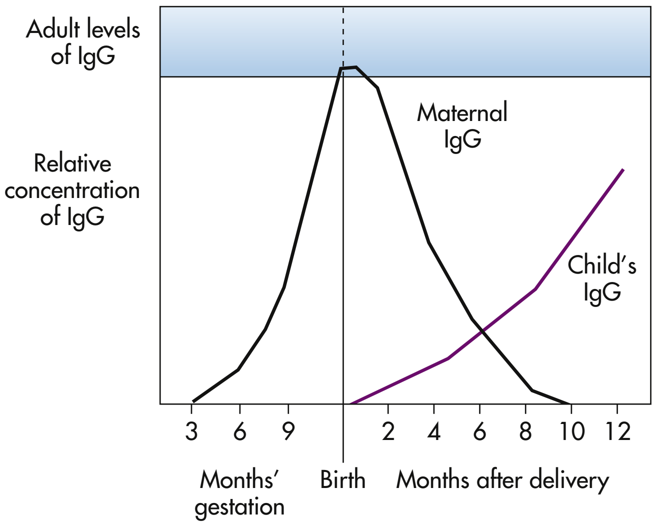

FIGURE 8-30 Antibody Levels in Umbilical Cord Blood and in Neonatal Circulation. Early in gestation maternal IgG begins crossing the placenta and enters the fetal circulation as shown in Figure 8-29. At birth, the fetal circulation may contain nearly adult levels of IgG, which is almost exclusively from the maternal source. The fetal immune system has the capacity to produce IgM and small amounts of IgA before birth (not shown). After delivery, maternal IgG is rapidly catabolized and neonatal IgG production increases.

AGING AND IMMUNE FUNCTION

Immune function decreases in old age as a result of changes in both lymphocyte function and relative lymphocyte populations. Individuals older than 60 years of age generally exhibit decreased T-cell activity as demonstrated by laboratory assays of T-cell function, as well as in vivo reductions in cell-mediated responses to infections. The thymus, where T cells begin their development, reaches its maximum size at

sexual maturity and then begins involuting until thymic size is only 15% of its maximum by middle age. Thymic capacity to mediate T-cell differentiation decreases with this atrophy.[47] Although the total number of circulating T cells does not decrease with age, there is a shift in the populations of T-cell subtypes.[48]

B-cell function is also altered with age as shown by decreases in specific antibody production in response to antigenic challenge, with concomitant increases in circulating immune complexes and in circulating autoantibodies (antibodies against self-antigens). A decrease in the number of circulating memory B cells is also observed.

SUMMARY REVIEW

General Characteristics of Adaptive Immunity

1. Compared with the innate inflammatory response, the adaptive immune response is slower, is specific (rather than nonspecific or general), and has "memory" that makes it much longer lived.
2. The adaptive immune response is most often initiated by cells of the innate system. These cells process and present portions of invading pathogens (i.e., antigens) to lymphocytes in peripheral lymphoid tissue.
3. The adaptive immune response is mediated by two different types of lymphocytes—B lymphocytes and T lymphocytes. Each has distinct functions. B cells are responsible for humoral immunity that is mediated by circulating antibodies, whereas T cells are responsible for cell-mediated immunity, in which they kill targets directly or stimulate the activity of other leukocytes.
4. Adaptive immunity can be either active or passive depending on whether immune response components originated in the host or came from a donor.

Recognition and Response

1. Antigens are the molecules that can react with components of the adaptive immune system, including antibodies and lymphocyte surface receptors. Immunogens are antigens that can initiate the adaptive immune response. To be immunogenic, an antigen must be of the correct type, size, and complexity and be present in sufficient quantities. Haptens are small-molecular-weight antigens that are not themselves immunogenic.
2. Both B and T lymphocytes bind antigen through cognate receptor complexes on their surfaces. These receptor complexes (i.e., the BCR and TCR complexes, respectively) work in conjunction with accessory proteins to produce lymphocyte activation.
3. The antigen-binding molecule of the BCR is antibody. Antibodies are composed of four polypeptide chains—two identical heavy chains and two identical light chains—held together by disulfide bonds. Each heavy chain has a variable region and a large constant region. Each light chain has a variable region and a short constant region. The class of antibody is determined by which constant regions make up their heavy chains, giving each class a slightly different molecular structure. The classes include IgG (the most prevalent), IgA (mostly in secretions), IgE (the most rare), IgD, and IgM (the first and largest immunoglobulin produced). The parts of antibody that bind antigen are called the Fab, and the part that reacts with cells and molecules of the innate system is called the Fc. Antigen binds to hypervariable regions (complementary-determining regions, or CDRs) of both the heavy and the light chains.
4. For most antigens to elicit an immune response, they must be presented to lymphocytes by molecules on the surface of antigen-presenting cells. Endogenous protein antigens are presented by class I molecules of MHC. Exogenous protein antigens are presented by class II MHC molecules. Lipid antigens are presented by CD1.
5. The MHC is a cluster of genes found on human chromosome 6. The products of these genes are also called *HLA antigens*. The MHC genes are highly polymorphic, having many different possible alleles. An individual will carry only two alleles at each locus, one from each parent. The particular combination of alleles a given individual carries defines his or her MHC haplotype.
6. For an immune response to develop, a variety of cells must interact through surface adhesion molecules.
7. During their interactions, cells must communicate with each other through soluble cytokines. In addition to their roles in the innate immune response, cytokines have multiple functions in the adaptive immune response including both positive and negative regulation of B-cell and T-cell maturation. In general, it is the precise combination of cytokines influencing a given cell that ultimately determines that cell's response.

Generation of Clonal Diversity

1. The generation of clonal diversity occurs in the primary lymphoid organs (thymus for T cells, bone marrow for B cells) in the fetus.
2. An individual's population of T cells and B cells has the collective ability to respond to virtually any antigen. This ability results from genetic rearrangement of various genes to form the variable regions for the TCR and BCR. Rearrangement of *V* and *J* genes results in the variable regions of the TCR α-chain and the BCR light chain, and rearrangement of *V, D,* and *J* genes result in the variable regions of the TCR β-chain and the BCR heavy chain.
3. Differentiation of B cells and T cells in the primary lymphoid organs results in expression of several characteristic surface markers, such as CD4 on helper T cells, CD8 on cytotoxic T cells, and CD21 and CD40 on B cells.
4. During generation of clonal diversity, B cells and T cells that produce receptors against self-antigens are eliminated by a process of central tolerance.

SUMMARY REVIEW—cont'd

5. Cells leaving the primary lymphoid organs are immunocompetent (capable of reacting to antigen) and enter the circulation and secondary lymphoid organs.

Induction of an Immune Response: Clonal Selection

1. Clonal selection is the process by which antigen selects lymphocytes with complementary TCRs or BCRs and induces an immune response with the production of specific antibody or cytotoxic T cells, or both.
2. For lymphocyte activation, most antigens must be processed and presented by an APC in the context of the appropriate molecule, either MHC class I, MHC class II, or CD1 molecules.
3. Most immune responses require helper T cells (Th cells). Precursor Th cells interact with APCs through the TCR-CD4 complex, a variety of adhesion molecules, and cytokines, especially IL-1, and develop into either Th1 or Th2 subsets. Th1 cells are responsible for helping to activate macrophages and cytotoxic T cells, whereas Th2 cells are responsible for helping to activate B cells.
4. Another set of Th cells, Th17 cells, provides help in developing inflammation, particularly attraction of neutrophils and macrophages and induction of chemokine and antimicrobial protein production by epithelial cells.
5. B-cell activation results from recognition of soluble antigen by the BCR, processing of the antigen, and presentation by MHC class II antigens to Th2 cells. Interactions between the B cells and Th2 cells through adhesion molecules (e.g., CD40 and CD40L) are also required. Depending on the particular combination of cytokines produced by the Th2 cell, the B cells can undergo class-switch from making IgM antibody to making and secreting either IgA, IgE, or IgG.
6. The humoral immune response is divided into two phases, primary and secondary. These differ in the relative amounts of IgG produced—the secondary response having a much higher proportion of IgG relative to IgM. The two responses also differ in the speed with which each occurs after antigen challenge—the secondary response being much more rapid than the primary response because of the presence of memory cells in the secondary phase.
7. B cells become activated upon recognition of a particular antigen to proliferate and differentiate either into plasma cells that function as factories for the synthesis of large amounts of antibody that is specific for the recognized antigen or into memory B cells.
8. T-cell activation results from recognition by the TCR and CD8 of antigen presented by MHC class I. Appropriate intercellular adhesion molecules and cytokines, such as IL-2 from Th1 cells, are also necessary for efficient differentiation. T cells become CTLs or memory T cells.
9. Superantigens are molecules produced by infectious agents that can bind to the TCR of the Th cell outside the normal antigen-binding site and to class II MHC on the APCs, resulting in activation of a large number of Th cells and excessive production of proinflammatory cytokines that may cause shock and death of the patient. Examples of these antigens, called *superantigens,* include the bacterial toxins that can cause toxic shock syndrome and food poisoning.

Effector Mechanisms

1. The antibodies that are produced by B cells affect antigens by several different mechanisms that can be categorized as either direct or indirect. Direct mechanisms are mediated by the antigen-binding portions of antibodies (the Fab portions containing the variable regions). This binding results in neutralization of the biologic activity of antigens and possibly removal of the antigen by agglutination or precipitation. Indirect mechanisms depend on both the Fab and the non–antigen-binding portion of antibodies (the Fc portions containing the constant regions), which interact with components of innate immunity.
2. Antibodies of the systemic immune system function throughout the body, whereas antibodies of the secretory (mucosal) immune system—primarily immunoglobulins of the IgA class—are associated with bodily secretions and function to prevent pathogenic infection on epithelial surfaces.
3. Cytotoxic T cells (Tc cells) adhere directly to antigen presented by MHC class I on target cells (virus-infected cells or cancer cells) through the TCR, CD8, and a variety of adhesion proteins. This contact results in killing of the target by apoptosis through the release of perforin and granzymes and/or direct stimulation of apoptotic receptors on the target (e.g., Fas).
4. NK cells kill targets in a fashion similar to that of Tc cells. However, NK cells recognize target cells that do not express MHC class I.
5. With infections that are resistant to cells of innate immunity, some Th1 cells produce cytokines that activate macrophages to become more efficient phagocytes.
6. Treg cells control (suppress) immune responses and prevent overreaction against foreign and self-antigens.

Fetal and Neonatal Immune Function

1. The human neonate has a poorly developed immune response, particularly in the production of IgG. The fetus and neonate are protected in utero and during the first few postnatal months by maternal antibody that was actively transported across the placenta.
2. The maternal antibodies are slowly catabolized after birth until they disappear altogether by about 10 months of age. The neonate begins producing IgG at birth, and the child's antibodies reach protective levels after about 6 months of age.

Aging and Immune Function

1. T-cell activity is deficient in older adults, and a shift in the balance of T-cell subsets is observed. These changes may result in increased susceptibility to infection.
2. Antibody production to specific antigens is inferior, although older adults tend to have increased levels of circulating autoantibodies.

CHAPTER OUTLINE

The immune system is a finely tuned network that protects the host against foreign antigens, particularly infectious agents. Sometimes this network breaks down, causing the immune system to react inappropriately. Inappropriate immune responses may be (1) exaggerated against environmental antigens (allergy); (2) misdirected against the host's own cells (autoimmunity); (3) directed against beneficial foreign tissues, such as transfusions or transplants (alloimmunity); or (4) insufficient to protect the host (immune deficiency). All of these can be serious or life threatening. Exaggerated immune responses (allergy) are the most common, but usually the least life threatening.

HYPERSENSITIVITY: ALLERGY, AUTOIMMUNITY, AND ALLOIMMUNITY

Hypersensitivity is an altered immunologic response to an antigen that results in disease or damage to the host. *Hypersensitivity reactions* can be classified in two ways: by the source of the antigen that the immune system is attacking (allergy, autoimmunity, alloimmunity; Table 9-1) and by the mechanism that causes disease (types I, II, III, and IV; see Table 9-3). The term **allergy** originally denoted both facets of the immune response: immunity, which is beneficial, and hypersensitivity, which is harmful. Allergy has now come to mean the deleterious effects of hypersensitivity to environmental antigens, and immunity means the protective responses to antigens expressed by disease-causing agents.

Autoimmunity is a disturbance in the immunologic tolerance of self-antigens. The immune system normally does not strongly recognize the individual's own antigens. Healthy individuals of all ages, but particularly older adults, may produce low quantities of antibodies against their own antigens *(autoantibodies),* without development of overt autoimmune disease. Therefore, the presence of low quantities of autoantibodies does not necessarily indicate a disease state. Autoimmune diseases occur when the immune system reacts against self-antigens to

TABLE 9-1 RELATIVE INCIDENCES AND EXAMPLES OF HYPERSENSITIVITY REACTIONS*

	MECHANISM			
TARGET ANTIGEN	TYPE I (IMMUNOGLOBULIN E–[IGE] MEDIATED)	TYPE II (TISSUE SPECIFIC)	TYPE III (IMMUNE COMPLEX)	TYPE IV (CELL MEDIATED)
Allergy	++++	+	+	++
Environmental antigens	Hay fever	Hemolysis in drug allergies	Gluten (wheat) allergy	Poison ivy allergy
Autoimmunity	±	++	+++	+
Self-antigens	May contribute to some type III reactions	Autoimmune thrombocytopenia	Systemic lupus erythematosus	Hashimoto thyroiditis
Alloimmunity	±	++	+	++
Another person's antigens	May contribute to some type III reactions	Hemolytic disease of the newborn	Anaphylaxis to IgA in IV gamma globulin	Graft rejection

*The frequency of each reaction is indicated in a range from rare (±) to very common (++++). An example of each reaction is given.

such a degree that the person's own tissues are damaged by autoantibodies or autoreactive T cells. Many clinical disorders are associated with autoimmunity and are collectively referred to as **autoimmune diseases** (Table 9-2).

Alloimmunity (also termed *isoimmunity*) occurs when the immune system of one individual produces an immunologic reaction against tissues of another individual. Alloimmunity can be observed during immunologic reactions against transfusions, transplanted tissue, or the fetus during pregnancy.

The mechanism that initiates the onset of hypersensitivity, whether it consists of allergy, autoimmunity, or alloimmunity, is not completely understood. It is generally accepted that genetic, infectious, and possibly environmental factors contribute to hypersensitivity. Most diseases caused by hypersensitivity develop because of the interactions of at least three variables: (1) an original "insult," which alters **immunologic homeostasis** (a steady state of tolerance to self-antigens or lack of immune reaction against environmental antigens); (2) the individual's genetic makeup, which determines the degree of the resultant immune response from the effects of the insult; and (3) an immunologic process that causes the symptoms of the disease.

Mechanisms of Hypersensitivity

Diseases caused by hypersensitivity reactions can be characterized also by the particular immune mechanism that results in the disease (see Table 9-1). These mechanisms are apparent in most hypersensitivity reactions and have been divided into four distinct types: **type I (immunoglobulin E [IgE]–mediated) hypersensitivity reactions, type II (tissue-specific) hypersensitivity reactions, type III (immune complex–mediated) hypersensitivity reactions,** and **type IV (cell-mediated) hypersensitivity reactions** (Table 9-3).[1] This classification is artificial and seldom is a particular disease associated with only a single mechanism. The four mechanisms are interrelated, and in most hypersensitivity reactions, several mechanisms can be at work simultaneously or sequentially. Some of the mechanisms are secondary to the disease and not directly involved in the pathologic process, whereas others are the primary cause of tissue destruction.

Hypersensitivity reactions require *sensitization* against a particular antigen that results in primary and secondary immune responses. An individual is sensitized when an adequate amount of antibodies or T cells is available to cause a noticeable reaction on reexposure to the antigen. Some individuals become sensitized quite rapidly (after an apparent single exposure to the antigen), whereas others require multiple exposures that may occur over years. After sensitization has been achieved, hypersensitivity reactions can be immediate or delayed, depending on the time between reexposure to the antigen and the onset of clinical symptoms. Reactions that occur within minutes to a few hours are termed **immediate hypersensitivity reactions. Delayed hypersensitivity reactions** may take several hours to appear and are at maximum severity days after reexposure to the antigen.

The most rapid and severe immediate hypersensitivity reaction is **anaphylaxis.**[2] Anaphylaxis occurs within minutes of reexposure to the antigen and can be either systemic (generalized) or cutaneous (localized).[3] Symptoms of systemic anaphylaxis include itching, erythema, headaches, vomiting, abdominal cramps, diarrhea, and breathing difficulties. In severe cases, contraction of bronchial smooth muscle, laryngeal edema, and vascular collapse may result in respiratory distress, decreased blood pressure, shock, and death. Examples of systemic anaphylaxis are allergic reactions to bee stings, peanuts, and fish. Cutaneous anaphylaxis causes the less severe symptom of local inflammation.

Type I: IgE-Mediated Hypersensitivity Reactions

Type I reactions are mediated by antigen-specific IgE and the products of tissue mast cells[4] (Figure 9-1). Most common allergies (e.g., pollen allergies) are type I reactions. In addition, most type I reactions occur against environmental antigens and are therefore allergic. Because of this strong association, many healthcare professionals use the term *allergy* to indicate only IgE-mediated reactions. However, IgE can contribute to a few autoimmune and alloimmune diseases, and many common allergies (e.g., poison ivy) are not mediated by IgE.

In some individuals, exposure to an environmental antigen causes primarily IgE production. Repeated exposure to the antigen usually is required to elicit enough IgE so that the person becomes "sensitized." IgE has a relatively short life span in the blood because it rapidly binds to very-high-affinity Fc receptors

TABLE 9-2 DISORDERS ASSOCIATED WITH AUTOIMMUNITY

SYSTEM DISEASE	ORGAN OR TISSUE	PROBABLE SELF-ANTIGEN
Endocrine System		
Hyperthyroidism (Graves disease)	Thyroid gland	Receptors for thyroid-stimulating hormone on plasma membrane of thyroid cells
Autoimmune thyroiditis	Thyroid gland	Thyroglobulin; microsomes
Primary myxedema	Thyroid gland	Microsomes
Insulin-dependent diabetes	Pancreas	Islet cells, insulin, insulin receptors on pancreatic cells
Addison disease	Adrenal gland	Surface antigens on steroid-producing cells; microsomes of adrenal cortex
Premature gonadal failure	Ovary	Interstitial cells; corpus luteum
Male infertility	Testis	Surface antigens on spermatozoa
Orchitis	Testis	Germinal epithelium
Female infertility	Ovary	Zona pellucida
Idiopathic hypoparathyroidism	Parathyroid gland	Surface antigens on chief cells (epithelial cells of gland)
Partial pituitary deficiency	Pituitary gland	Prolactin-producing cells; growth hormone–producing cells
Skin		
Pemphigus vulgaris	Skin	Intercellular substances in stratified squamous epithelium
Bullous pemphigoid	Skin	Basement membrane
Dermatitis herpetiformis	Skin	Basement membrane (immunoglobulin A [IgA])
Vitiligo	Skin	Surface antigens on melanocytes (melanin-producing cells)
Neuromuscular Tissue		
Polymyositis (dermatomyositis)	Muscle	Nuclear materials; myosin
Multiple sclerosis	Neural tissue	Unknown
Myasthenia gravis	Neuromuscular junction	Acetylcholine receptors; striations of skeletal and cardiac muscle
Polyneuritis	Nerve cell	Peripheral myelin
Rheumatic fever	Heart	Cardiac tissue (subsarcolemmal membrane); cross reaction with group A streptococcal antigen
Cardiomyopathy	Heart	Cardiac muscle
Postvaccinal or postinfectious encephalitis	Central nervous system	Central nervous system myelin or basic protein
Gastrointestinal System		
Celiac disease (gluten-sensitive enteropathy)	Intestine	Gluten
Ulcerative colitis	Colon	Mucosal cells
Crohn disease	Ileum	Unknown
Pernicious anemia	Stomach	Surface antigens of parietal cells; intrinsic factor
Atrophic gastritis	Stomach	Parietal cells
Primary biliary cirrhosis	Liver	Mitochondria; cells of bile duct
Chronic active hepatitis	Liver	Surface antigens, nuclei, microsomes, mitochondria or hepatocytes; smooth muscle
Eye		
Sjögren syndrome	Lacrimal gland	Antigens of lacrimal gland, salivary gland, thyroid, and nuclei of cells; immunoglobulin G (IgG)
Uveitis	Uveal structures	Antigens of the iris, ciliary body, and choroid
Connective Tissue		
Ankylosing spondylitis	Joints	Sacroiliac and spinal apophyseal joint
Rheumatoid arthritis	Joints	IgG, collagen
Systemic lupus erythematosus	Multiple sites	Numerous antigens in nuclei, organelles, and extracellular matrix
Mixed connective tissue disease	Multiple sites	Ribonucleoprotein and numerous other nucleoproteins
Polyarteritis nodosa (necrotizing vasculitis)	Arterioles (small arteries)	Unknown
Scleroderma (progressive systemic sclerosis)	Multiple organs	Nuclear antigens; IgG
Felty syndrome	Joints	IgG
Antiphospholipid antibody syndrome	Platelets, endothelial cells, trophoblast of placenta	Membrane phospholipids, especially phosphatidylserine
Renal System		
Immune complex glomerulonephritis	Kidney	Numerous immune complexes
Goodpasture syndrome	Kidney	Glomerular basement membrane

TABLE 9-2 **DISORDERS ASSOCIATED WITH AUTOIMMUNITY—cont'd**

SYSTEM DISEASE	ORGAN OR TISSUE	PROBABLE SELF-ANTIGEN
Hematologic System		
Idiopathic neutropenia	Neutrophil	Surface antigens on polymorphonuclear neutrophils
Idiopathic lymphopenia	Lymphocytes	Surface antigens on lymphocytes
Autoimmune hemolytic anemia	Erythrocytes	Surface antigens on erythrocytes
Autoimmune thrombocytopenic purpura	Platelets	Surface antigens on platelets
Respiratory System		
Goodpasture syndrome	Lung	Septal membrane of alveolus

TABLE 9-3 **IMMUNOLOGIC MECHANISMS OF TISSUE DESTRUCTION**

TYPE	NAME	RATE OF DEVELOPMENT	CLASS OF ANTIBODY INVOLVED	PRINCIPAL EFFECTOR CELLS INVOLVED	COMPLEMENT PARTICIPATION	EXAMPLES OF DISORDERS
I	IgE-mediated reaction	Immediate	IgE	Mast cells	No	Seasonal allergic rhinitis
II	Tissue-specific reaction	Immediate	IgG IgM	Macrophages in tissues	Frequently	Autoimmune thrombocytopenic purpura, Graves disease, autoimmune hemolytic anemia
III	Immune complex–mediated reaction	Immediate	IgG IgM	Neutrophils	Yes	Systemic lupus erythematosus
IV	Cell-mediated reaction	Delayed	None	Lymphocytes, macrophages	No	Contact sensitivity to poison ivy and metals (jewelry)

Ig, Immunoglobulin.

on the plasma membranes of mast cells (see Figure 9-1). The subclass IgG4 also has specific receptors on the mast cell and may contribute to the type I mechanism. Antibody that binds to mast cells is termed **cytotropic antibody** (able to bind to cell surfaces) or **reagin** (skin-sensitizing antibody). Unlike Fc receptors on phagocytes, which bind IgG that has reacted with antigen, the Fc receptors on mast cells bind with IgE that has not previously interacted with antigen.

If further exposure of a sensitized individual to the antigen occurs, one molecule of antigen may bind simultaneously to two molecules of IgE-Fc receptor complexes on the mast cell's surface (cross-link) resulting in activation of intracellular signaling pathways and mast cell degranulation (see Figure 9-1, *B*, and Chapter 7). The antigen that triggers cross-linking must have at least two antigenic determinants on the same molecule. Sometimes an IgE-mediated response is beneficial to the host, as is the case of some immune reactions against parasites. (This mechanism is described in Chapter 8 and illustrated in Figure 8-26.)

The products of mast cell degranulation can modulate almost all aspects of an acute inflammatory response. (The effects of biochemical mediators released by mast cells are illustrated in Figure 7-11). The most potent mediator is histamine, which affects several key target cells. Acting through the H1 receptors, histamine contracts bronchial smooth muscles, causing bronchial constriction; increases vascular permeability, causing edema; and causes vasodilation, increasing blood flow into the affected area (see Figures 7-3 and 7-12). The interaction of histamine with H2 receptors results in increased gastric acid secretion and a decrease of histamine released from mast cells and basophils. The action of histamine through H2 receptors suggests an important negative-feedback mechanism that stops degranulation. That is, the released histamine inhibits release of additional histamine by interacting with H2 receptors on the mast cells. Histamine also may affect control of the immune response through H2 receptors on most cells of the immune system. Another important activity of histamine is enhancement of the chemotactic activity of other factors, such as eosinophil chemotactic factor of anaphylaxis (ECF-A), which attracts eosinophils into sites of allergic inflammatory reactions and prevents them from migrating out of the inflammatory site. (The role of the eosinophil in inflammation is discussed in Chapter 7.)

Type II: Tissue-Specific Hypersensitivity Reactions

Type II hypersensitivity reactions are generally characterized by a specific cell or tissue being the target of an immune response. In addition to major histocompatibility locus antigens (HLAs; discussed in Chapter 8), most cells have other antigens on their surfaces. Some of these other antigens are called **tissue-specific antigens** because they are expressed on the plasma membranes of only certain cells in specific tissues. Platelets, for example, have groups of antigens that are found on no other cells of the body. The symptoms of many type II diseases are determined by which tissue or organ expresses the particular antigen. Environmental antigens (e.g., drugs or their metabolites) may bind to the plasma membranes of specific cells (especially erythrocytes and platelets) and function as targets of type II reactions.

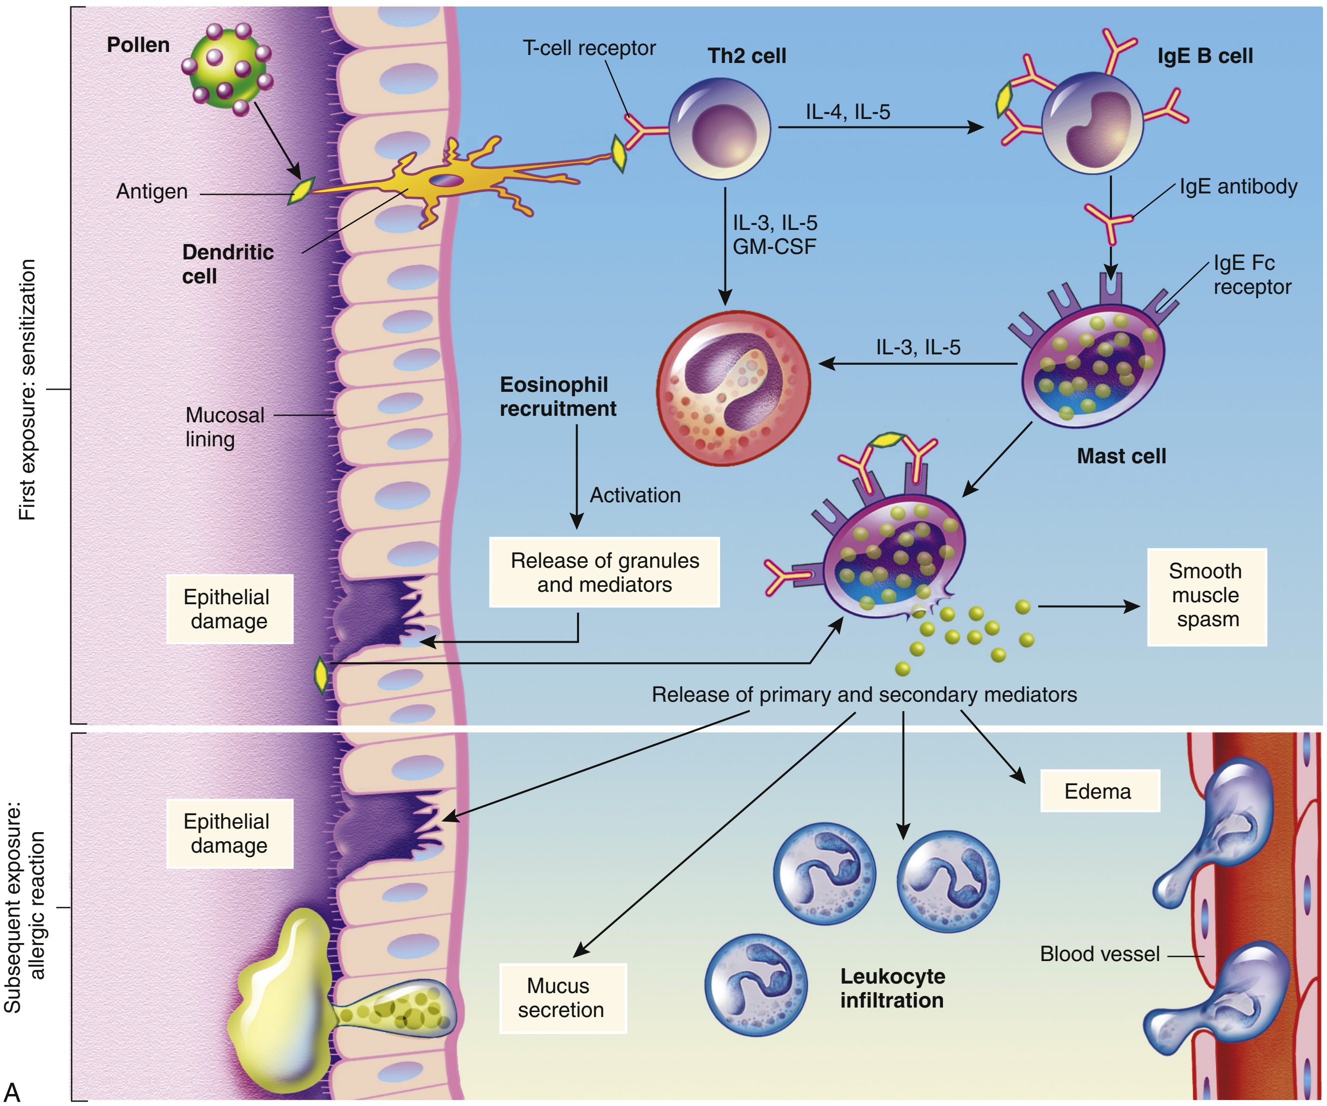

FIGURE 9-1 **Mechanism of Type I IgE–Mediated Reactions. A,** Th2 cells are activated by antigen-presenting dendritic cells to produce cytokines, including IL-3, IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). IL-3, IL-5, and GM-CSF attract and promote the survival of eosinophils. Other cytokines (e.g., IL-4) induce B cells to class-switch to IgE-producing plasma cells. The IgE coats the surface of the mast cell by binding with IgE-specific Fc receptors on the mast cell's plasma membrane (sensitization). Further exposure to the same allergen cross-links the surface-bound IgE and activates signals from the cytoplasmic portion of the IgE Fc receptors. These signals initiate two parallel and interdependent processes: mast cell degranulation and discharge of preformed mediators (e.g., histamine, eosinophil-chemotactic factor of anaphylaxis) and production of newly formed mediators such as arachidonic metabolites (leukotrienes, prostaglandins). Many local type I hypersensitivity reactions have two well-defined phases. The initial phase is characterized by vasodilation, vascular leakage, and, depending on the location, smooth muscle spasm or glandular secretions. These changes usually become evident within 5 to 30 minutes after exposure to the antigen. The late phase occurs 2 to 8 hours later without additional exposure to the antigen. The late phase has more intense infiltration of tissues with eosinophils, neutrophils, basophils, monocytes, and Th cells and tissue destruction in the form of mucosal epithelial cell damage.

The five general mechanisms by which type II hypersensitivity reactions can affect cells are shown in Figure 9-2. All of these mechanisms begin with antibody binding to tissue-specific antigens or antigens that have attached to particular tissues. First, the cell can be destroyed by antibody (IgG or IgM) and activation of the complement cascade through the classical pathway. Formation of the membrane attack complex (C5-9) damages the membrane and may result in lysis of the cell (see Figure 9-2, *A*). For example, erythrocytes are destroyed by complement-mediated lysis in individuals with autoimmune hemolytic anemia (see Chapter 28) or as a result of an alloimmune reaction to ABO-mismatched transfused blood cells.

Second, antibody may cause cell destruction through phagocytosis by macrophages. IgG and also C3b of the complement system are opsonins that bind to receptors on the macrophage (see Figure 9-2, *B*). Phagocytosis of the target cell follows.

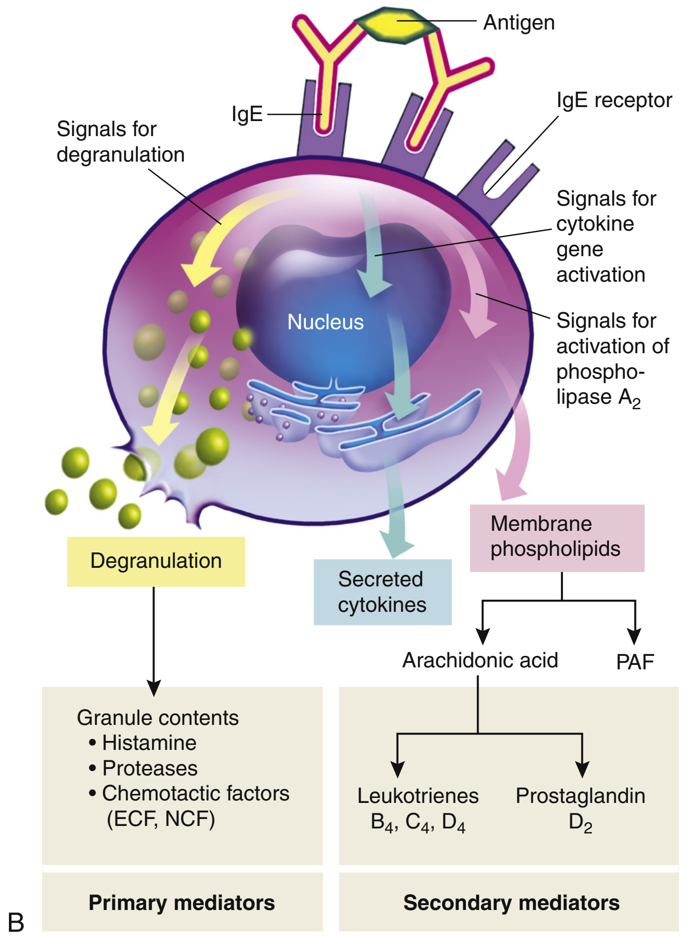

FIGURE 9-1, cont'd B, Activation of mast cells leading to degranulation of preformed mediators (primary mediators) and synthesis of newly formed (de novo) mediators (secondary mediators). *ECF,* Eosinophilic chemotactic factor; *NCF,* neutrophil chemotactic factor; *PAF,* platelet-activating factor.

(Phagocytosis is illustrated in Figures 7-15 and 7-16.) For example, antibodies against platelet-specific antigens or against red blood cell antigens of the Rh system coat those cells at low density, resulting in their preferential removal by phagocytosis in the spleen, rather than by complement-mediated lysis.

Third, antibody and complement may attract neutrophils. Either antigen expressed normally on the vessel walls or soluble antigen in the circulation (e.g., released from cells within the body or from infectious agents or by way of drugs or medications) that has been deposited on the surface of endothelial cells may bind antibody (see Figure 9-2, *C*). The antibody initiates the complement cascade, resulting in the release of C3a and C5a, which are chemotactic for neutrophils, and deposition of complement component C3b. Neutrophils bind to the tissues through receptors for the Fc portion of antibody (Fc receptor) or for C3b and attempt to phagocytose the tissue. Because the tissue is large, phagocytosis cannot be completed; even so, neutrophils release their granules onto the healthy tissue. The components of neutrophil granules, as well as the several toxic oxygen products produced by these cells, will damage the tissue.

The fourth mechanism is **antibody-dependent cell-mediated cytotoxicity (ADCC)** (see Figure 9-2, *D*). This mechanism involves a subpopulation of cytotoxic cells that are not antigen specific (natural killer [NK] cells). Antibody on the target cell is recognized by Fc receptors on the NK cells, which release toxic substances that destroy the target cell.

The fifth mechanism does not destroy the target cell, but rather causes it to malfunction. In this mechanism of type II injury, the antibody is usually directed against antigenic determinants associated with specific cell surface receptors, and the symptoms of the disease are a result of a direct effect of antibody binding alone (see Figure 9-2, *E*). The antibody reacts with the receptors on the target cell surface and modulates the function of the receptor by preventing interactions with their normal ligands, replacing the ligand and inappropriately stimulating the receptor, or destroying the receptor. For example, in the hyperthyroidism (excessive thyroid activity) of Graves disease, autoantibody binds to and activates receptors for thyroid-stimulating hormone (TSH) (a pituitary hormone that controls the production of the hormone *thyroxine* by the thyroid). In this way the antibody stimulates the thyroid cells to produce thyroxine.[5] Under normal conditions, the increasing levels of thyroxine in the blood would signal the pituitary to decrease TSH production, which would result in less stimulation of the TSH receptor in the thyroid and a concomitant decrease in thyroxine production. Because the level of anti-TSH receptor

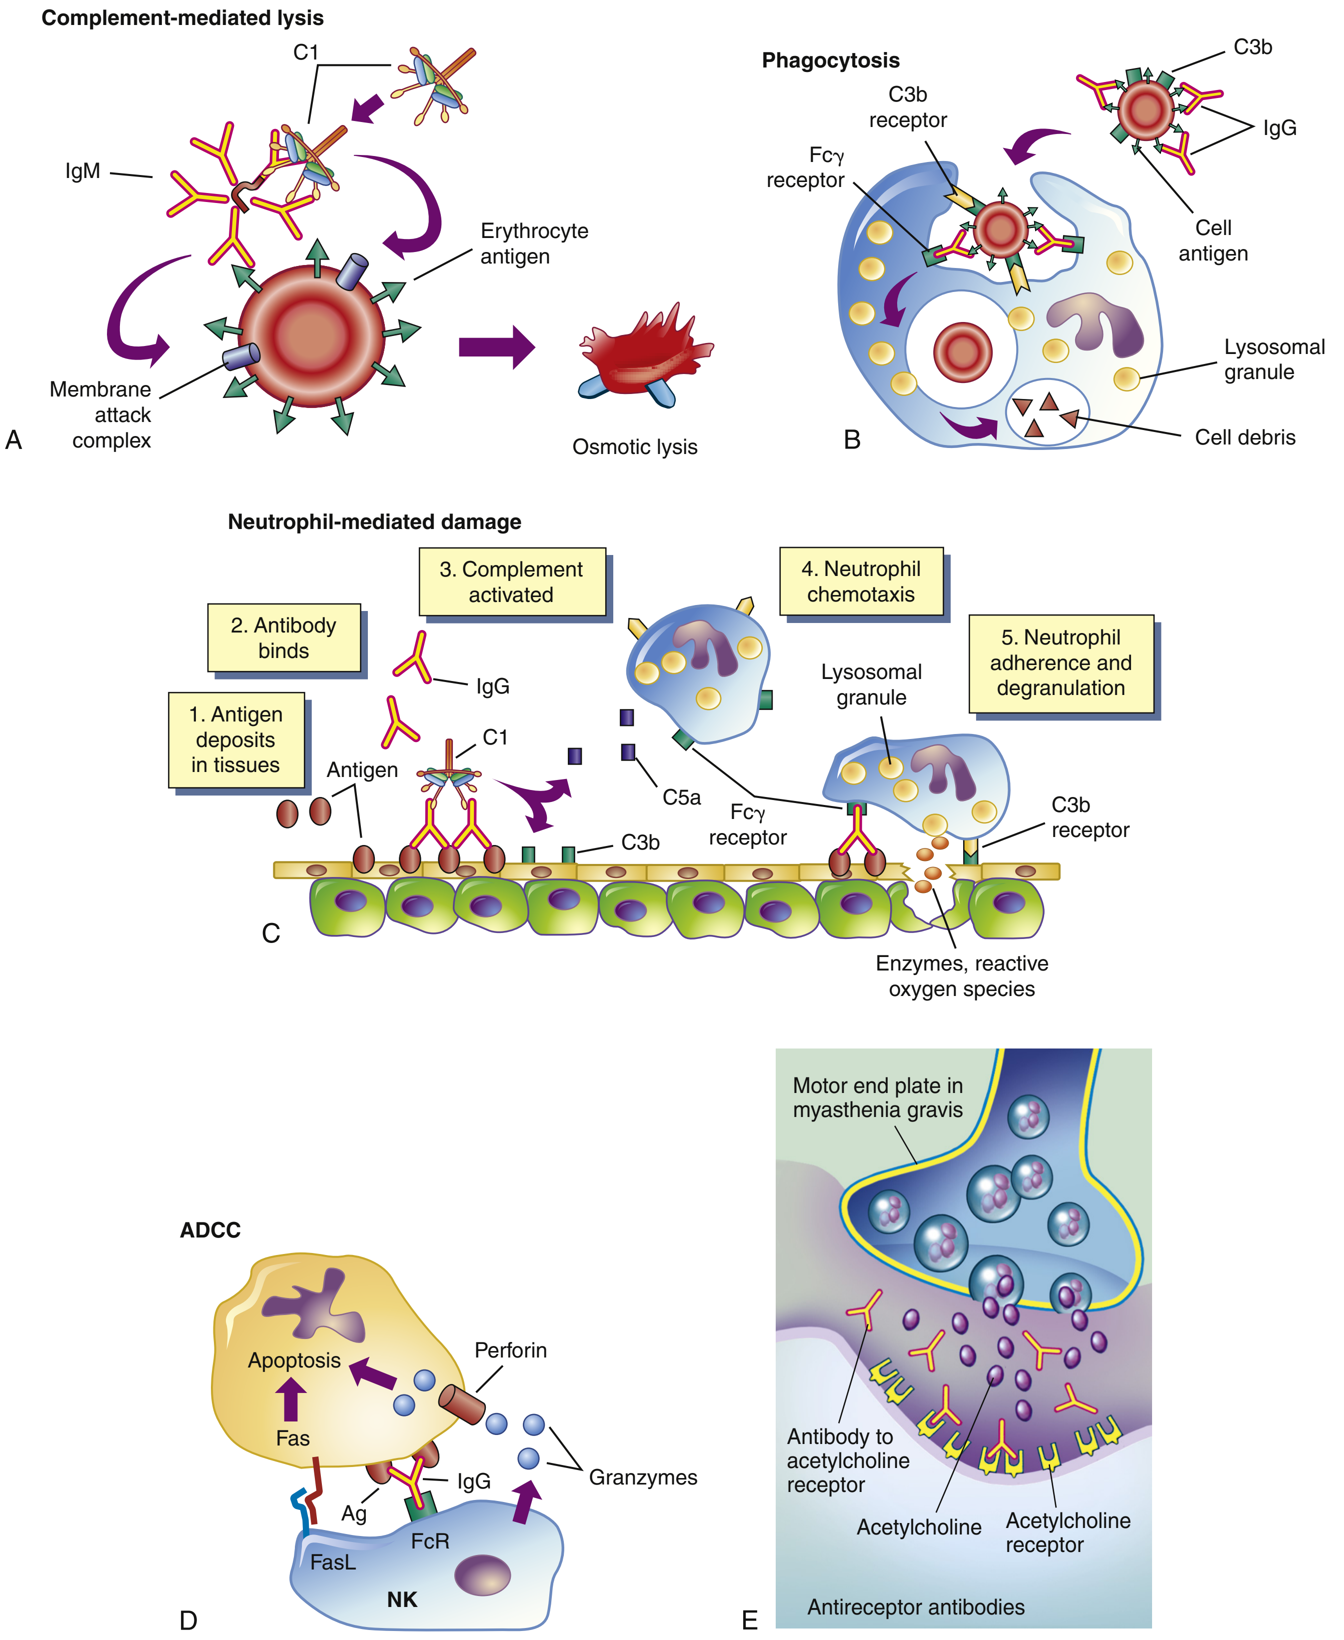

FIGURE 9-2 **Mechanisms of Type II, Tissue-Specific, Reactions.** Antigens on the target cell bind with antibody and are destroyed or prevented from functioning by **A,** complement-mediated lysis (an erythrocyte target is illustrated here); **B,** clearance (phagocytosis) by macrophages in the tissue; **C,** neutrophil-mediated immune destruction; **D,** antibody-dependent cell-mediated cytotoxicity (ADCC) (apoptosis of target cells is induced by granzymes and perforin produced by natural killer [NK] cells and interactions of Fas ligand [FasL] on the surface of NK cells with Fas on the surface of target cells); or **E,** modulation or blocking the normal function of receptors by antireceptor antibody. This example of mechanism **E** depicts myasthenia gravis in which acetylcholine receptor antibodies block acetylcholine from attaching to its receptors on the motor end plates of skeletal muscle, thereby impairing neuromuscular transmission and causing muscle weakness. *C1,* Complement component C1; *C3b,* complement fragment produced from C3, which acts as an opsonin; *C5a,* complement fragment produced from C5, which acts as a chemotactic factor for neutrophils; *Fcγ receptor,* cellular receptor for the Fc portion of IgG; *FcR,* Fc receptor.

antibody is not controlled by the pituitary, increasing amounts of thyroxine in the blood have no effect on antibody levels, and thyroxine production continues to increase despite decreasing amounts of TSH (see Chapter 22).

Type III: Immune Complex–Mediated Hypersensitivity Reactions

Mechanisms of Type III Hypersensitivity. Most type III hypersensitivity diseases are caused by antigen-antibody (immune) complexes that are formed in the circulation and deposited later in vessel walls or extravascular tissues (Figure 9-3). The primary difference between type II and type III mechanisms is that in type II hypersensitivity antibody binds to the antigen on the cell surface, whereas in type III the antibody binds to soluble antigen that was released into the blood or body fluids, and the complex is then deposited in the tissues. Type III reactions are not organ specific, and symptoms have little to do with the particular antigenic target of the antibody. The harmful effects of immune complex deposition are caused by complement activation, particularly through the generation of chemotactic factors for neutrophils. The neutrophils bind to antibody and C3b contained in the complexes and attempt to ingest the immune complexes.

They are often unsuccessful because the complexes are bound to large areas of tissue. During the attempted phagocytosis, large quantities of lysosomal enzymes are released into the inflammatory site instead of into phagolysosomes. The attraction of neutrophils and the subsequent release of lysosomal enzymes cause most of the resulting tissue damage.

Immune complexes can be of various sizes, depending on the relative amounts of antigen and antibody. Fairly large immune complexes are cleared rapidly from the circulation by tissue macrophages, whereas very small complexes eventually are filtered from blood through the kidneys, without any pathologic consequences. Intermediate-sized immune complexes (formed at a ratio of antigen to antibody that has a slight excess of antigen) are likely to be deposited in certain target tissues, where they have severe pathologic consequences, such as inflammation in the kidneys (glomerulonephritis), the vessels (vasculitis), or the joints (arthritis or degenerative joint disease).

Immune Complex Disease. The nature of the immune complexes may change during the progression of the disease, with resultant changes in the severity of the symptoms. Immune complex formation is dynamic as variations in the ratio of antigen to antibody, the class and subclass of antibody, and the quantity and quality of circulating antigen occur. Thus complexes formed early in a disease process may differ from those formed later, and several types of immune complexes may be present simultaneously. With the tremendous potential heterogeneity of immune complexes, it is not surprising that immune complex diseases are characterized by a variety of symptoms and periods of remission or exacerbation of symptoms.

Because many immune complexes activate complement very effectively, complement levels in the blood may decrease during active disease. At times the individual's blood may become **hypocomplementemic** (i.e., contains below normal amounts of complement activity). During type I, II, or IV hypersensitivity

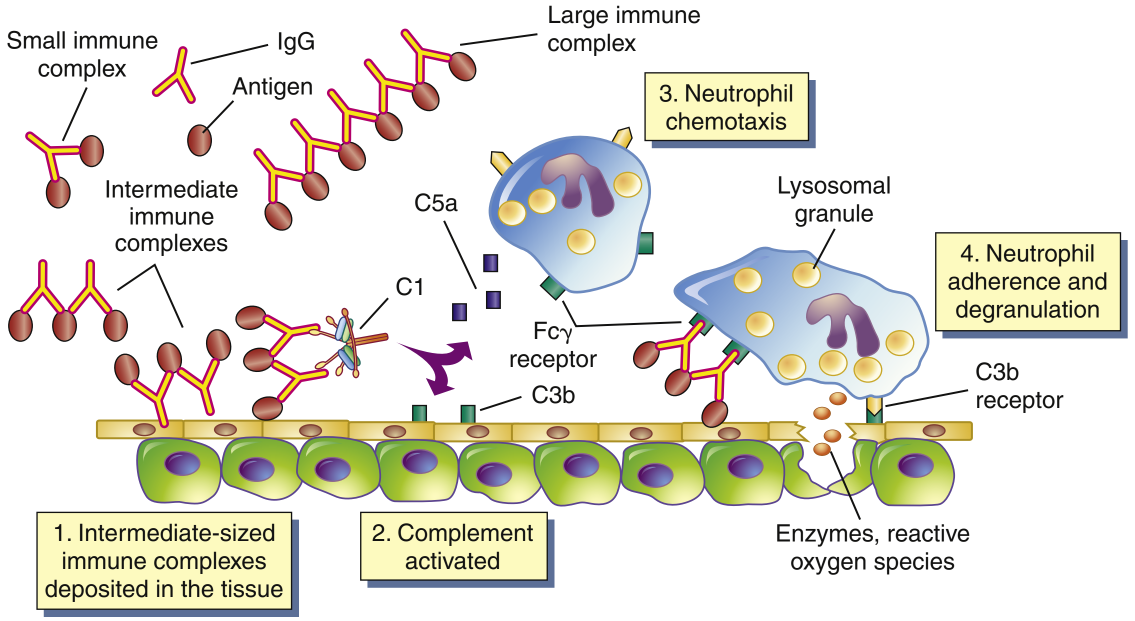

FIGURE 9-3 **Mechanism of Type III, Immune Complex–Mediated, Reactions.** Immune complexes form in the blood from circulating antigen and antibody. Both small and large immune complexes are removed successfully from the circulation and do not cause tissue damage. Intermediate-sized complexes are deposited in certain target tissues in which the circulation is slow or filtration of the blood occurs. The complexes activate the complement cascade through C1 and generate fragments including C5a and C3b. C5a is chemotactic for neutrophils, which migrate into the inflamed area and attach to the IgG and C3b in the immune complexes. The neutrophils attempt unsuccessfully to phagocytose the tissue and in the process release a variety of degradative enzymes that destroy the healthy tissues. Fcγ receptor is the cellular receptor for the Fc portion of IgG.

reactions, complement levels are unaffected, or some components of the complement cascade, such as C3, may even be increased.

Two prototypic models of type III hypersensitivity help explain the variety of diseases in this category. Serum sickness is a model of systemic type III hypersensitivities, and the Arthus reaction is a model of localized or cutaneous reactions.

Serum Sickness. The systemic prototype of immune complex–mediated disease is called **serum sickness** because it was initially described as being caused by the therapeutic administration of foreign serum, such as horse serum that contained antibody against tetanus toxin.[6] Foreign serum generally is not administered to individuals today, although serum sickness reactions can be caused by the repeated intravenous administration of other antigens, such as drugs, and the characteristics of serum sickness are observed in systemic type III autoimmune diseases. Serum sickness–type reactions are caused by the formation of immune complexes in the blood and their subsequent generalized deposition in target tissues. Typically affected tissues are the blood vessels, joints, and kidneys. Other symptoms include fever, enlarged lymph nodes, rash, and pain at sites of inflammation.

A form of serum sickness is **Raynaud phenomenon,** a condition caused by the temperature-dependent deposition of immune complexes in the capillary beds of the peripheral circulation. Certain immune complexes precipitate at temperatures below normal body temperature, particularly in the tips of the fingers, toes, and nose, and are called **cryoglobulins.** The precipitates block the circulation and cause localized pallor and numbness, followed by cyanosis (a bluish tinge resulting from oxygen deprivation) and eventually gangrene if the circulation is not restored.

Arthus Reaction. An **Arthus reaction** is the prototypic example of a localized immune complex–mediated inflammatory response.[7] It is caused by repeated local exposure to an antigen that reacts with preformed antibody and forms immune complexes in the walls of the local blood vessels. Symptoms of an Arthus reaction begin within 1 hour of exposure and peak 6 to 12 hours later. The lesions are characterized by a typical inflammatory reaction, with increased vascular permeability, an accumulation of neutrophils, edema, hemorrhage, clotting, and tissue damage.

Type IV: Cell-Mediated Hypersensitivity Reactions

Whereas types I, II, and III hypersensitivity reactions are mediated by antibody, type IV reactions are mediated by T lymphocytes and do not involve antibody (Figure 9-4). Type IV mechanisms occur through either cytotoxic T lymphocytes (Tc cells) or lymphokine-producing Th1 and Th17 cells. Tc cells attack and destroy cellular targets directly. Th1 and Th17 cells produce cytokines that recruit and activate phagocytic cells, especially macrophages. Destruction of the tissue is usually caused by direct killing by toxins from Tc cells or by the release of soluble factors, such as lysosomal enzymes and toxic reactive oxygen species (ROS), from activated macrophages.

Clinical examples of type IV hypersensitivity reactions include graft rejection and allergic reactions resulting from contact with such substances as poison ivy and metals. A type IV component also may be present in many autoimmune diseases. For example, T cells against type II collagen (a protein present in joint tissues) contribute to the destruction of joints in rheumatoid arthritis; T cells against a thyroid cell surface antigen contribute to the destruction of the thyroid in autoimmune thyroiditis (Hashimoto disease); and T cells against an antigen on the surface of pancreatic beta cells (the cell that normally produces insulin) are responsible for beta-cell destruction in insulin-dependent (type 1) diabetes mellitus.[8]

A type IV hypersensitivity reaction in the skin was thoroughly described first by Ehrlich in 1891 and led to the development of a diagnostic skin test for tuberculosis.[9] The reaction follows an intradermal injection of tuberculin antigen into a suitably sensitized individual and is called a *delayed hypersensitivity skin test* because of its slow onset—24 to 72 hours to reach maximum intensity. The reaction site is infiltrated with T lymphocytes and macrophages, resulting in a clear hard center (induration) and a reddish surrounding area (erythema).

Antigenic Targets of Hypersensitivity Reactions

Allergy

Allergy is a hypersensitivity response against an environmental antigen **(allergen).** Although the most common allergies are type I hypersensitivities, any of the other three mechanisms may cause allergic responses.[10]

Typical allergens that induce type I hypersensitivity include pollens (e.g., ragweed), molds and fungi (e.g., *Penicillium notatum*), foods (e.g., milk, eggs, fish), animals (e.g., cat dander, dog dander), cigarette smoke, components of house dust (e.g., fecal pellets of house mites), and almost anything else we

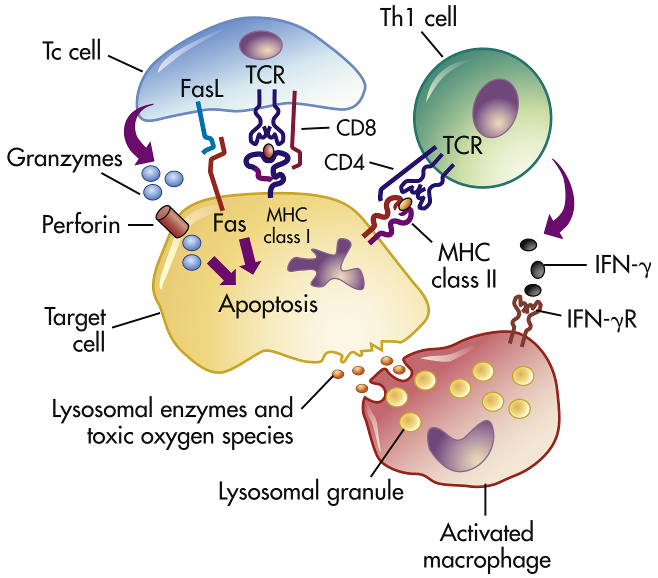

FIGURE 9-4 Mechanism of Type IV, Cell-Mediated, Reactions. Antigens from target cells stimulate T cells to differentiate into cytotoxic T cells (Tc cells), which have direct cytotoxic activity, and helper T cells (Th1 cells) involved in delayed hypersensitivity. The Th1 cells produce lymphokines (especially interferon-gamma [IFN-γ]) that activate the macrophage through specific receptors (e.g., IFN-γ receptor [IFN-γR]). The macrophages can attach to targets and release enzymes and reactive oxygen species that are responsible for most of the tissue destruction.

may encounter in our environment. Allergens that primarily elicit type IV allergic hypersensitivities include plant resins (e.g., poison ivy, poison oak), metals (e.g., nickel, chromium), acetylates, and chemicals in rubber, cosmetics, detergents, and topical antibiotics (e.g., neomycin). Type II and type III allergic hypersensitivities are relatively rare but may include antibiotics (e.g., penicillin, sulfonamides) and soluble antigens produced by infectious agents (e.g., hepatitis B).

Usually a sensitization process involving multiple exposures to the allergen occurs before adequate amounts of antibody or T cells are available to elicit a hypersensitivity response. In some instances, exposure to a particular allergen may not be apparent in the case of allergens that are drugs, additives, or preservatives in food. For example, an individual may become sensitized by drinking milk that contains trace amounts of penicillin used for treating cows for mastitis. Thus, the first therapeutic exposure to penicillin may cause an unexpected hypersensitivity reaction. Additionally, penicillin shares a β-lactam structure with cephalosporin, so that one antibiotic may be sensitive against another.

Genetic Predisposition. Certain individuals are genetically predisposed to develop allergies, particularly type I allergies, and are called **atopic.**[11] In families in which one parent has an allergy, allergies develop in about 40% of the offspring. If both parents have allergies, the incidence in the offspring may be as high as 80%. (Principles of genetic inheritance are discussed in Chapter 4.)

Atopic individuals tend to produce higher quantities of IgE and to have more Fc receptors for IgE on their mast cells. The airways and the skin of atopic individuals are also more responsive to a wide variety of both specific and nonspecific stimuli than are the airways and skin of individuals who are not atopic. Multiple genes have been associated with the atopic state, including polymorphisms in a large variety of cytokines that regulate IgE synthesis (e.g., interleukin [IL]-4, IL-5, IL-12, IL-13) and cellular receptors.

Clinical Symptoms of Type I Allergies

The clinical manifestations of type I reactions are attributable mostly to the biologic effects of histamine. Tissues most commonly affected contain large numbers of mast cells and are sensitive to the effects of histamine released from them. These tissues are found in the gastrointestinal tract, the skin, and the respiratory tract (Figure 9-5 and Table 9-4). The particular symptoms frequently reflect the main portal of entry for the allergen. For instance, pollens and other airborne allergens usually cause respiratory symptoms.

Effects of allergens on the mucosa of the eyes, nose, and respiratory tract include conjunctivitis (inflammation of the membranes lining the eyelids), rhinitis (inflammation of the mucous membranes of the nose), and asthma (constriction of the bronchi).[12] Symptoms are caused by vasodilation, hypersecretion of mucus, edema, and swelling of the respiratory mucosa. Because

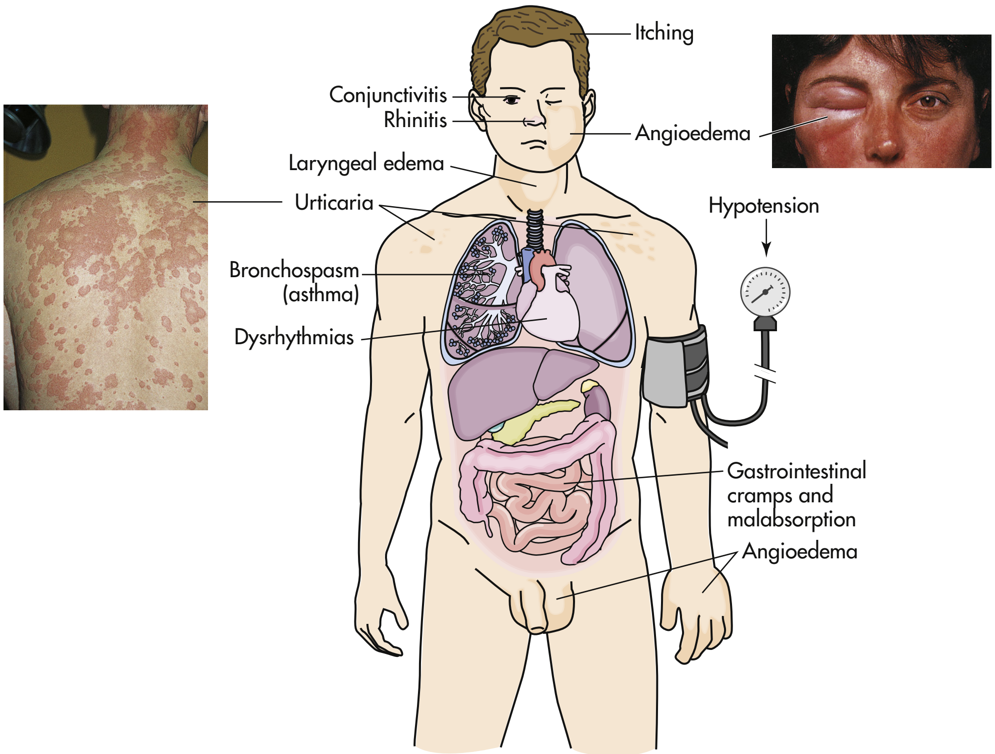

FIGURE 9-5 Type I Hypersensitivity Reactions. Manifestations of allergic reactions as a result of type I hypersensitivity include itching, angioedema (swelling caused by exudation), edema of the larynx, urticaria (hives), bronchospasm (constriction of airways in the lungs), hypotension (low blood pressure), and dysrhythmias (irregular heartbeat) because of anaphylactic shock, and gastrointestinal cramping caused by inflammation of the gastrointestinal mucosa. Photographic inserts show a diffuse allergic-like eye and skin reaction on an individual. The skin lesions have raised edges and develop within minutes or hours, with resolution occurring after about 12 hours. (Inserts from Male D et al: *Immunology,* ed 8, St Louis, 2013, Mosby.)

the mucous membranes lining the respiratory tract (accessory sinuses, nasopharynx, and upper and lower respiratory tracts) are continuous, they are all adversely affected. The degree to which each is affected determines the symptoms of the disease.

Gastrointestinal allergies are caused primarily by allergens that enter through the mouth—usually foods or medicines. Symptoms include vomiting, diarrhea, or abdominal pain and may be severe enough to result in malabsorption or protein-losing enteropathy, if the reactions are prolonged or recurrent. Foods most often implicated in gastrointestinal allergies are milk, chocolate, citrus fruits, eggs, wheat, nuts, peanut butter, and fish.[13] When food is the allergen, the active immunogen may be a product of food breakdown by digestive enzymes.

Urticaria, or **hives,** is a dermal (skin) manifestation of type I allergic reactions (see Figure 9-5). The underlying mechanism is the localized release of histamine and increased vascular permeability, resulting in limited areas of edema. Urticaria is characterized by white fluid-filled blisters (wheals) surrounded by areas of redness (flares). The **wheal and flare reaction** is usually accompanied by itching. Not all urticarial symptoms are caused by allergic (immunologic) reactions. Some, termed *nonimmunologic urticaria,* result from exposure to cold temperatures, emotional stress, medications, systemic diseases, hyperthyroidism, or malignancies (e.g., lymphomas).

If possible, avoidance of the allergen is the best method to limit allergic responses. Approximately 30% of laboratory animal handlers have allergies to animal dander and must use face masks or other devices to avoid contact.

Although some type I allergic responses can be controlled by blocking histamine receptors with antihistamines, the primary mechanism of control is the autonomic nervous system. The autonomic nervous system includes biochemical mediators (e.g., epinephrine, acetylcholine) that, like the mediators of the inflammatory response, have profound effects on cells. These mediators bind to appropriate receptors on mast cells and the target cells of inflammation (e.g., smooth muscle), thereby controlling (1) the release of inflammatory mediators from mast cells and (2) the degree to which target cells respond to inflammatory mediators (see Chapter 7).

TABLE 9-4 CAUSES OF CLINICAL MANIFESTATIONS OF ALLERGY

TYPICAL ALLERGEN	MECHANISM OF HYPERSENSITIVITY	CLINICAL MANIFESTATION
Ingestants		
Foods	Type I	Gastrointestinal allergy
Drugs	Types I, II, III	Urticaria, immediate drug reaction, hemolytic anemia, serum sickness
Inhalants		
Pollens, dust, molds	Type I	Allergic rhinitis, bronchial asthma
Aspergillus fumigatus	Types I, III	Allergic bronchopulmonary aspergillosis
Thermophilic actinomycetes*	Types III, IV	Extrinsic allergic alveolitis
Injectants		
Drugs	Types I, II, III	Immediate drug reaction, hemolytic anemia, serum sickness
Bee venom	Type I	Anaphylaxis
Vaccines	Type III	Localized Arthus reaction
Serum	Types I, III	Anaphylaxis, serum sickness
Contactants		
Poison ivy, metals	Type IV	Contact dermatitis

*An order of fungi that is stimulated by warmth to grow and proliferate.
Modified from Bellanti JA: *Immunology III,* Philadelphia, 1985, Saunders.

Allergic Disease: Bee Sting Allergy

An example of a life-threatening allergy is an anaphylactic reaction to a bee sting. Bee venoms contain a mixture of enzymes and other proteins that may serve as allergens. About 1% of children may have an anaphylactic reaction to bee venom. Within minutes they may develop excessive swelling (edema) at the bee sting site, followed by generalized hives, itching, and swelling in areas distal from the sting (e.g., eyes, lips), and other systemic symptoms including flushing, sweating, dizziness, and headache. The most severe symptoms may include gastrointestinal (e.g., stomach cramps, vomiting), respiratory (e.g., tightness in the throat, wheezing, difficulties breathing), and vascular (e.g., low blood pressure, shock) reactions. Severe respiratory and vascular reactions may lead to death.

If a child has had a previous anaphylactic reaction to bee stings, the chance of having another is about 60%. During the reaction the administration of antihistamines has little effect because histamine has already bound H1 receptors and initiated severe bronchial smooth muscle contraction. Most individuals carry self-injectable epinephrine. Autonomic nervous system mediators, such as epinephrine, bind to specific receptors on smooth muscle and reverse the effects of histamine and result in muscle relaxation. Similar anaphylactic reactions have been described against peanuts and other nuts, shellfish, fish, milk, eggs, and some medications.

Tests of IgE-Mediated Allergy

Allergic reactions can be life threatening; therefore, it is essential that severely allergic individuals be made aware of the specific allergen against which they are sensitized and instructed to avoid contact with that material.[14] Several tests are available, including food challenges, skin tests with allergens, and laboratory tests for measurements of total IgE and allergen-specific IgE in the blood.[15]

Reactivity to a particular food allergen may be tested by controlled administration of small doses of the suspected allergen in order to evoke a mild allergic response. This approach can be dangerous if the individual has a history of anaphylactic responses. A safer approach is injection of an allergen into (intradermal) or onto (epicutaneous or prick test) the skin. If the individual is allergic to a particular allergen, a local wheal and flare reaction may occur within a few minutes at the site of injection. The diameter of the flare reaction is usually indicative

of the individual's degree of sensitivity to that allergen. In the most severely allergic individuals, even the extremely small amounts of allergen used for the skin test may evoke a systemic anaphylaxis. Skin test is also contraindicated if the individual is using medications that may affect the test or has diffuse dermatitis, which would make the reaction difficult to interpret.

A variety of laboratory tests can detect IgE antibodies in serum. These assays have various commercial acronyms, depending on whether they are radioimmunoassays (RIAs; reactivity detected by measuring a radioactive reagent) or enzyme immunoassays (EIAs or ELISA [enzyme-linked immunosorbent assay]; reactivity detected by measuring a color change caused by an enzyme-labeled reagent). One set of assays measures circulating levels of total IgE, with atopic individuals usually having elevated levels. Other assays are capable of measuring circulating levels of specific IgE antibodies against selected allergens. The amount of IgE against a specific allergen correlates well with the degree of skin test reactivity and the severity of clinical symptoms related to the same allergen, although the laboratory text is less sensitive.

Desensitization. Clinical **desensitization** to allergens can be achieved in some individuals. Minute quantities of the allergen are injected in increasing doses over a prolonged period. The procedure may reduce the severity of the allergic reaction in the treated individual. However, this form of therapy is associated with a risk of systemic anaphylaxis, which can be severe and life threatening. This approach works best for routine respiratory allergens[16] and biting insect allergies (80% to 90% rate of desensitization over 5 years of treatment). Food allergies have been very difficult to suppress, but some promising trials are underway to evaluate desensitization by oral or sublingual administration of increasing amounts of allergen.[17]

The mechanisms by which desensitization occurs may be several, one of which is the production of large amounts of so-called blocking antibodies, usually circulating IgG. A **blocking antibody** presumably competes in the tissues or in the circulation for binding with antigenic determinants on the allergen so that the allergen is "neutralized" and is unable to bind with IgE on mast cells. Sublingual desensitization (another approach that works best with some food allergies) produces sIgA and circulating IgG that may prevent the allergen from accessing mast cells. Desensitization injections also may stimulate the generation of clones of T-regulatory lymphocytes, which inhibit hypersensitivity by suppressing the production of IgE or modifying the Th1/Th2 interactions in favor of production of anti-inflammatory cytokines.

Other approaches to suppressing type I allergic responses have been tested, with some preliminary success. An example is injection of anti-IgE antibody directed against the Fc portion of the IgE in order to decrease binding of IgE to mast cells.

Type IV Allergic Hypersensitivities. The allergens that induce a type IV allergic reaction are mostly haptens that react with normal self-proteins in the skin. When presented in this fashion, these antigens are recognized by pattern recognition receptors (PRRs) on antigen-presenting cells in the skin and induce a cell-mediated response.[18] (Pattern recognition receptors are discussed in Chapter 7.) The primary result is an allergic **contact dermatitis** that is confined to the area of contact with the allergen. The best-known example is poison ivy (Figure 9-6). The antigen in that instance is a plant catechol, *urushiol,* that reacts with normal skin proteins and evokes a cell-mediated immune response.

As noted, type I hypersensitivity reactions may result in a skin reaction (e.g., hives formed during an allergic reaction to a particular food). The distribution of the lesions may suggest whether the reaction is caused by immediate (type I) or delayed (type IV) hypersensitivity mechanisms.[19] Immediate hypersensitivity reactions, termed **atopic dermatitis,** are usually characterized by widely distributed lesions, whereas contact dermatitis (delayed hypersensitivity) consists of lesions only at the site of contact with the allergen, such as a metal allergy to jewelry (see Figure 9-6).

Types II and III Allergic Hypersensitivities. Type II allergic hypersensitivities are usually against allergic haptens that bind to the surface of cells and elicit an IgG or IgM response. For instance, allergic reactions against many drugs (e.g., penicillin, sulfonamides) occur after the drug binds to proteins on the plasma membranes of a person's cells and becomes immunogenic.[20] The immune system attacks the allergen on the cell membrane and destroys the cell as well. In allergic reactions to penicillin, the immunogenic antigen is a metabolite of penicillin catabolism that binds to the plasma membranes of erythrocytes or platelets and induces an antibody response that destroys the cells (type II hypersensitivity), causing anemia or thrombocytopenia. Type II allergic reactions also can occur against antigens of infectious diseases. For instance, encephalitis secondary to a rubella infection may result from damage to cells of the nervous system by an immune response against rubella virus antigen on the cell's plasma membrane.

Type III allergic reactions occur after the formation of immune complexes containing soluble allergens. For instance, Arthus reactions may be observed after injection, ingestion, or inhalation of allergens. Skin reactions can follow subcutaneous or intradermal inoculation with drugs, fungal extracts, or antigens used in skin tests. Gastrointestinal reactions, such as gluten-sensitive enteropathy (celiac disease), follow ingestion of antigen, usually gluten from wheat products (see Chapter 41). Allergic alveolitis is a type III acute hemorrhagic inflammation of the air sacs (alveoli) of the lungs resulting from inhalation of fungal antigens, usually particles from moldy hay (farmer's lung) or pigeon feces (pigeon breeder's disease)[21] (see Chapter 35). Circulating drugs (e.g., penicillin) or antigens produced from infectious diseases (e.g., hepatitis B, streptococcal infection) may form circulating immune complexes that are deposited in the circulation (vasculitis) or the kidneys (glomerulonephritis).

Autoimmunity

Breakdown of Tolerance. Self-antigens are usually in a state of tolerance, or immunologic homeostasis, with the host's own immune system. *Central tolerance* develops in humans during the embryonic period as autoreactive lymphocytes are either eliminated or suppressed in the primary lymphoid organs during differentiation and proliferation of immature T or B lymphocytes (see Figures 8-10 and 8-12). Clones of cells with antigen receptors

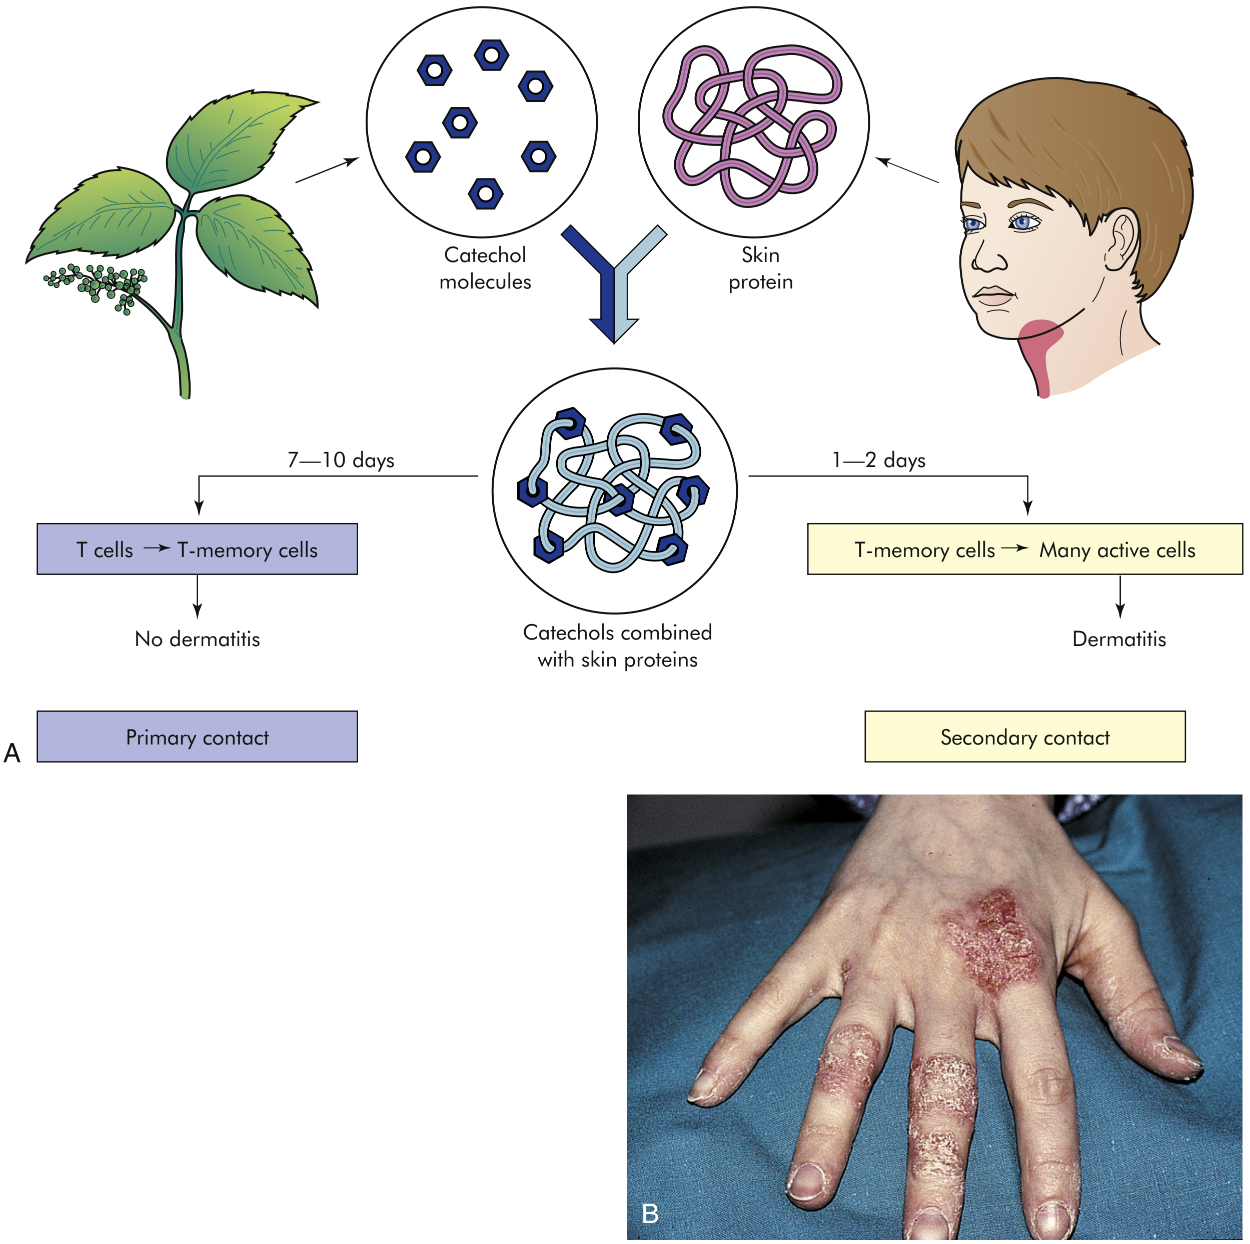

FIGURE 9-6 Development of Allergic Contact Dermatitis, a Delayed Hypersensitivity Reaction. A, Shown here is the development of allergy to catechols from poison ivy. No dermatitis results from the primary contact because the antigens (catechols) are sensitizing the immune response and producing memory T cells. Secondary contact, however, quickly activates a type IV, cell-mediated reaction that causes dermatitis. **B,** This contact dermatitis was caused by a delayed hypersensitivity reaction that led to vesicles and scaling at the sites of contact. (From Damjanov I, Linder J: *Anderson's pathology,* ed 10, St Louis, 1996, Mosby.)

for self-antigens are deleted. *Peripheral tolerance* is maintained in the secondary lymphoid organs through the action of T-regulatory lymphocytes or antigen-presenting dendritic cells. **Autoimmunity** is a breakdown of tolerance in which the body's immune system begins to recognize self-antigens as foreign. In most autoimmune conditions the mechanism of tolerance breakdown is unknown, although several potential mechanisms have been suggested.

Sequestered Antigen. The induction of central tolerance requires that the self-antigen be present in the fetus and exposed to the developing fetal immune system. Some self-antigens may not normally encounter the immune system in either fetal or adult life, but are sequestered or hidden from the immune system in **immunologically privileged sites,** so named because foreign tissues can be transplanted into these sites with less chance of immunologic rejection. For example, several sites (e.g., anterior chamber of the eye, the brain) are separated from the circulation by barriers (blood-ocular and blood-brain barriers) that offer protection against many immune cells and lead to relatively poor lymphatic drainage. Lymphocytes that enter these sites encounter tissue that expresses Fas ligand (FasL) and tumor necrosis factor (TNF)–related apoptosis-inducing ligand (TRAIL).

These molecules induce the lymphocytes to undergo apoptosis, thus protecting the tissue. Self-antigens in these sites are not normally seen by the immune system and are therefore not immunogenic. However, if the barriers are damaged, antigenic sensitization can occur, and the resultant antibodies and lymphocytes can enter the site and cause additional damage to the tissue. For instance, physical trauma to one eye may result in release of sequestered antigen into the blood or lymphatics, resulting in immunologic injury to the other eye (sympathetic uveitis).

Infectious Disease. A long-standing hypothesis is that foreign antigens from infectious microorganisms can initiate autoimmune disease through a process of **molecular mimicry.** Some antigens of infectious agents so closely resemble (mimic) a particular self-antigen that antibodies or T cells produced to protect against the infection also recognize the self-antigen as foreign **(cross-reactive antibody** or **T cell).** The relationship between many autoimmune diseases and predisposing infections, such as enterovirus infection and type 1 diabetes, is being investigated.[22] However, the only clearly defined example so far is acute rheumatic fever that may occur after a group A streptococcal sore throat (see following).

Neoantigen. In certain situations a neoantigen that induces an allergic reaction may also lead to autoimmunity. Many **neoantigens** (new antigens) are haptens that become immunogenic after binding to self-proteins. The immune reaction against the neoantigen may lead to an immunologic reaction against normal antigenic determinants on the protein. Other new antigenic determinants may result from posttranslational modifications of a normal protein so that one or more amino acids are chemically altered (e.g., addition or removal of amino acid side groups, phosphorylation) without affecting the protein's function.[23] Many experimental autoimmune diseases (e.g., experimental autoimmune thyroiditis) can be initiated by immunization with molecules containing neoantigenic determinants.

Forbidden Clone. During differentiation and proliferation of lymphoid stem cells into immature T and B lymphocytes (see Figures 8-10 and 8-12), some lymphocytes produce receptors that react with self-antigens. Many autoreactive lymphocytes interact with self-antigens and other co-stimulatory molecules on the surface of thymic epithelial cells and are induced to undergo clonal deletion by a process of apoptosis. Thus lymphocytes reactive against self-antigen are prevented, or "forbidden," from maturing. Autoimmunity may result from the survival of a forbidden clone and its proliferation later in life.

Defective Peripheral Tolerance. Tolerance to some self-antigens is controlled in the secondary lymphoid organs. This process is controlled by a variety of cells, including antigen-presenting dendritic cells and members of a family of T-regulatory lymphocytes (Treg cells) that normally suppress immune responses against self. Defects in particular regulatory cells may result in expansion of clones of autoreactive cells and the development of autoimmune disease. Systemic lupus erythematosus, which is characterized by the production of a large array of autoantibodies, may be caused by a general breakdown in the regulatory network.

Original Insult. Although many theories exist, the initial cause of most autoimmune diseases is unknown (see What's New? Maternal Microchimerism and Autoimmune Disease).

WHAT'S NEW?

Maternal/Fetal Microchimerism and Autoimmune Disease

A rapidly growing body of evidence suggests that we are in a state of **microchimerism (Mc);** possessing a small number of cells originating from another individual.[1] The placenta, which was once considered a cellular "barrier," is more porous than suspected and routinely allows bidirectional passage of both maternal and fetal cells. Passage results during normal pregnancy, as well as spontaneous miscarriages and elective terminations,[2] and includes a broad spectrum of cells, ranging from erythrocytes and mature white blood cells, to stem cells at various stages of differentiation. Most gravid women (having been pregnant) have detectable fetal cells (fetal Mc) in their blood and many organs (e.g., white blood cells, hepatocytes, kidney tubular epithelium, neurons and glia, cardiomyocytes, endothelial cells, thyrocytes, intestinal epithelium, and islet β cells), which apparently originated as fetal stem cells that differentiated in the maternal tissues. As early as 6 weeks gestation, maternal Mc is apparent in fetal blood and tissues (e.g., thymus, lung, heart, pancreas, liver, spleen, kidney, adrenal gland, ovary, testis, and brain).[3] Maternal Mc originates predominately from maternal cells, but may also include cells from one's grandmother, a nonidentical twin, or older siblings, all of which were harbored in the mother's blood and tissues. Both maternal and fetal Mc persists for decades after pregnancy.

The long-term implications of Mc may include both detrimental and beneficial effects. Fetal cells express both maternal and paternal **HLA** antigens and are recognized as partially foreign by maternal immune cells. Most studies of maternal Mc use assays for the presence of the Y chromosome in maternal blood or organs. Many autoimmune diseases are associated with increased numbers of male cells in the diseased organs (e.g., scleroderma, dermatomyositis, Sjögren syndrome, thyroiditis, primary biliary cirrhosis, hyper- and hypothyroidism, and systemic lupus erythematosus) suggesting that Mc may contribute to the etiology of these diseases.[1] Maternal Mc in the offspring also may affect their risk for autoimmune disease. Increased levels of maternal cells in the child's blood have been reported in cases of juvenile inflammatory myopathy, neonatal lupus syndrome, type 1 diabetes, and biliary atresia. Maternal cells were found as myocytes in the myocardium of infants with fatal neonatal lupus-associated heart block and as insulin-producing cells in the pancreas of diabetics.[1] It cannot yet be determined whether the foreign cells are initiators of autoimmune damage or whether injury to the tissue results in increased proliferation. Thus these observations remain intriguing but of unknown significance.

Beneficial effects of Mc are also observed. Treg cells may control immunologic tolerance to maternal cells. A significantly greater success rate of liver transplantation was observed with maternal or sibling donors than paternal donors.[4] Thus Mc may modulate the immune response and minimize rejection of organs from selected donors. Fetal Mc occurs in several regions of the brain, but at a significantly lower incidence and concentration in women with Alzheimer's disease than those without neurologic disease.[5] Whether Mc is protective or not remains unknown.

It is suspected that some autoimmune diseases are initiated by infections that have resolved without leaving evidence that would lead to identification of the particular infectious agent. The evidence for an infectious causation is clear for only one autoimmune disease: acute rheumatic fever. In a small number of individuals with group A streptococcal sore throats, the M proteins in the bacterial capsule induce antibodies that also react with proteins in the heart valve, damaging the valve.

Additionally, some streptococcal skin or throat infections result in the release of bacterial antigens into the blood and the formation of circulating immune complexes. The complexes may deposit in the kidneys and initiate an immune complex glomerulonephritis (inflammation of the kidney). Thus capsular antigens of the group A *Streptococcus* may mimic *(antigenic mimicry)* normal heart antigens resulting in a type II autoimmune hypersensitivity (rheumatic fever), whereas in another person this infection may release bacterial antigen (an environmental antigen) into the blood, resulting in a type III allergic hypersensitivity (poststreptococcal glomerulonephritis).

Genetic Factors. Genetic factors that contribute to autoimmunity are easier to identify than the original insult that initiates the disease. It is fairly well established that autoimmune diseases can be familial. Affected family members may not all develop the same disease, but several members may have different disorders characterized by a variety of hypersensitivity reactions, including autoimmune and allergic.

Associations with particular autoimmune diseases have been identified for a variety of major histocompatibility complex (MHC) alleles (see Chapter 8) or non-MHC genes. The specific HLA alleles of susceptible and resistant individuals have been analyzed for almost every known disease, and almost universally individuals with certain diseases are more likely than the general population to have a specific HLA allele or set of alleles. Some associations are strong; others are more tenuous (Table 9-5). The reason some HLA alleles are associated with inappropriate immune function is unclear, but it may directly involve the ability of particular HLA molecules to present antigen or the use of particular HLAs as receptors for disease-causing microorganisms. These genes may determine an individual's susceptibility to specific infectious agents or the capacity of that individual to mount an immune response against specific antigens. Therefore, an individual of a specific HLA type may have inappropriate or exaggerated immune responses against a microorganism, resulting in a hypersensitivity reaction.

A large variety of non-MHC genes also have been identified as risk factors for the development of specific autoimmune diseases. Most of these genes encode for inflammatory cytokines or co-stimulatory molecules found on the cell surface.

Alloimmunity

Alloimmunity occurs when an individual's immune system reacts against antigens on the tissues of other members of the same species. The two clinically relevant examples of this reactivity are (1) several transient neonatal diseases (in which the maternal immune system becomes sensitized against antigens expressed by the fetus) and (2) transplant rejection and transfusion reactions (in which the immune system of a recipient of an organ transplant or blood transfusion reacts against antigens on the donor cells).

Transient Neonatal Alloimmunity. Because the fetus is a hybrid between the mother and father, it expresses paternal antigens that are not found in the mother. Occasionally these fetal antigens cross the placenta and elicit an immune response in the mother (e.g., production of alloantibodies against the fetal antigens). The maternal alloantibody may be transported across the placenta into the fetal circulation, bind to the fetal cells, and produce alloimmune disease in the fetus and neonate. The mother's immune system produces the antibody, but because her cells do not express the target antigen, she has no symptoms of the disease.

Neonatal alloimmune disease may be secondary to maternal autoimmune diseases in which the mother produces an IgG autoantibody specific for maternal self-antigens that are found on fetal cells as well. Therefore, symptoms of the same autoimmune disease may affect mother and child, even though the autoantibody is being produced only by the mother's immune system. This form of disease usually occurs only in association with type II (tissue-specific) hypersensitivity reactions. It does not occur in association with IgE-mediated (type I) reactions, immune complex–mediated (type III) reactions, or cell-mediated (type IV) reactions because the immunologic factors (IgE, immune complexes, T cells) that cause these reactions do not readily cross the placenta and enter the fetal circulation in sufficient quantity.

TABLE 9-5 EXAMPLES OF ASSOCIATIONS BETWEEN SPECIFIC HLA ALLELES AND DISEASE

DISEASE	HLA ALLELE	RR
Acute anterior uveitis	B27	14
Addison disease	DR3	6
Ankylosing spondylitis	B27	90

Myasthenia gravis	DR3	3
Pemphigus vulgaris	DR4	13
Postgonococcal arthritis	B27	14
Reiter syndrome	B27	37
Rheumatoid arthritis	DR4	4
Sjögren syndrome	DR3	9
Systemic lupus erythematosus	DR3	6

HLA, Human leukocyte antigen; *RR,* the approximate relative risk, which is the frequency of a disease in individuals with the particular HLA allele compared with individuals without that allele.

Symptoms of the alloimmune disease may be present in utero or immediately after birth and may be fatal to the fetus or neonate. At birth, maternal circulating antibody can no longer enter the child, and if symptoms are successfully treated, the disease will disappear as the maternal antibody is catabolized. Examples of maternal immunologic hypersensitivity diseases in which the child can be affected include the following antibody-mediated diseases:

1. Graves disease—an autoimmune disease in which maternal antibody against the receptor for TSH causes neonatal hyperthyroidism
2. Myasthenia gravis—an autoimmune disease in which maternal antibody binds with receptors for neural transmitters on muscle cells (acetylcholine receptors), causing neonatal muscular weakness (see Chapter 18)
3. Immune thrombocytopenic purpura—both autoimmune and alloimmune variants in which maternal antiplatelet antibody destroys platelets in the fetus and neonate (see Chapter 29)
4. Alloimmune neutropenia—in which maternal antibody against neutrophils destroys neutrophils in the neonate
5. Systemic lupus erythematosus—autoimmune disease in which diverse maternal autoantibodies induce anomalies (e.g., congenital heart defects) in the fetus or cause pregnancy loss
6. Rh and ABO alloimmunization (e.g., erythroblastosis fetalis)—in which maternal antibody against erythrocyte antigens induces anemia in the child (see Chapter 30)

Autoimmune and Alloimmune Diseases

Many examples of autoimmune or **alloimmune diseases** have been described. Several basic principles are exemplified by two examples: systemic lupus erythematosus (an autoimmune disease) and tissue rejection (i.e., transplant rejection or transfusion reaction) (an alloimmune phenomenon). Most of the classic autoimmune diseases, including disorders of the endocrine system (autoimmune thyroiditis and Graves disease), hematologic system (the hemolytic and pernicious anemias), nervous system (myasthenia gravis), and connective tissue in joints (rheumatoid arthritis), are discussed in Unit II of this book.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, multisystem, inflammatory disease and is one of the most common, complex, and serious of the autoimmune disorders.[24] SLE is characterized by the production of a large variety of autoantibodies against nucleic acids, erythrocytes, coagulation proteins, phospholipids, lymphocytes, platelets, and many other self-components. The most characteristic autoantibodies produced in SLE are against nucleic acids (e.g., single-stranded deoxyribonucleic acid [DNA], double-stranded DNA), histones, ribonucleoproteins, and other nuclear materials.

Deposition of circulating immune complexes containing antibody against DNA produces tissue damage in individuals with SLE. DNA and DNA-containing immune complexes have a high affinity for glomerular basement membranes and therefore may be selectively deposited in the glomerulus (Figure 9-7). (Kidney structures are described in Chapter 37.) The presence of DNA in the circulation increases from cellular damage in response to trauma, drugs, or infections and is usually removed in the liver. Removal of circulating DNA is slowed in the presence of immune complexes, thereby increasing the potential for deposition in the kidney. (The liver's role in removing waste products from the blood is discussed in Chapter 40.) Deposition of immune complexes composed of DNA and antibody also causes inflammatory lesions in the renal tubular basement membranes, brain (choroid plexus), heart, spleen, lung, gastrointestinal tract, skin (see Figure 9-7), and peritoneum.

SLE, as with most autoimmune diseases, occurs more often in women (approximately a 10:1 predominance of females), especially in the 20- to 40-year-old age group. Blacks are affected more often than whites (about an eightfold increased risk). A genetic predisposition for the disease has been implicated on the basis of increased incidence in twins and the existence of autoimmune disease in the families of individuals with SLE.

A transient lupus-like syndrome that is indistinguishable both clinically and in the laboratory from spontaneously occurring SLE can develop from the prolonged use of medications, particularly hydralazine (an antihypertensive agent) and

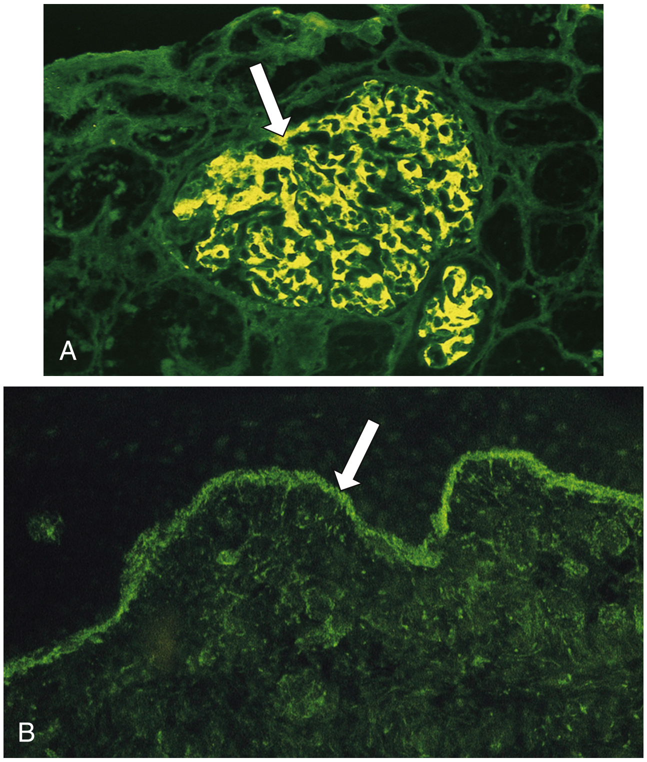

FIGURE 9-7 **Deposition of IgG in the Kidney and Skin of Individuals with Lupus.** These photographs of tissue were obtained from individuals with lupus and stained with fluorescent anti-IgG. **A,** Section from a kidney showing a glomerulus with deposits of IgG (*arrow,* indicating bright areas of staining). **B,** Section of the skin showing deposition of IgG along the dermal-epidermal junction (*arrow,* indicating bright green staining). procainamide (an antidysrhythmic drug). In genetically susceptible individuals, certain environmental agents, such as ultraviolet light, and several infectious agents may trigger lupus-like immune reactions.

Clinical manifestations of SLE include arthralgias or arthritis (90% of individuals), vasculitis and rash (70% to 80% of individuals), renal disease (40% to 50% of individuals), hematologic abnormalities (50% of individuals, with anemia being the most common complication), and cardiovascular diseases (30% to 50% of individuals). As with most autoimmune diseases, the disease process develops slowly (up to 10 years from occurrence of the first autoantibody until diagnosis)[25] and is characterized by frequent remissions and exacerbations. Because the signs and symptoms affect almost every body system and tend to be intermittent, SLE is extremely difficult to diagnose. This has led to the development of a list of 11 common clinical findings. The serial or simultaneous presence of at least four of them indicates that the individual has SLE[26]:

1. Facial rash confined to the cheeks (malar rash)
2. Discoid rash (raised patches, scaling)
3. Photosensitivity (skin rash developed as a result of exposure to sunlight)
4. Oral or nasopharyngeal ulcers
5. Nonerosive arthritis of at least two peripheral joints
6. Serositis (pleurisy, pericarditis)
7. Renal disorder (proteinuria of 0.5 g/day or cellular casts)
8. Neurologic disorders (seizures or psychosis)
9. Hematologic disorders (hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia)
10. Immunologic disorders (positive lupus erythematosus [LE] cell preparation, anti–double-stranded DNA, anti-Smith [Sm] antigen, false-positive serologic test for syphilis, or antiphospholipid antibodies [anticardiolipin antibody or lupus anticoagulant])
11. Presence of antinuclear antibody (ANA)

There is no cure for SLE or most other autoimmune diseases. The goals of treatment are to control symptoms and prevent further damage by suppressing the autoimmune response. Nonsteroidal anti-inflammatory drugs, such as aspirin, ibuprofen, or naproxen, reduce inflammation and relieve pain. Corticosteroids are often prescribed for more serious active disease. Immunosuppressive drugs (e.g., methotrexate, azathioprine, or cyclophosphamide) are used to treat severe symptoms involving internal organs. Ultraviolet light can worsen symptoms (known as flares), and protection from sun exposure is helpful. Prolonged use of certain drugs can cause transient SLE-like symptoms, and the medication history is important for diagnostic evaluation.

Other therapeutic approaches have been attempted for SLE and other autoimmune diseases. Several decades ago preparations of intravenous immune globulin (IVIg), which was routinely used to replenish antibodies in persons with antibody deficiencies, were administered to children with autoimmune thrombocytopenia (an autoimmune disease in which platelets were destroyed by an autoantibody).[27] IVIg therapy resulted in a rebound of platelet levels and temporary resolution of the thrombocytopenia. IVIg is currently being used for a variety of autoimmune diseases, including SLE. More recently, monoclonal antibodies and other reagents have specifically targeted and suppressed B and T cells that are participating in autoimmune responses.[28] This approach has been somewhat successful in SLE, rheumatoid arthritis, and other autoimmune diseases. Improved outcomes may be available in the future with the continued advances in medical research and the use of stem cell treatments.

Transfusion Reactions

Red blood cells (erythrocytes) express several important surface antigens, known collectively as the **blood group antigens,** which can be targets of alloimmune reactions. More than 80 different red cell antigens are grouped into several dozen blood group systems, each determined by a different locus or set of loci. The most important of these, because they provoke the strongest humoral alloimmune response, are the ABO and Rh systems.

ABO System. Human blood transfusions were carried out as early as 1818, but they were often unsuccessful. Sometimes after a transfusion, the recipient's red blood cells would clump together, thereby blocking the capillaries and causing death in some instances. In 1901, Karl Landsteiner reported that this reaction was related to the ABO antigens located on the surface of erythrocytes.

The **ABO blood group** consists of two major carbohydrate antigens, labeled A and B (Figure 9-8). These two carbohydrate antigens are codominant, which means that both A and B can be simultaneously expressed, resulting in an individual having any one of four different blood types. The erythrocytes of persons with blood type A have the type A carbohydrate antigen (i.e., carry the A antigen), those with blood type B carry the B antigen, those with blood type AB carry both A and B antigens, and those of blood type O carry neither the A nor the B antigen. A person with type A blood also has circulating antibodies to the B carbohydrate antigen. If this person receives blood containing B antigens (i.e., blood from a type AB or B individual), a severe transfusion reaction occurs and the transfused erythrocytes are destroyed by agglutination (Figure 9-9) or complement-mediated lysis. Similarly, a type B individual (whose blood contains anti-A antibodies) cannot receive blood from a type A or AB donor. Type O individuals, who have neither A nor B antigen but have both anti-A and anti-B antibodies, cannot accept blood from any of the other three types. These naturally occurring antibodies, called **isohemagglutinins,** are immunoglobulins of the IgM class and are induced by similar antigens expressed on naturally occurring bacteria in the intestinal tract.

Because individuals with type O blood lack both types of antigens, they are considered **universal donors,** meaning that anyone can accept their red blood cells. Similarly, type AB individuals are considered **universal recipients** because they lack both anti-A and anti-B antibodies and can be transfused with any ABO blood type. When large volumes of *whole blood* (i.e., cells plus plasma) are transfused, however, antibodies in the *donor's* blood can bind to antigenic determinants on the *recipient's* erythrocytes, causing agglutination of the recipient's own cells. Agglutination and lysis cause harmful transfusion

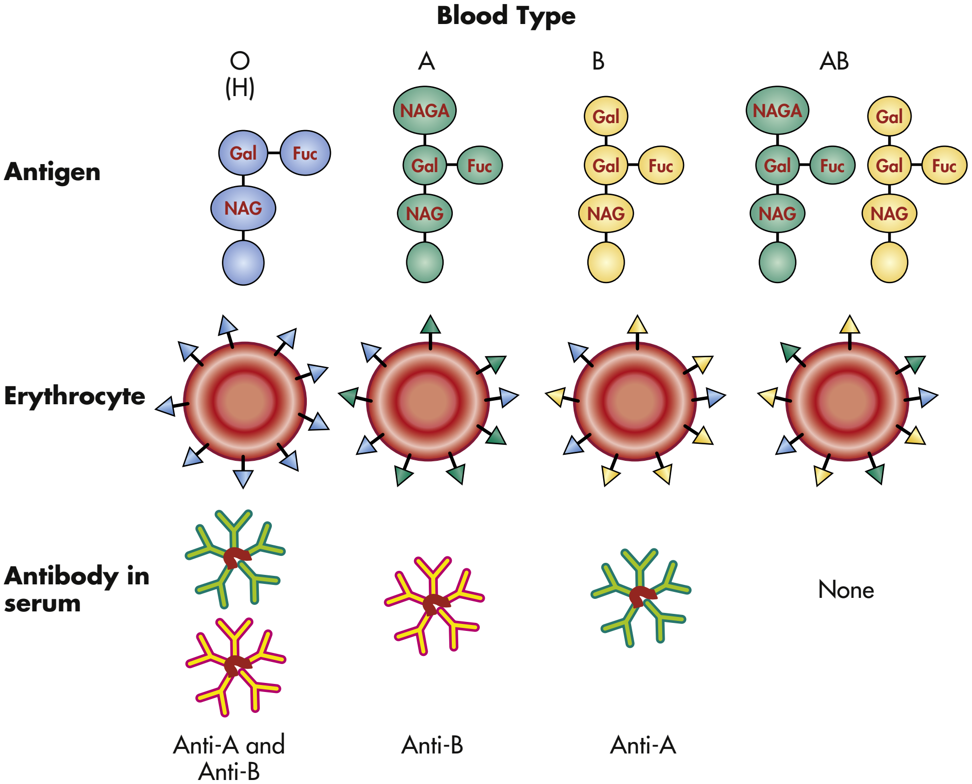

FIGURE 9-8 ABO Blood Types. This figure shows the antigens and antibodies associated with the ABO blood groups. The surfaces of erythrocytes of individuals with blood group O have the core H antigenic carbohydrate. Their sera contain IgM antibodies against both A and B carbohydrates. In individuals of the blood group A, some of the H antigens have been modified into A antigens by the addition of *N*-acetylgalactosamine (NAGA). The sera of these individuals have IgM antibodies against the B antigen. In individuals with blood group B, some of the H antigens have been modified into B antigens by the addition of galactose (Gal). These individuals have IgM antibodies against the A antigen in their sera. In individuals of the blood group AB, some of the H antigens have been modified into both the A and B antigens. These individuals do not have antibody to either A or B antigens. *Fuc,* Fucose; *NAGA, N*-acetylgalactosamine.

reactions that can be prevented only by complete and careful ABO matching between donor and recipient.

Rh System. The **Rh blood group** is the most polymorphic system of red cell antigens, consisting of at least 50 separate antigens. At least five major antigens and a large number of rare variants have been identified and are expressed primarily on erythrocytes. The major antigens are contained on two proteins encoded from two closely linked genes, *RHD* and *RHCE*. The RhD protein expresses the dominant antigen, which determines whether an individual is Rh-positive or Rh-negative. Individuals who express the D antigen on the RhD protein are Rh-positive, whereas individuals who do not express the D antigen are Rh-negative. The letter *d* is used to indicate lack of D. Rh-positive individuals can have either a *DD* or a *Dd* genotype, whereas Rh-negative individuals have the *dd* genotype. About 15% of North American whites are Rh-negative, whereas the Rh-negative genotype is much less common among members of other ethnic groups. Rh-negative individuals can make anti-D if exposed to Rh-positive erythrocytes, but because the letter *d* is used to indicate the lack of the D antigen and does not represent a different antigen, Rh-positive individuals do not produce an antibody against *d*. The second protein, RhCE, expresses two different antigens, C and E, each of which has two different alleles (*C* or *c, E* or *e*). Therefore, four potential haplotypes of C and E antigens are commonly observed: *CE, Ce, cE,* and *ce*.

IgG anti-D alloantibody produced by Rh-negative mothers against erythrocytes of their Rh-positive fetuses was the primary cause of Rh maternal-fetal incompatibility and the resulting hemolytic disease of the newborn (see Chapter 30). However,

over the past several decades, the incidence of mothers with high titers of anti-D antibody has decreased dramatically because of the use of prophylactic anti-D immunoglobulin. By mechanisms that are still not completely understood, administration of anti-D antibody within a few days of exposure to RhD-positive erythrocytes completely prevents sensitization against the D antigen. Because hemolytic disease of the newborn related to the D antigen has been controlled, alloantibodies against the other Rh antigens (usually C, c, or E) have become more important. In general, these alloantibodies are associated with a less severe hemolytic disease.

A form of autoimmune hemolytic anemia is often caused by autoantibodies against Rh antigens, especially e. This variant is caused by IgG antibodies that react with erythrocytes at normal body temperature (thus called *warm autoimmune hemolytic anemia*) and increase phagocytic destruction of the red blood cell. This characteristic differentiates the warm variant from another form of autoimmune hemolytic anemia, which is caused by IgM autoantibodies that react optimally with erythrocytes in the cooler portions of the body (e.g., fingers, toes) and is referred to as *cold autoimmune hemolytic anemia*.

Graft Rejection

Transplantation of organs commonly is complicated by an immune response against antigens—primarily HLA—on the donated tissue. Most of our knowledge on the transplantation of organs is based on renal transplant studies. The primary mechanism of the rejection of transplanted organs is a type IV cell-mediated reaction. Two randomly chosen individuals are almost certainly antigenically different to some degree. Organ transplants between them could be rejected in approximately 2 weeks without the extensive use of immunosuppressive drugs.

After the donor and recipient are matched for ABO antigens, antigens of the HLA system are the principal targets of the rejection reaction; HLA matching of donor and recipient enhances the probability of acceptance of the graft. Not all HLA loci are equally important; matching at the HLA-DR locus appears to be the most critical for graft acceptance, and matching at HLA-A and HLA-B of slightly lesser importance. (These loci are discussed in Chapter 8.)

Transplant rejection may be classified as hyperacute, acute, or chronic, depending on the amount of time that elapses between transplantation and rejection. **Hyperacute rejection** is immediate and rare. When the circulation is reestablished to the grafted area, the graft may immediately turn white (the so-called *white graft*) instead of a normal pink. Hyperacute rejection usually occurs in recipients with preexisting antibody to antigens in the graft. The antibodies may have resulted from rejection of a previous graft or from prior blood transfusions that contained platelets and white blood cells with foreign HLA. Additionally, about half of women who have had multiple pregnancies have circulating antibodies against their husband's HLA antigens. As the circulation to the graft is established, antibodies bind to the vascular endothelial cells in the grafted tissue and activate the inflammatory response, including the coagulation cascade, which results in stasis of blood flow into the tissue (Figure 9-10). (Coagulation is described in Chapters 7 and 27.)

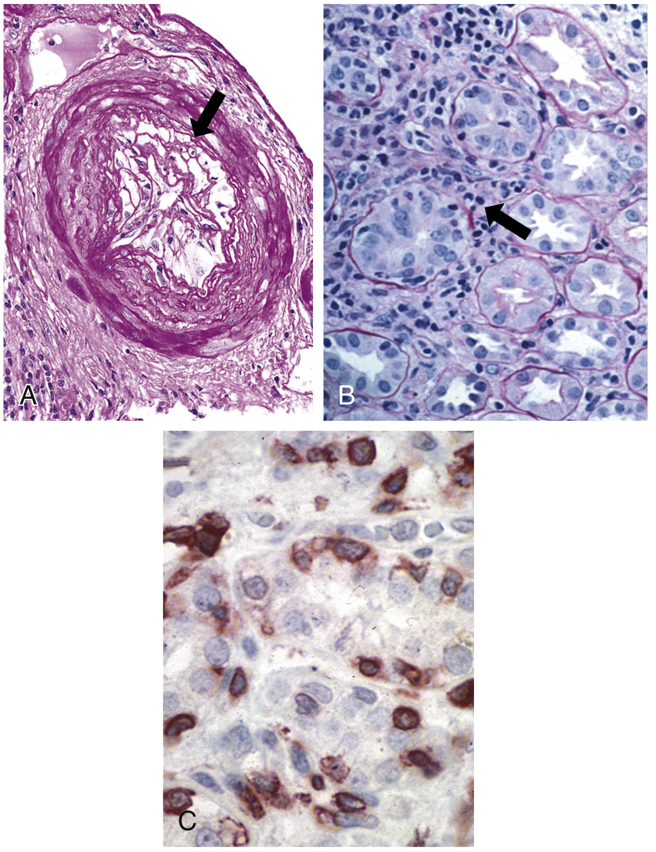

FIGURE 9-10 Examples of Hyperacute and Acute Rejection of Renal Allografts. **A,** Hyperacute antibody-mediated damage to the blood vessel of a renal allograft. The blood vessel is thickened, and the lumen *(arrow)* is obstructed by proliferating fibroblasts and macrophages. **B,** Acute cellular rejection of a renal allograft with intense mononuclear cell infiltrate *(arrow)*. **C,** Acute cellular rejection stained with immunoperoxidase reagent *(brown)* against T cells, which are infiltrating the tissue. (**A** courtesy Dr. Ihsan Housini, Department of Pathology, University of Texas Southwestern Medical School, Dallas; **B** and **C** courtesy Dr. Robert Colvin, Department of Pathology, Massachusetts General Hospital, Boston.)

Biopsies of the graft often show deposits of antibody (IgG and IgM), complement, and neutrophils. This condition is rare because of effective pretransplantation cross-matching during which a recipient is tested for antibodies against the HLA antigens of the potential donor.

Acute rejection is primarily a cell-mediated immune response that occurs within days to months after transplantation. This type of rejection occurs when the recipient develops an immune response against unmatched HLAs after transplantation. Sensitization is usually initiated by the recipient's lymphocytes interacting with the donor's dendritic cells within the transplanted tissue, resulting in induction of recipient Th1 and Tc cells against the donor's antigens. The Th1 cells release cytokines that activate infiltrating macrophages, and the Tc cells directly attack the endothelial cells in the transplanted tissue. A biopsy of the rejected organ usually shows an infiltration of lymphocytes and macrophages characteristic of a type IV reaction. Immunosuppressive drugs may delay or lessen the intensity of acute rejection.

Another form of acute rejection, *acute antibody-mediated rejection,* has recently been recognized and accounts for about

10% of acute rejections. This form of rejection is mediated by antibody and complement.[29] The predominant antibodies are against HLA antigens or, on occasion, autoantigens in the graft (e.g., vimentin, angiotensin receptor), but, unlike those antibodies that cause hyperacute rejection, are not present at the time of transplantation. Sensitization takes 2 weeks or longer and results in the accumulation of antibody, complement, neutrophils, and thrombi in the vasculature of the graft (a type II hypersensitivity reaction).

Chronic rejection may occur after a period of months or years of normal function. It is characterized by slow, progressive organ failure. Chronic rejection may be caused by inflammatory damage to endothelial cells lining blood vessels as a result of a weak cell-mediated immunologic reaction against minor histocompatibility antigens on the grafted tissue.[30] Antibodies against HLA and other antigens also may cause chronic rejection through activation of complement or antibody-dependent cellular cytotoxicity (ADCC) with NK cells.[31]

DEFICIENCIES IN IMMUNITY

Disorders resulting from immune deficiency are the clinical sequelae (results) of impaired function of one or more components of the immune or inflammatory response, including B cells, T cells, phagocytes, and complement (Table 9-6). An **immune deficiency** is the failure of these mechanisms of self-defense to function at their normal capacity, resulting in increased susceptibility to infections. **Primary (congenital) immune deficiency** is caused by a genetic anomaly, whereas **secondary (acquired) immune deficiency** is caused by another illness, such as cancer or viral infection, or by normal physiologic changes, such as aging. Acquired forms of immune deficiency are far more common than the congenital forms.

Initial Clinical Presentation

The clinical hallmark of immune deficiency is a tendency to develop unusual or recurrent, severe infections. Preschool and school-age children normally may have 6 to 12 infections per year, of which 3 or 4 are ear infections, and adults may have 2 to 4 infections per year. Most of these are not severe and are limited to viral infections of the upper respiratory tract, recurrent streptococcal pharyngitis, or mild otitis media.

Potential immune deficiencies are considered if the individual has had severe, documented bouts of pneumonia, otitis media, sinusitis, bronchitis, septicemia, or meningitis or infections with opportunistic microorganisms that normally are not pathogenic or usually confined to one site (e.g., *Pneumocystis jirovecii,* disseminated *Candida* infection, cytomegalovirus [CMV]).[32] Infections are generally recurrent with only short intervals of relative health, and multiple simultaneous infections are common. Individuals with primary immune deficiencies often have eight or more ear infections, two or more serious sinus infections, and two or more pneumonias, recurrent abscesses or infections in unusual sites, or persistent fungal infections (particularly thrush in an individual at least 1 year old) within a year. Recurrent internal infections, such as meningitis, osteomyelitis, or sepsis, are common. Prolonged antibiotic use is commonly ineffective by oral or injected routes and may necessitate intravenous administration. Additional symptoms may include failure to thrive and chronic diarrhea. A familial history of immune deficiency may be found in some types of primary deficiency.

The type of recurrent infections that manifest may indicate the type of immune defect. Deficiencies in T-cell immune responses are suggested when recurrent infections are caused by certain viruses (e.g., varicella, vaccinia, herpes, cytomegalovirus), fungi and yeasts (e.g., *Candida, Histoplasma*), or certain atypical microorganisms (e.g., *P. jirovecii*). B-cell deficiencies and phagocyte deficiencies, however, are suggested if the individual has documented, recurrent infections with microorganisms that require opsonization (e.g., encapsulated bacteria) or viruses against which humoral immunity is normally effective (e.g., rubella). Some complement deficiencies resemble defects in antibody or phagocyte function, but others are commonly associated with disseminated infections with bacteria of the genus *Neisseria (Neisseria meningitidis* and *Neisseria gonorrhoeae)*.

Much of our current understanding of the development of the immune system and the interactions of the cells in the immune response was developed by studying congenital and acquired immune deficiencies or, as they have been called, "experiments of nature." Many immune deficiencies result from selective alteration or removal of one component of the immune system. We can understand the importance of that component by observing the effect of its removal on the remainder of the immune response.

Primary Immune Deficiencies

Most primary immune deficiencies are the result of a single gene defect[33] (Figure 9-11). Generally, the mutations are sporadic and not inherited: a family history exists in only about 25% of individuals. The sporadic mutations occur before birth, but the onset of symptoms may be early or later, depending on the particular syndrome. In approximately 60% of the cases symptoms of immune deficiency appear within the first 2 years of life, whereas other immune deficiencies are progressive, with the onset of symptoms appearing in the second or third decade of life. The most common symptoms include sinusitis (68% of individuals), pneumonia (51%), ear infections (51%), diarrhea (30%), and bronchitis (55%), with the incidence varying depending on the specific syndrome.

Many immune deficiencies also are associated with other characteristic defects, some of which appear to be unrelated to the immune system yet may be inherently life threatening. Examples include eczema and thrombocytopenia (in Wiskott-Aldrich syndrome); cardiac anomalies, low levels of calcium in the blood, and structural anomalies of the face (in DiGeorge syndrome); or a severe lack of muscular coordination and dilation of the small blood vessels (in ataxia-telangiectasia). These associated symptoms can be useful diagnostically. For instance, the principal immunologic defect in **DiGeorge syndrome** is the partial or complete absence of T-cell immunity. However, this syndrome is also characterized by severe congenital structural defects of the heart and low levels of calcium, which may result in seizures.

TABLE 9-6 CLASSES OF PRIMARY IMMUNE DEFICIENCIES

CLASSIFICATION	EXAMPLE	MUTATION	IMMUNE DEFICIENCY
B-Cell Defects			
B-cell receptor signaling	Bruton's/X-linked agammaglobulinemia	Btk	Little or no B-cell maturation or antibody
	Autosomal agammaglobulinemia	IgM μ-chain	
Class-switch: hyper-IgM	X-linked hyper-IgM syndrome	CD40 ligand	Little or no class-switch to IgG or IgA, with overproduction of IgM
	Autosomal hyper-IgM syndrome	CD40	
	AICD deficiency	AICD	
Class-switch: selective	IgG subclass deficiency	Unknown	Defective switch to an IgG subclass
	Selective IgA deficiency	Unknown	Defective switch to IgA
	Common variable immune deficiency	Multiple	Defective switch to ≥1 antibody class
T-Cell Defects			
Defective primary lymphoid organ for T-cell development	DiGeorge syndrome	Development of 3rd and 4th pharyngeal pouches	Little or no T-cell maturation
Antigen specific response	Chronic mucocutaneous candidiasis	Unknown	Little or no response to *Candida*
Combined T- and B-Cell Defects			
SCID: No WBC stem cells	Reticular dysgenesis	Unknown	Complete; lack of white blood cells
SCID: Enzyme defects	Adenosine deaminase deficiency	ADA	Complete; few or no T, B, or NK cells
	Purine nucleoside phosphorylase deficiency	PNP	Partial; few T or NK cells
SCID: Cytokine receptor defects	X-linked SCID	IL-2Rγ	Partial; little or no maturation of Th or NK cells
	IL-7 receptor deficiency	IL-7Rα	
	JAK3 deficiency	JAK3	
SCID: TCR/BCR defects	RAG-1 or RAG-2 deficiency	RAG-1/RAG-2	Complete; little or no maturation of T or B cells; normal NK cells
SCID: TCR defects	CD45 deficiency	CD45	Partial; incomplete T-cell maturation, normal B and NK cells
	CD3 deficiency	CD3 γ-, δ-, or ε-chains	
	ZAP-70 deficiency	ZAP-70	
Antigen presentation defects	MHC class I deficiency	TAP1 or TAP2	Abnormal cytotoxic T-cell activity
	MHC class II deficiency	Multiple	Abnormal helper T-cell activity
Cytoskeletal defect	Wiskott-Aldrich syndrome	WASP	Altered T and B cells; decreased IgM
DNA repair defect	Ataxia-telangiectasia	ATM	Altered T and B cells; absent IgA
Complement Defects			
Classical pathway	C1q,r,s, C4, or C2 deficiency	C1q,r, or s, C4, or C2	Defective classical pathway, intact alternative pathway
Lectin pathway	Mannose-binding lectin deficiency	MBL	Defective lectin pathway
Alternative pathway	Properdin, factor D or B deficiency	Properdin, factor D or B	Defective alternative pathway
	Factor H, factor I deficiency	Factor H, factor I	Secondary C3 deficiency
C3	C3 deficiency	C3	Entire complement cascade blocked
Terminal pathway	C5, C6, C7, C8, or C9 deficiency	C5, C6, C7, C8, or C9	Membrane attack complex blocked, normal opsonization and chemotaxis
Phagocyte Defects			
Quantitative defects	Severe congenital neutropenia	ELA2, WASP	Inadequate numbers of neutrophils
	Cyclic neutropenia	ELA2	
Adhesion defects	Leukocyte adhesion defect-1 (LAD-1)	CD18	Decreased phagocyte adhesion to endothelium
	LAD-2	Transport enzymes for fucose	
Phagocytosis defects	C3 receptor deficiency	C3R	Defective opsonization
Bacterial killing defects	Chédiak-Higashi syndrome	CHS1	Defective lysosomal granules
	Myeloperoxidase deficiency	MPO	Lack of myeloperoxidase
	Chronic granulomatous disease	NADPH oxidase	Defective production of H_2O_2

AICD, Activation-induced cytidine deaminase; *MHC,* major histocompatibility complex; *NADPH,* nicotinamide adenine dinucleotide phosphate; *NK,* natural killer; *RAG,* recombination activating gene; *SCID,* severe combined immune deficiency; *TCR/BCR,* T-cell receptor/B-cell receptor; *ZAP,* zeta-chain associated protein.

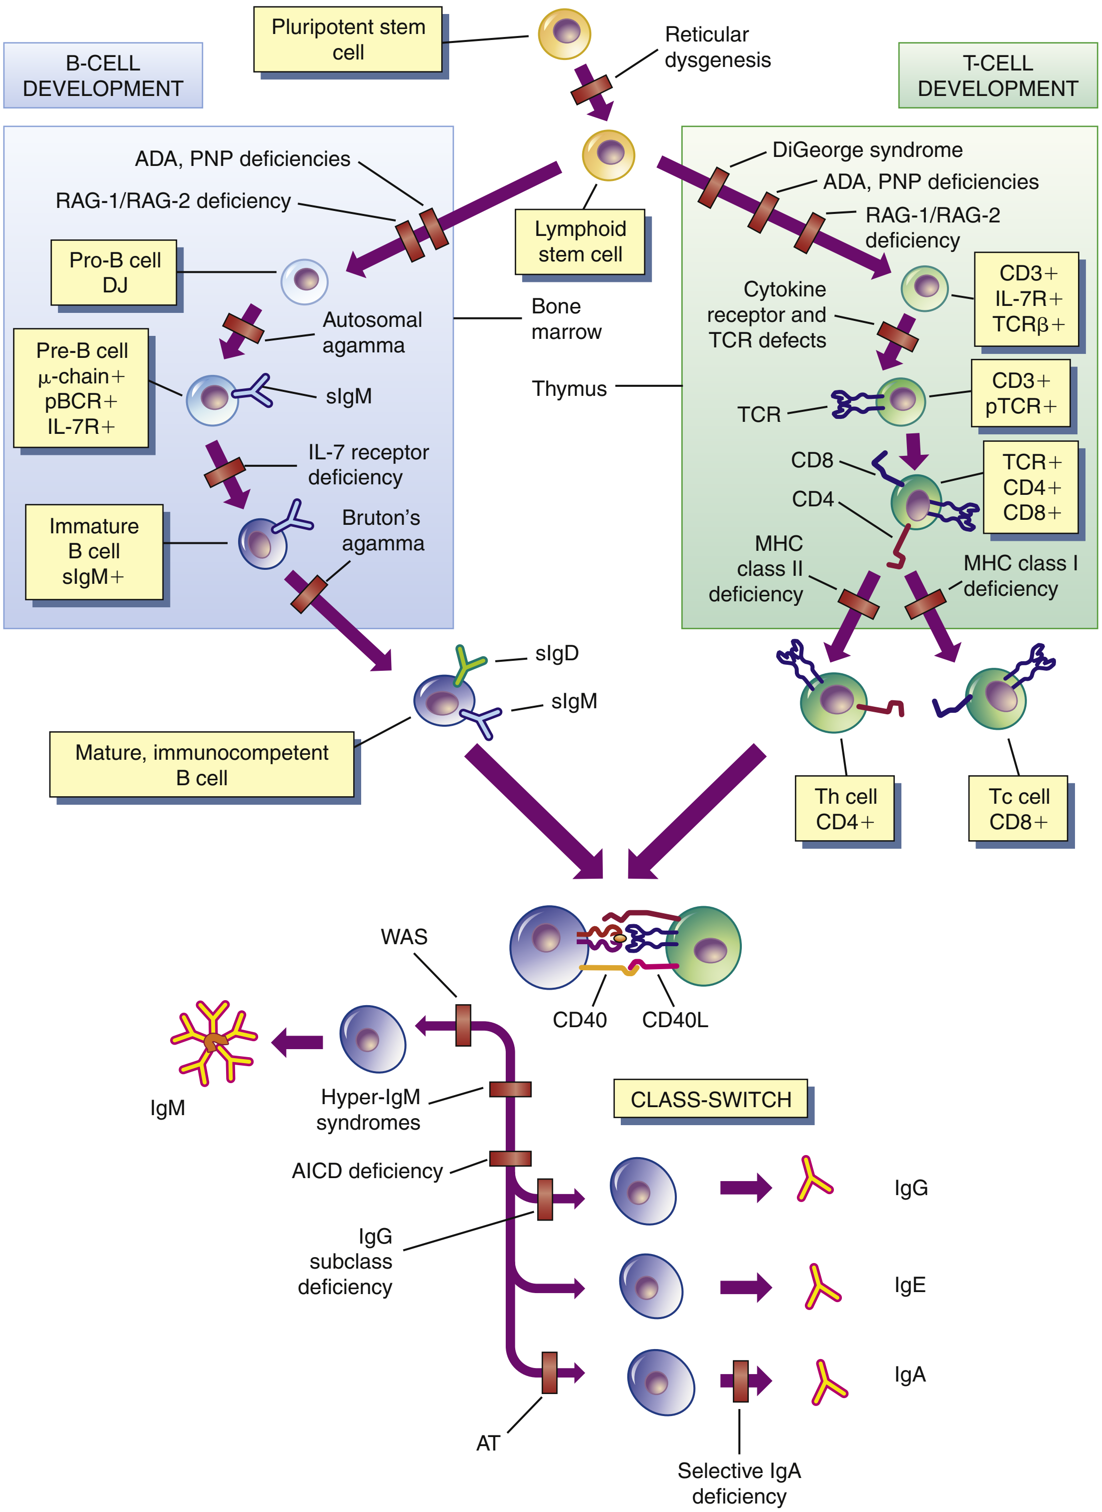

FIGURE 9-11 Lymphocyte Development Defects. This diagram shows defects in lymphocyte development that may account for congenital (primary) immune deficiencies. See the text and refer to Figures 8-10 through 8-12 for more detailed information. Pluripotent stem cell indicates the common stem cells for lymphocytic, granulocytic, and monocytic lineages. Cytokine receptor defects include X-linked severe combined immunodeficiency (SCID) (IL-2 receptor defect), JAK3 defects, and IL-7 receptor defects. T-cell receptor (TCR) defects include defects in CD3, CD45, and ZAP-70. Neither common variable immune deficiency nor chronic mucocutaneous candidiasis is included in this figure because the cause of these defects remains unknown. See Table 9-6 for further information on each defect. *ADA,* Adenosine deaminase deficiency; *agamma,* agammaglobulinemia; *AICD deficiency,* activation-induced cytidine deaminase deficiency; *AT,* ataxia-telangiectasia; *PNP,* purine nucleoside phosphorylase deficiency; *sIgM and sIgD,* surface IgM and IgD, respectively; *WAS,* Wiskott-Aldrich syndrome.

Individual primary immune deficiencies are very rare. For instance, only 30 to 50 new cases of severe combined immune deficiency are diagnosed in the United States yearly. However, approximately 150 different genetic defects resulting in immune deficiencies have been identified. Together, primary immune deficiencies are more common than cystic fibrosis, hemophilia, childhood leukemia, or many other well-known diseases. An estimated 50,000 cases of clinically significant primary immune deficiency have been reported in the United States. The gender distribution depends on the specific disease, but in general those diagnosed within the first 2 years of life have a male preponderance (5:1) because many are X-linked, whereas those diagnosed later are evenly distributed. The three most commonly diagnosed deficiencies are common variable immune deficiency (34%), selective IgA deficiency (24%), and IgG subclass deficiency (17%).

Primary immune deficiencies are classified into five groups, based on which principal component of the immune or inflammatory systems is defective. This chapter uses the five classifications proposed by the National Institutes of Health.[34] **B-lymphocyte deficiencies** result from defects in B-cell immune responses. T-cell immunity rarely depends on competent B-cell responses; thus T-cell immune responses are not affected in pure B-lymphocyte deficiencies. **T-lymphocyte deficiencies** are defects in the development and function of T lymphocytes. Because T-helper cells are obligatory in the development of many B-lymphocyte responses, antibody production is often diminished in these conditions, although the B cells are fully capable of producing an adequate antibody response. Many textbooks disagree on the classification of several specific immune deficiencies because of the difficulty in distinguishing between primary B-cell defects and those that are secondary to a primary T-cell defect. The classifications described below define T-cell defects as those with a clear defect in T-cell immunity, with normal B-cell immune responses. **Combined T- and B-lymphocyte deficiencies** result from inherent defects that directly affect the development of both T and B lymphocytes. Some combined deficiencies result in major defects in both T- and B-cell immune responses, whereas others are "partial" and more adversely affect T cells than B cells. The partial combined deficiencies include many conditions that may be classified as T-cell defects in other textbooks. **Complement deficiencies** and **phagocytic deficiencies** frequently present like antibody deficiencies because of the close interactions among antibody, complement, and phagocytes.

B-Lymphocyte Deficiencies

A defect in B-cell development results in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism.[35] The condition in which immunoglobulin levels are lower than normal is termed **hypogammaglobulinemia.** The condition in which they are totally or almost totally absent is termed **agammaglobulinemia.** (Normal lymphocyte development is discussed in Chapter 8.) Recurrent infections range from life threatening to mild, depending on the severity of the deficiency. Characteristic infections include encapsulated bacteria (e.g., *Streptococcus pneumoniae* or *Haemophilus influenzae*) that may cause pneumonia or sepsis and other microorganisms that cause infections of the sinuses, ears, and gastrointestinal tract.

The most severe B-lymphocyte deficiency is **Bruton's agammaglobulinemia,** also referred to as X-linked agammaglobulinemia. Somewhat less than a third of the mutations are sporadic. This condition results from mutations in the gene for Bruton's tyrosine kinase (Btk)—an enzyme involved in intracellular signaling from several B-cell receptors, including the IgM B-cell antigen receptor, the IL-5 receptor, and the IL-6 receptor. Ineffective signaling results in the arrest of the development in the bone marrow of early cells in the B-cell lineage into mature B cells[36] (see Figure 9-11). Few or no circulating mature B cells are present, although T-cell number and function are normal. At 6 months of life the approximate normal serum concentrations of immunoglobulins are IgG, 400 mg/dl; IgM, 40 mg/dl; and IgA, 30 mg/dl. In 6-month-old children with Bruton's agammaglobulinemia, serum IgG levels are well below 100 mg/dl and IgM and IgA are almost absent.

An autosomal recessive form of agammaglobulinemia **(autosomal agammaglobulinemia)** results from other mutations in the B-cell receptor. The most common is a mutation of the mu (μ) chain of the IgM portion of the receptor. This mutation prevents intracellular signaling after antigen binds to the receptor, leading to blocked maturation, the absence of antibody production, and very severe infections.

Several defects in antibody class-switch have been identified (see Figure 9-11). **X-linked hyper-IgM syndrome** results from a mutation in CD40 ligand, which is expressed on the surface of T-helper (Th) cells. Th cells stimulate B cells to undergo a switch in the class of antibody they produce through multiple Th–B-cell interactions involving ligands expressed on one cell binding to specific receptors on the other cell. The ligand-receptor interaction results in an intracellular signal facilitating rearrangement of the genes for the antibody variable region from a site near the constant region gene for the μ chain to the constant region for a different antibody H chain (see Figure 8-20). A critical ligand-receptor interaction occurs between the receptor CD40 on the B cell and its ligand (CD154 or CD40L) on the Th cell. A mutation in CD40L results in **defective class-switch,** decreased or absent production of IgG and IgA, poor development of memory B cells, and overproduction of IgM. T-cell immunity is not affected.

Defects in other components of the Th–B-cell interaction result in **autosomal hyper-IgM syndrome.** Mutations in CD40 on B cells result in a similar effect to that described previously. A defect in a DNA editing enzyme (activation-induced cytidine deaminase; AICD) also inhibits class-switch. During class-switch and movement of the H chain genetic information for the variable region to a different constant region gene, the double-stranded DNA must be cut and mended. This enzyme is responsible for cutting and mending the DNA.

Deficiencies in certain subclasses of antibody (**IgG subclass deficiency),** particularly IgG2, may result from a defect in switch to a particular subclass constant region (see Figure 9-11). The level of IgG2 subclass is often increased in response to polysaccharide antigens such as those on the surface of encapsulated

bacteria. Low levels of IgG2 may be responsible for recurrent risk for pneumonias caused by these bacteria. Whether IgG subclass deficiencies are unique immune deficiency conditions is unclear because many are apparently early indications of the development of common variable immune deficiency (see following) or are secondary to selective IgA deficiency.

One of the most common primary immune deficiencies is a **selective IgA deficiency.** Because many affected individuals are asymptomatic, the true incidence is uncertain, although estimates ranging from 1 person in 300 to 1 in 3000 have been made. Individuals with selective IgA deficiency are able to produce other classes of immunoglobulins but fail to produce IgA (see Figure 9-11). Many will have B cells that have undergone class-switch to IgA, but for unknown reasons, cannot undergo the terminal steps of differentiation to IgA-secreting plasma cells. Although many individuals are asymptomatic, others present with a history of severe recurring sinus, lung, and gastrointestinal infections. They commonly also have chronic intestinal candidiasis (infection with *Candida albicans*). (The secretory, or mucosal, immune system is described in Chapter 8.)

Complications of IgA deficiency include severe atopic disease and autoimmune diseases; selective IgA deficiency is two or three times more common in atopic individuals than in others. Secretory IgA normally may prevent the uptake of allergens from the environment so that IgA deficiency may lead to increased allergen uptake and a more intense challenge to the immune system because of prolonged exposure to environmental antigens. One of the most severe complications of IgA deficiency is an anaphylactic reaction that can follow administration of blood products that contain IgA. Serious anaphylactic reactions can occur in individuals totally lacking IgA because the immune system recognizes donor IgA as a foreign antigen. Initial sensitization can occur in fetal life through exposure to maternal IgA that leaks across the placenta or later through the ingestion of maternal IgA in breast milk or bovine IgA in cow's milk. Sensitization also can occur with initial administration of blood products containing IgA. The individual's primed immune system then acts against donor IgA on subsequent exposure.

Common variable immune deficiency is the most commonly diagnosed immune deficiency. As the name implies, the presentation is very heterogeneous. It is characterized by hypogammaglobulinemia, but the particular class of antibody that is decreased varies: most have low amounts of IgG, which may or may not be accompanied by decreased levels of IgA or IgM, or both, with normal numbers of B cells. Some may have accompanying T-cell defects. Multiple genetic defects in terminal differentiation account for this condition, although the specific defects have not been identified in most people. The age of onset of symptoms, such as recurrent bacterial respiratory tract infections, is generally later than most primary immune deficiencies (late twenties). Secondary complications include arthritis (infectious and noninfectious), gastrointestinal symptoms (malabsorption, chronic diarrhea), autoimmune disease (anemia, thrombocytopenia, endocrine diseases), and cancer (of the lymphoid system, skin, and gastrointestinal tract).

T-Lymphocyte Deficiencies

Two well-studied examples of T-lymphocyte defects that represent different ends of the T-cell differentiation process include DiGeorge syndrome and chronic mucocutaneous candidiasis. Lymphoid stem cells begin maturing into functional T lymphocytes in the thymus. DiGeorge syndrome (congenital thymic aplasia or hypoplasia) is caused by the lack, or more commonly partial lack, of the thymus, resulting in greatly decreased T-cell numbers and function and in life-threatening viral, fungal, and intracellular bacterial infections[37] (see Figure 9-11). The defect is attributed usually to deletions on chromosome 22 (some deletions also have been identified on chromosome 10),[38] about 25% of which are inherited. The deleted region encodes information for formation of organs that originate from the third and fourth pharyngeal pouches during the twelfth week of gestation. In addition to the lack of thymus development, the individual may present with a partial or complete absence of the parathyroid gland (resulting in decreased blood calcium levels), major structural defects in the heart and the aorta (resulting in inadequate blood flow and inadequate oxygenation of the tissues), and abnormal facial characteristics (e.g., underdeveloped chin, low-set ears, shortened structure of the upper lip) (Figure 9-12).

Chronic mucocutaneous candidiasis is a primary defect of T lymphocytes in response to a specific infectious agent, the yeast *C. albicans*. At least seven variants of this condition have been described. All are characterized by mild to extremely severe chronic mucocutaneous candidiasis: *Candida* infections that involve the mucous membranes, nails, and skin. Invasive candidiasis is extremely rare. Although most B- and T-cell immune responses may be normal, most individuals with this defect cannot react to antigens from *Candida*. The cause of this defect is unknown.

Combined T- and B-Lymphocyte Deficiencies

The most severe deficiencies usually occur when both the B- and T-cell immune responses are affected. A great deal of knowledge about the evolution of bone marrow stem cells into functional B- and T-cell effectors came from studying children with the

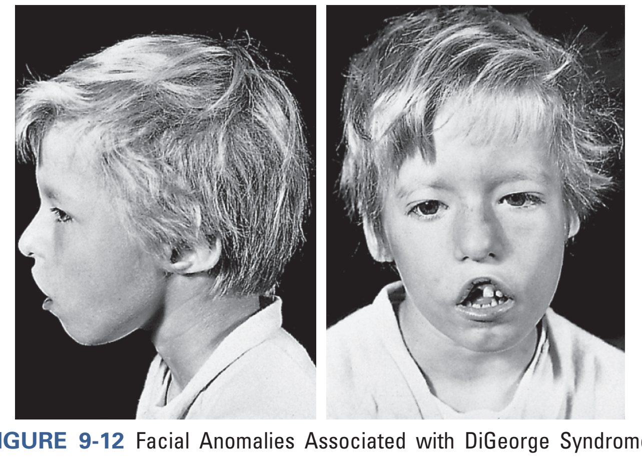

FIGURE 9-12 Facial Anomalies Associated with DiGeorge Syndrome. Note the wide-set eyes, low-set ears, and shortened structure of the upper lip. (From Roitt I, Brostoff J, Male D: *Immunology,* ed 6, St Louis, 2001, Mosby.)

most severe immune deficiency, **severe combined immune deficiency (SCID).** The most severe form of SCID is **reticular dysgenesis** (failure of blood cells to develop), in which a common stem cell for all white blood cells is absent; therefore, T cells, B cells, and phagocytic cells never develop (see Figure 9-11). Most children with reticular dysgenesis die in utero or very soon after birth. More typically, a defect occurs after some stem cells become committed to developing into lymphocytes (lymphoid stem cells); therefore, most individuals with SCID are deficient in lymphocyte development, but have normal numbers of all other white blood cells. SCID often results in few or absent T and B lymphocytes in the circulation and secondary lymphoid organs (spleen, lymph nodes). The thymus is usually hypoplastic (underdeveloped) because of the absence of T cells. Immunoglobulin levels, especially of IgM and IgA, are absent or greatly reduced, although IgG levels may be almost normal in the first months of life because of the presence of maternal antibodies. In the most severe defects, death occurs at about 1 year of life.

At least 20 different forms of SCID have been identified. Depending on the specific genetic mutation, the defect may involve T cells, B cells, and NK cells or may suppress more severely the function of one cell type, with relatively minor effects on the others. All three cells are adversely affected (T−, B−, NK−) in SCID resulting from a deficiency of adenosine deaminase **(adenosine deaminase [ADA] deficiency),** which is an enzyme involved in purine metabolism (see Figure 9-11). This defect is autosomal recessive and results in the accumulation of toxic purine metabolites to which rapidly dividing cells, such as lymphocytes, are especially sensitive. ADA deficiency accounts for about 16% of all persons with SCID. The development of T cells, B cells, and NK cells is arrested very early, and very few lymphocytic cells are found in the blood. In some forms of SCID, the defect resides in receptors for cytokines that are necessary for maturation of lymphocytes (see Figure 9-11). T cells and NK cells are preferentially affected (T−, B+, NK−), but often the defect results in the production of immature B cells that cannot respond well to antigen because of the lack of Th cells. The most common (44% of those with SCID) is an **X-linked SCID** resulting from a defect in the IL-2 receptor gamma (γ)-chain (IL-2Rγ). This protein is a component of several receptors for cytokines, including IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21. These cytokines participate in the early development of immunocytes, particularly T and NK cells. Defective IL-2Rγ results in arrested maturation of T and NK cells and the production of immature B cells. A similar deficiency occurs with mutation in JAK3 **(JAK3 deficiency),** which is an enzyme (a tyrosine kinase) that associates with IL-2Rγ in normal cells and communicates information from the receptor to the nucleus. Thus cells with defects in JAK3 cannot respond to cytokines that bind to these receptors on the cell surface. An autosomal form results from mutations of one of the protein chains (α-chain) of the IL-7 receptor **(IL-7 receptor deficiency).** IL-7 appears to be necessary for the maturation of T cells, so that this deficiency has relatively normal levels of B cells and NK cells.

Mutations in another purine metabolism enzyme, purine nucleoside phosphorylase **(purine nucleoside phosphorylase [PNP] deficiency),** are less severe than ADA deficiency (see Figure 9-11). T cells and NK cells appear to be more susceptible to mutations in PNP so that B-cell function can be relatively normal.

Another form of SCID preferentially affects T cells and B cells (T−, B−, NK+). T and B lymphocytes possess receptors for antigen, whereas NK cells do not. Those receptors result from a process of genetic rearrangement of *V* and *J* genes to form the variable regions of the L chain (B-cell receptor [BCR]) and the α-chain (T-cell receptor [TCR]) and the *V, D,* and *J* genes to form the variable regions of the H chain (BCR) and the β-chain (TCR). Successful rearrangement is controlled by two recombination activating enzymes (RAG-1 and RAG-2). RAG enzymes cut and repair double-stranded breaks in DNA that are necessary for genetic rearrangement. **RAG-1** or **RAG-2 deficiencies** are autosomal recessive and result in arrested lymphocyte development from blocked recombination of variable regions of B-cell and T-cell receptors (see Figure 9-11).

Forms of partial SCID, with the defect being primarily of T cells, arise from mutations in several components of the TCR complex (see Figure 9-11). Defects in the TCR result in inadequate maturation of T cells, with normal B and NK cells. Antibody production may be depressed because of the lack of Th cells. The TCR is a complex organization of proteins that react with antigen (α- and β-chains), and then provide an intracellular signal to the nucleus (γ-, δ-, and ε-chains [collectively called CD3] and the associated molecules CD45 and ZAP-70). Examples of these deficiencies include mutations in CD3, CD45, or ZAP-70. The T-cell defect in each can range from mild to severe in nature, with normal B lymphocytes.

Even if nearly adequate numbers of B and T cells are produced, their ability to process and present antigen may be defective. The **bare lymphocyte syndrome** is a group of immune deficiencies characterized by an inability of lymphocytes and macrophages to present antigen because of defects in class I or class II MHC antigen expression (see Figure 9-11). **MHC class I deficiency** results from mutations in the genes for TAP1 or TAP2, which control the transport of antigenic protein fragments across the endoplasmic reticulum and the formation of MHC class I/antigen complexes for transportation to the cell surface (see Figure 8-16). Because MHC class I molecules preferentially present antigen to CD8+ Tc cells, the resultant deficiency is of CD8+ cytotoxic cells, with normal levels of CD4+ helper cells and normal antibody production. **MHC class II deficiency** is more severe. A variety of mutations prevent normal production of MHC class II molecules, which present antigen to CD4+ helper cells. Because of defective recruitment of T-helper cells, normal antibody responses are greatly suppressed. Children with this deficiency develop life-threatening infections and usually die before age 5 years.

Some combined immune deficiencies are secondary to mutations that affect a variety of cells other than immunocytes. For instance, **Wiskott-Aldrich syndrome** (WAS; an X-linked recessive disorder) results from sporadic mutations in the WAS protein (WASP), which is involved in intracellular signaling and regulation of the organization of the cell's actin cytoskeleton (see Figure 9-11). The defects in the cytoskeleton lead to the classic symptoms of thrombocytopenia (with resultant bleeding disorders), scaly eczema, and defective T and B cells. IgA and IgG

levels are usually normal, but IgM responses are highly depressed. Antibody responses against antigens that elicit primarily an IgM response, such as polysaccharide antigens from bacterial cell walls (e.g., of *Pseudomonas aeruginosa, S. pneumoniae, H. influenzae,* and other microorganisms with polysaccharide outer capsules), are deficient. Persons with WAS have a very high risk of lymphoid malignancies (leukemias and lymphomas).

Ataxia-telangiectasia (AT) is an autosomal recessive disorder resulting from a large variety of sporadic mutations in the *ATM* gene, which encodes a protein involved in repair of double-stranded breaks in DNA. Affected infants often develop ataxia (unsteady gait), which usually becomes apparent when the child is learning to walk. The neurologic defect may eventually lead to confinement in a wheelchair. Telangiectasia (dilation of capillaries) can occur in the eyes and skin, especially on the ears, neck, and extremities. Both B and T cells are variably affected and unrepaired double-stranded DNA breaks are commonly observed in the regions encoding the T-cell and B-cell receptors. About 70% of those with AT are IgA deficient, occasionally accompanied by deficiencies in IgG (see Figure 9-11). Individuals with AT are at high risk for developing leukemias and lymphomas.

Complement Deficiencies

Complement activation is a necessary component of protection against many infectious agents. IgG and complement components, such as C3b, are opsonins and facilitate phagocytosis by neutrophils and macrophages. Defects in the complement cascade often resemble antibody deficiencies, with recurrent infections with encapsulated bacteria (e.g., *H. influenzae* and *S. pneumoniae*) that are highly sensitive to opsonin-assisted phagocytosis. In addition to recurrent infections, deficiencies in the classical pathway commonly lead to a SLE-like syndrome. As noted previously, excessive levels of circulating complexes of antibody, antigen, and complement may lead to type III hypersensitivity diseases (immune complex diseases). However, healthy individuals release small amounts of soluble intracellular antigens into the blood during normal cell turnover. Low levels of naturally occurring autoantibodies and limited activation of the classical pathway of the complement system through C3 facilitate the removal of this debris by phagocytes. Some complement defects may slow the clearance from the blood of natural immune complexes, leading to SLE-like symptoms.

C3 deficiency is the most severe complement defect (Figure 9-13). C3 is the component that unites all pathways of complement activation, and complement component C3b is a major opsonin. Persons with C3 deficiency are at risk for recurrent life-threatening infections with encapsulated bacteria at an early age, as well as a SLE-like syndrome that may be complicated by kidney disease (glomerulonephritis). **C2 deficiency,** more so than **C1** or **C4 deficiencies,** also has an increased risk for recurrent respiratory tract infections with encapsulated bacteria (e.g., *S. pneumoniae, H. influenzae*).

Mannose-binding lectin (MBL) deficiency is the primary defect of the lectin pathway of complement activation.

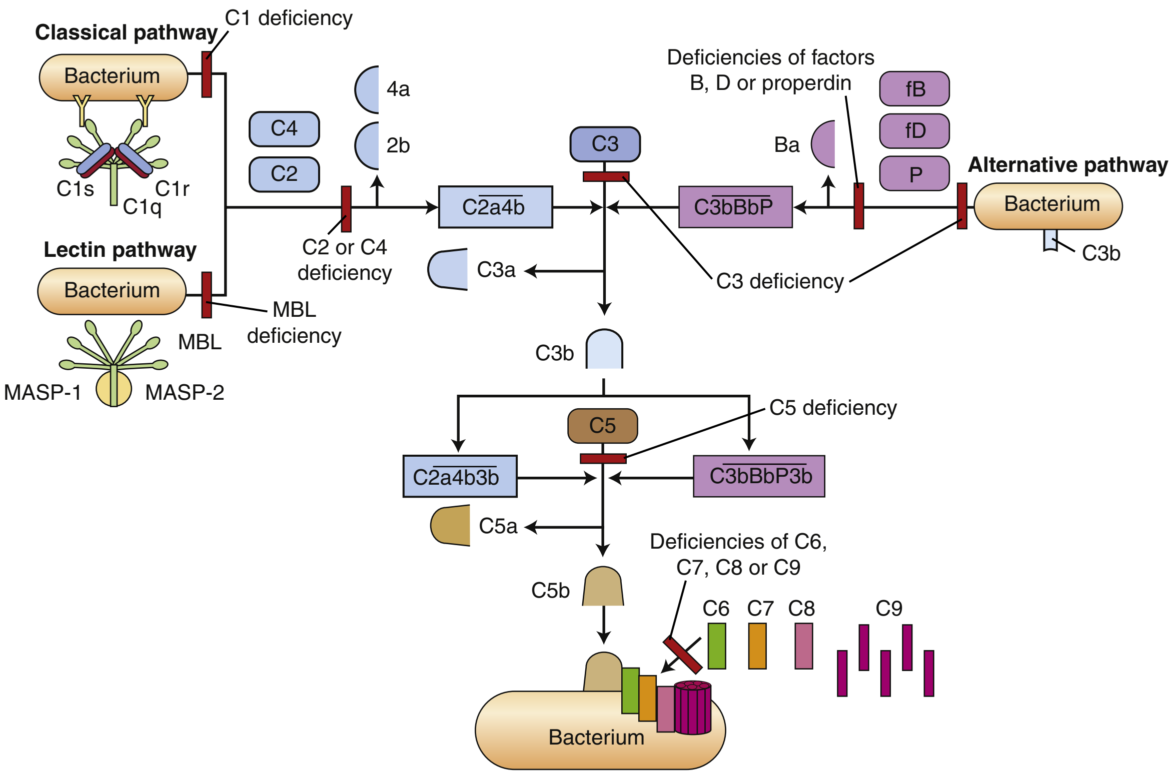

FIGURE 9-13 **Complement Defects.** The complement cascade is initiated through three pathways: the classical pathway, the lectin pathway, and the alternative pathway. Each of the three pathways produces a C3 convertase, which activates C3 leading to the formation of a C5 convertase. The activation of C5 initiates formation of the membrane attack complex (MAC). For more details, see the text and Figure 7-5. The most severe defect is a C3 deficiency because it blocks all three pathways. *MASP,* MBL-associated serine protease; *MBL,* mannose-binding lectin.

The defect results in increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose, particularly the yeast *Saccharomyces cerevisiae* and encapsulated bacteria such as *N. meningitidis* and *S. pneumoniae.*

Deficiencies in the alternative pathway also result in recurrent infections with encapsulated bacteria. **Properdin deficiency** is associated with recurrent meningococcal infections and is X-linked, whereas all other complement deficiencies are autosomal recessive. Symptoms generally appear in the second decade of life. Factor I and factor H are major regulators of the complement cascade and control the level of spontaneous activation of C3. **Factor I deficiency** and **factor H deficiency** can be severe because they lead to increased spontaneous destruction of C3 and a secondary C3 deficiency.

Deficiencies of components of the terminal portion of the complement cascade (C5, C6, C7, C8, or C9 deficiencies) are associated with increased infections with only one group of bacteria—those of the genus *Neisseria (N. meningitidis* or *N. gonorrhoeae)*. *Neisseria* usually cause localized infections (meningitis or gonorrhea), but those individuals with terminal pathway defects have more than an 8000-fold increased risk for systemic infections with atypical strains of these microorganisms. **C9 deficiency** is the most common terminal pathway defect, appears primarily in Japanese populations, and is generally asymptomatic. The other deficiencies of the terminal pathway are extremely rare, but are characterized by more aggressive infections. The risk for systemic infections with *Neisseria* is also increased in those with deficiencies of C2, factor D, factor B, and properdin.

Phagocytic Deficiencies

Phagocytosis is generally aided by bacterial opsonization with IgG or C3b; therefore, defects in phagocytic killing usually result in recurrent infections with the same group of microorganisms (encapsulated bacteria) associated with antibody and complement deficiencies. Phagocytosis is a multistep process that involves initial adhesion between circulating phagocytes and the endothelial cells lining the circulation (see Figure 7-15). The phagocytes exit the circulation and move to a site of infection by a chemotactic process in response to soluble chemotactic factors released by the infection. The process of phagocytosis itself begins with attachment of the phagocyte to the targeted bacteria through the interaction of opsonins on the microorganism and matched receptors on the phagocyte's surface. Phagocytic engulfment results in internalization of the infectious agent and activation of a variety of oxygen-dependent and oxygen-independent killing mechanisms. Deficiencies can arise from mutations that affect one or more of these steps (Figure 9-14).

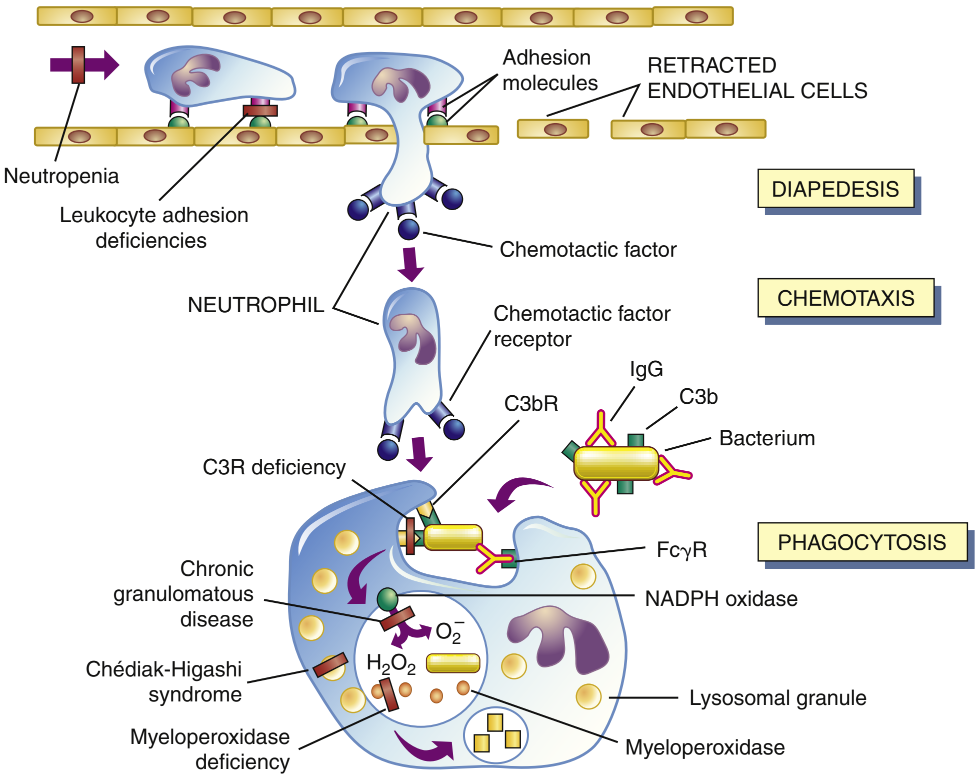

FIGURE 9-14 **Phagocytic Defects.** Several genetic defects in the process leading up to and including phagocytosis result in increased susceptibility to bacterial infections. See the text and refer to Figure 7-15 and Table 7-3 for more detailed information. The phagocyte leaves the bloodstream and enters the tissue through interactions between leukocyte and endothelial adhesion molecules and the process of diapedesis. The cell is attracted to the inflammatory site by chemotaxis, where it encounters opsonized bacteria, and attaches to and engulfs the microorganism. Inside the phagocyte the bacteria are killed and broken down by the combination of lysosomal granule constituents and reactive oxygen products of the hexose-monophosphate shunt and nicotinamide adenine dinucleotide phosphate (NADPH) oxidase. *C3R,* C3 receptor, which includes the C3b receptor *(C3bR); FcγR,* receptor for the Fc portion of IgG; H_2O_2, hydrogen peroxide; O_2^-, reactive oxygen.

Inadequate numbers of phagocytes, particularly neutrophils **(severe congenital neutropenias),** result in a variety of recurrent and severe bacterial infections beginning early in life. Approximately 50% of these individuals have a mutation in the neutrophil elastase gene *(ELA2)*. Other mutations have been identified (e.g., *WAS* gene) in the other 50%. A milder form, **cyclic neutropenia,** is autosomal dominant with almost 100% of affected individuals having a mutation in the *ELA2* gene. Changes in neutrophil levels are cyclic and may remain at or near normal for 2 to 3 weeks, followed by periods of neutropenia lasting a few days to weeks. During the neutropenia, the individual has increased susceptibility to recurrent bacterial infections.

Near sites of inflammation, soluble mediators diffuse into the circulation and induce expression of a variety of adhesion molecules on the phagocyte surface, which interact with complementary molecules on the endothelial cells to increase adherence between the phagocyte and the vessel wall and allow for margination and diapedesis to occur. **Leukocyte adhesion deficiencies (LADs)** result from mutations in various phagocyte adhesion molecules (see Table 7-3). Leukocyte adhesion deficiency, type 1 (LAD-1) results from an autosomal recessive mutation in CD18, which is a β_2-integrin chain that is shared by several different receptors. LAD-2 results from a defect in adding the monosaccharide fucose to carbohydrates on the phagocyte surface. Surface carbohydrates with fucose are ligands for selectins on the endothelial and leukocyte. These and other defects in leukocyte adhesion molecules usually result in increased levels of neutrophils in the blood (leukocytosis) because they cannot leave the circulation and in increased recurrent bacterial and fungal infections.

Additional deficiencies diminish the leukocyte's recognition of opsonins of the complement cascade (e.g., C3b). Deficiencies in the complement receptor for C3 **(C3 receptor deficiency)** result in recurrent bacterial infections, particularly of the skin.

A variety of defects in killing of microorganisms have been described. **Chédiak-Higashi syndrome** results from a defect in cytoplasmic granules from an autosomal recessive mutation in the lysosomal trafficking regulator gene *(CHS1)*. The CHS1 protein helps control movement of granules to cellular membranes in preparation for degranulation. As a result of these mutations, the granules remain in the cytoplasm and form large aggregates that are readily apparent microscopically. Leukocytes from individuals with Chédiak-Higashi syndrome have decreased chemotaxis, granular fusion, and bacterial killing. Platelet granules also may be affected, resulting in prolonged bleeding, and partial albinism can occur because of defects in melanocyte granules. Affected children develop recurrent infections of the skin, respiratory tract, and mucous membranes, especially with gram-positive bacteria.

The enzyme myeloperoxidase participates in a major mechanism of bacterial killing in phagocytes. Myeloperoxidase is found in primary granules and catalyzes the formation of acids from halides (e.g., chloride ion) and hydrogen peroxide (H_2O_2). As a result of phagocytosis, neutrophils and other phagocytes switch much of their glucose metabolism to the hexose-monophosphate shunt. A byproduct of this pathway is the conversion of molecular oxygen by nicotinamide adenine dinucleotide phosphate (NADPH) oxidase and other enzymes into highly reactive and toxic oxygen derivatives, including hydrogen peroxide. Two deficiencies in the myeloperoxidase–hydrogen peroxide killing process have been extensively studied. **Myeloperoxidase deficiency** is a relatively mild disorder characterized by a complete or partial deficiency in myeloperoxidase. Individuals do not have severe recurrent infections because most infectious bacteria are sensitive to direct killing by many of the toxic oxygen molecules produced by NADPH oxidase. The exception is the person with concurrent diabetes, who may have recurrent disseminated candidiasis.

Chronic granulomatous disease (CGD) is a more severe defect in the myeloperoxidase–hydrogen peroxide system.[39] Several forms of the disease have been characterized, both X-linked (about 70% of the individuals) and autosomal recessive, with the X-linked form being more severe. CGD occurs from a variety of mutations (at least four have been identified) in portions of the NADPH oxidase complex, resulting in deficiencies in the production of hydrogen peroxide and other oxygen products. Thus individuals have adequate myeloperoxidase and chloride but lack the necessary hydrogen peroxide. Individuals with CGD have recurrent severe pneumonias; tumor-like granulomas in lungs, skin, and bones; and other infections with some normally relative innocuous microorganisms, such as *Staphylococcus aureus, Serratia marcescens, Aspergillus* spp., and others. These are catalase-positive microorganisms. Infections with more virulent, but catalase-negative, microorganisms (e.g., *S. pneumoniae*) are rare. Most microorganisms produce their own hydrogen peroxide as a byproduct, which accumulates in the phagocytic vacuole and can be used by the phagocyte's myeloperoxidase to kill the microorganism. Some microorganisms also produce the enzyme catalase, which breaks down hydrogen peroxide. Thus catalase-negative microorganisms donate hydrogen peroxide to the phagocyte's myeloperoxidase, leading to their own death. Catalase-positive microorganisms, however, destroy the bacterial hydrogen peroxide and survive and cause infection.

Secondary Immune Deficiencies

Secondary, or acquired, immune and inflammatory deficiencies are far more common than primary deficiencies.[40] These deficiencies are not related to genetic defects, but are complications of other physiologic or pathophysiologic conditions. Some conditions that are known to be associated with acquired deficiencies include:

- Normal physiologic conditions
  - Pregnancy
  - Infancy
  - Aging
- Psychologic stress
  - Emotional trauma
  - Eating disorders
- Dietary insufficiencies
  - Malnutrition caused by insufficient intake of large categories of nutrients, such as protein or calories
  - Insufficient intake of specific nutrients, such as vitamins, iron, or zinc

- Malignancies
    - Malignancies of lymphoid tissues, such as Hodgkin disease, acute or chronic leukemia, or myeloma
    - Malignancies of nonlymphoid tissues, such as sarcomas and carcinomas
- Metabolic diseases or genetic syndromes
    - Diabetes
    - Cystic fibrosis
    - Alcoholic cirrhosis
    - Sickle cell disease
    - SLE
    - Chromosome abnormalities, such as trisomy 21 (Down syndrome)
- Environmental agents
    - Ultraviolet (UV) light
    - Ionizing radiation
    - Chronic hypoxia
- Physical trauma
    - Burns
- Medical treatments
    - Stress caused by surgery
    - Anesthesia
    - Immunosuppressive treatment with corticosteroids or antilymphocyte antibodies
    - Splenectomy
    - Cancer treatment with cytotoxic drugs or ionizing radiation
- Infections
    - Congenital infections, such as rubella, cytomegalovirus, hepatitis B
    - Acquired infections, such as acquired immunodeficiency syndrome (AIDS)

Although secondary deficiencies are common, many are not clinically relevant. In many cases, the degree of the immune deficiency is relatively minor and without any apparent increased susceptibility to infection. Alternatively, the immune system may be substantially suppressed, but only for a short duration, thus minimizing the incidence of clinically relevant infections. Some secondary immune deficiencies, however, are extremely severe and may result in recurrent life-threatening infections.

Normal Physiologic Conditions

The competence of an individual's immune system varies throughout life. Pregnancy itself is considered by many to be an immunocompromised condition. Pregnant women may have decreased reactivity or altered results in several tests of the immune system, including skin tests against various antigens, circulating numbers of T lymphocytes, and other very general tests. Pregnancy itself, however, is not associated with a marked change in infections, suggesting that the mother's immune system is not severely altered.

The newborn child is immunologically immature. Although T-cell immune responses may be normal or near normal, other components of the immune system (especially antibody production) are just beginning to mature. Beginning at about 32 weeks of pregnancy, the placenta transports maternal antibodies into the fetal blood to protect the child during the first months of life (see Figure 8-30). After the delivery, the level of the mother's antibodies slowly decreases in the newborn so that maternal antibodies no longer protect the child by about 6 months of life. By 6 to 8 months, the newborn should be efficiently protected by antibodies produced by its own B cells. In some infants, the development of antibody production is delayed, and a transient low level of antibody may persist for several months (**transient hypogammaglobulinemia of infancy**), during which the child has increased susceptibility to infections. Premature infants are particularly immunologically immature and are at increased risk for neonatal infections. The blood of infants born before 32 weeks' gestation is generally devoid of maternal antibody.

Aging is also associated with a progressive depression in immune responses. Older adults generally have more severe bacterial and fungal infections, greater difficulty resolving those infections, and lower responses to vaccination.

Several meaningful changes occur during aging, although variations in the degree of change and a corresponding increased susceptibility to infection can be considerable among individuals. The thymus involutes over time, resulting in decreased production of fresh T cells. A concurrent depletion of T-memory cells results in depressed responses to both new and "recall" antigens. A shift toward Th2 cells also may occur with a resultant decrease in Th1 cytokines. Total numbers of B cells may decrease. Numbers of NK cells may remain normal, although their activity is decreased. Similarly, neutrophil numbers may remain normal, with decreased phagocytosis and killing.

Psychologic Stress

The relationship between emotional stress and depressed immune function has become an area of intense clinical and research interest. For many decades anecdotal reports have suggested that increased incidences of infection and malignancy are associated with periods of both intense stress (e.g., the loss of a loved one, divorce) and relatively minor stress (e.g., final examination periods at colleges and universities). In addition, early studies showed that immune function, as demonstrated by delayed hypersensitivity skin test results, could be depressed through posthypnotic suggestion.

We are now beginning to understand the mechanisms of the relationship between emotional stress and the immune system. Many lymphoid organs are innervated and can be affected by nerve stimulation. In addition, lymphocytes have receptors for many hormones (e.g., sex hormones, neurotransmitters, and neuropeptides) and can respond to changing levels of these chemicals with increased or decreased function. For instance, stress-induced catecholamines affect the expression of adhesion molecules and the movement of lymphocytes among lymphoid organs. (Further discussion of the effects of stress on susceptibility to disease is the subject of Chapter 11.)

Dietary Insufficiencies

Nutritional status can have a profound effect on immune function, and malnutrition is the predominant cause of secondary immune deficiencies worldwide. Severe deficits in calorie or protein intake lead to deficiencies in T-cell function and numbers. The humoral immune response is less affected by starvation,

although complement activity, neutrophil chemotaxis, and bacterial killing within neutrophils often are depressed, resulting in infections with microorganisms that are normally destroyed by opsonization and phagocytosis.

Deficient zinc intake can profoundly depress both T- and B-cell function. Zinc is required as a cofactor for at least 70 different enzymes, some of which are found in lymphocytes and are necessary for their function. Secondary zinc deficiencies may be associated with malabsorption syndrome (failure to absorb zinc), chronic renal disease (loss of zinc in the urine), chronic diarrhea (loss of zinc through the gut), or burns or severe psoriasis (loss of zinc through the skin). Deficiencies of other enzyme cofactors, such as vitamins (e.g., pyridoxine, pantothenic acid, folic acid, and vitamins A, C, E, and B_{12}), also may result in severe depressions of B- and T-cell function, phagocytosis, and complement activity.

Malignancies

Many malignancies are complicated by a wasting syndrome (cachexia) in the later stages, which can suppress the immune system secondary to the resultant malnutrition. Additionally, a very close relationship exists between the immune system and the development of malignancies. It is generally accepted that successful malignancies have developed mechanisms to avoid rejection by the individual's immune system. Persons with primary immune deficiencies are usually at greater risk for developing malignancies, particularly malignancies of lymphoid tissues, such as leukemias or lymphomas. Malignancies aggressively depress the individual's immune system. The effect is commonly nonspecific, resulting in a generalized deficiency of the immune response and a greatly increased susceptibility to developing life-threatening infections. In fact, many people with malignancies die from infection rather than from direct effects of the tumor.

Malignancies of lymphoid tissues, such as Hodgkin disease, acute or chronic leukemia, or myeloma, result in depletion of normal lymphocytes and their replacement by the malignant cells. Thus the number of B or T cells capable of responding to infections is depleted. Many malignancies, even those of non–lymphoid tissues, produce cytokines (e.g., transforming growth factor-beta [TGF-β] and vascular endothelial growth factor [VEGF]) that nonspecifically suppress the immune responses.

Metabolic Diseases or Genetic Syndromes

Diabetes suppresses many aspects of the immune and inflammatory responses, including phagocytosis and chemotaxis, lymphocyte proliferation, and glucose metabolism. The effects of trisomy 21 are less severe, but primarily include diminished neutrophil function. People with cystic fibrosis have decreased airway clearance of bacteria, thus increasing the probability of major respiratory tract infections.

Environmental Agents

Individuals are constantly exposed to environmental agents that affect the immune system. UV light from sun exposure or tanning salons induces apoptosis of lymphoid stem cells, increases production of Treg cells that suppress defenses against cancer, and increases production of anti-inflammatory cytokines. Ionizing radiation affects rapidly dividing cells, including those of the immune system. At very high doses, the entire immune system can be depleted.

Physical Trauma

Trauma that compromises the epithelial barrier also predisposes an individual to infection. Burn victims are susceptible to severe bacterial infections. Thermal burns appear to be associated with suppressed neutrophil function (especially chemotaxis), complement levels, cell-mediated immunity, and primary humoral responses, although secondary humoral responses are normal. The mechanism of this immunosuppression may be twofold. Blood from burned individuals contains nonspecific immunosuppressive factors (all immune responses are suppressed, regardless of the antigen involved). In addition, burn victims also have increased regulatory T-cell function, which may increase antigen-specific suppression.

Medical Treatments

Medical treatments themselves may produce suppression of immune responses. Depression of B- and T-cell formation is manifested as a progressive increase in infections with opportunistic microorganisms (especially *P. jirovecii,* cytomegalovirus, *C. albicans,* and other fungi), the extent and location of which are unusual.

Many drugs that are used to fight cancer (e.g., cancer chemotherapeutic agents) are not specific for cancer cells, but are designed to attack cells in susceptible stages in their cell cycles or rapidly proliferating cells, which includes cells of the immune system as well as malignant cells. The immunosuppressive effects of chemotherapeutic drugs are exacerbated by concurrent treatment with ionizing radiation (x-rays), which also affect cells that are rapidly making new DNA. Therefore, a person's immune response can be profoundly depressed as a result of the therapy. Other drugs, such as corticosteroids, are intentionally used to suppress the immune system and control hypersensitivity diseases (especially autoimmune disease) or prevent rejection of transplants. Because of their nonspecific activity, however, immune responses against infectious agents also can be suppressed, increasing an individual's susceptibility to infection. The list of drugs that affect the immune response is ever increasing and includes analgesics, antithyroid medications, anticonvulsants, antihistamines, antimicrobial agents, antilymphocyte antibodies, and tranquilizers.

Surgery and anesthesia also can suppress T- and B-cell function. Transient, severe lymphopenia is a common postoperative condition that can last as long as 1 month. Surgery to remove the spleen (splenectomy) can result in a depressed humoral response against encapsulated bacteria (especially *S. pneumoniae, H. influenzae, S. aureus,* group A streptococci, and *N. meningitidis*), depressed serum IgM levels, and decreased levels of opsonins.

Infections

Many infectious microorganisms are successful at invading the human body because they have evolved mechanisms for

fighting off specific immune/inflammatory responses against themselves (discussed in Chapter 10). However, some infectious agents (e.g., human immunodeficiency virus [HIV], Epstein-Barr virus [EBV], CMV, herpes simplex virus type 6, measles) can generally suppress the immune response. HIV is one of the few microorganisms that directly attacks the central processes involved in the development of an immune response (discussed in detail in Chapter 10). It infects and destroys the T-helper cell, which is necessary to provide help for the maturation of both plasma cells and T-cytotoxic cells.[41] Therefore, HIV suppresses the immune response against itself and secondarily creates a generalized immune deficiency by suppressing the development of immune responses against other pathogens and opportunistic microorganisms.

Several viruses (e.g., hepatitis B, rubella, CMV) can establish congenital infections through transmission from an infected mother to her child at birth when the child's immune system is immature. These children may have suppressed immune responses, although the degree of the deficiency is not usually severe; however, as the child's immune system develops, the viral antigens may be partially seen as "self" so that a chronic infection is established.

Evaluation and Care of Those with Immune Deficiency

Routine care of individuals with immune deficiencies must be tempered with the knowledge that the immune system may be totally ineffective. Administration of conventional immunizing agents or blood products to these individuals may be unsafe because of the risk that the immunizing agent will cause an uncontrolled infection. Attenuated vaccines contain live but weakened microorganisms (e.g., live polio vaccine; vaccines against measles, mumps, and rubella) that can cause disseminated infection. Although the vaccine virus is attenuated enough to be destroyed by a normal immune system, it can survive, multiply, and cause severe disease in an immune-deficient recipient. Additionally, even healthy recipients of vaccines containing live microorganisms can shed those microorganisms for a short time, increasing the risk of infection to family members or other close associates who are immune deficient. Even simple procedures, such as penetrating the skin for routine blood tests, may lead to fatal septicemia (bacterial infection of the blood) in the immune-deficient person.

Individuals with immune deficiencies are also at risk for **graft-versus-host disease (GVHD)**. Mature T cells in a transplanted graft (e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient. Symptoms of an acute graft-versus-host reaction usually appear within 10 to 30 days after the transplant. The primary targets for GVHD are the skin (e.g., rash, loss or increase of pigment, thickening of skin), liver (e.g., damage to bile duct, hepatomegaly), mouth (e.g., dry mouth, ulcers, infections), eyes (e.g., burning, irritation, dryness), and gastrointestinal tract (e.g., severe diarrhea) and may lead to death from infections.

GVHD is not a problem when the recipient is immunocompetent, that is, has an immune system that can control the donor's lymphocytes. If, however, the recipient's immune system is deficient, the grafted T cells remain unchecked and attack the recipient's tissues. Most GVHD is prevented by treating whole blood with irradiation to kill white blood cells before transfusion.

The most common presenting symptom of immune deficiencies is recurrent severe infections. Significant information concerning the nature of the specific immune deficiency can be obtained by noting the types of infection, as well as certain characteristics of the affected individual, including gender, age of disease onset, the presence of any associated anomalies, family history, and risk factors associated with secondary immune deficiencies. Humoral deficiencies are generally characterized by recurrent sinopulmonary infections with encapsulated bacteria, gastrointestinal malabsorption, and poor growth. T-cell defects generally present with failure to thrive, chronic diarrhea, persistent thrush, and opportunistic infections (e.g., *Mycobacterium, Pneumocystis, Candida,* and certain viruses). Phagocytic defects are usually associated with recurrent abscesses, oral ulcers, and infections with specific bacteria (e.g., catalase-positive bacteria). Complement defects may be linked to SLE-like disease and recurrent and disseminated infections with *Neisseria* spp.

A variety of laboratory tests are available to evaluate specific immune deficiencies[42] (Table 9-7). The choice of which particular tests to perform is determined on the characteristics described previously. A basic screening test is a **complete blood count (CBC)** with a differential. The CBC provides information on the numbers of red cells, white cells, and platelets, and the differential indicates the quantities of lymphocytes, granulocytes, and monocytes in the blood. Quantitative determination of immunoglobulins (IgG, IgM, IgA) is a screening test for antibody production, and an assay for total complement (total hemolytic complement, CH_{50}) is useful if a complement defect is suspected.

If the nature of the immune deficiency remains uncertain after the screening tests, additional relatively common tests can be performed. For instance, subpopulations of lymphocytes (T or B) can be quantified using characteristic surface markers, such as surface immunoglobulin for B cells and CD3 for T cells. T-cell populations can be further subdivided using additional surface markers, such as CD4 (T-helper cells) or CD8 (T-cytotoxic cells). For antibodies, routine assays are available to quantify subclasses of IgG, such as IgG2.

An additional level of testing would include determination of immune responses against specific antigens. Determination of isohemagglutinins is informative about antigen-specific IgM production. Antibody responses to vaccines (e.g., tetanus, pertussis, measles, diphtheria, hepatitis B) are usually indicative of IgG responses. T-cell immunity against specific antigens can be measured by skin tests against antigens to which the individual had been exposed: "recall antigens." These include antigens from vaccines (e.g., mumps, tetanus) or from microorganisms with which the person had a previous active infection (e.g., *Candida*). An adequate T-cell immunity results in a positive delayed hypersensitivity skin test reaction.

If the tests do not identify the immune deficiency, more esoteric tests are offered by reference laboratories or research

TABLE 9-7 LABORATORY EVALUATION OF IMMUNODEFICIENCIES

FUNCTION TESTED	LABORATORY TEST	INTERPRETATION OF TEST
Tests of Humoral Immune Function		
Antibody production	Total immunoglobulin levels	Presence of antibody-producing B cells
	Levels of isohemagglutinins	Capacity to produce specific IgM antibodies
	Levels of antibodies against vaccines—especially diphtheria and tetanus toxoids	Capacity to produce specific IgG antibodies
B-cell numbers	Numbers of lymphocytes with surface immunoglobulin	Presence of circulating B cells
Tests of Cellular Immune Function		
Delayed hypersensitivity	Skin test reaction against previously encountered antigens—especially *Candida albicans* or tetanus toxoid	Presence of antigen-responsive T cells and skin test cellular interactions (e.g., lymphokine activity and macrophage function)
T-cell numbers	Numbers of T cells forming rosettes with sheep erythrocytes or expressing membrane CD3 or CD11 antigen	Presence of circulating T cells
T-cell proliferation in vitro	Proliferative response to nonspecific mitogens (e.g., phytohemagglutinin)	Capacity of all T cells to divide in response to nonspecific stimulation (mitogens)
	Proliferative response to antigens (e.g., tetanus toxoid)	Capacity of antigen-reactive T cells to respond to antigen

laboratories. These include quantification of individual complement components, in vitro proliferation (mitogenic response) of T or B cells to antigens or nonspecific mitogens, and a variety of tests of phagocyte function (e.g., nitroblue tetrazolium test [NBT] for hexose-monophosphate shunt activity, specific tests for phagocytosis, chemotaxis, or bacterial killing).

Replacement Therapies for Immune Deficiencies

Gamma-Globulin Therapy

Individuals with B-cell deficiencies that cause hypogammaglobulinemia or agammaglobulinemia usually can be treated successfully with administration of gamma globulins, which are antibody-rich fractions prepared from plasma pooled from large numbers of donors. Administration of gamma globulin temporarily replaces the individual's antibodies. Antibodies from these preparations are removed slowly from the person's blood, with half of the antibodies being removed by 3 to 4 weeks. Thus individuals must be treated repeatedly to maintain a protective level of antibodies in the blood.

Commercial gamma-globulin preparations are usually administered intramuscularly or by intravenous (IV) infusion. The dosage varies among individuals and is primarily determined by body weight. The schedule and dosage are also determined according to titers of circulating immunoglobulins and the incidence of infections in the individual. Commercial gamma-globulin preparations usually contain small amounts of IgM and IgA. Individuals with selective IgA deficiency occasionally develop allergic reactions to IgA in gamma-globulin preparations.[43]

Individuals who need larger amounts of IgM or IgA can be given fresh frozen plasma in monthly IV infusions. Complications associated with plasma therapy include the potential transmission of hepatitis or AIDS. The plasma is irradiated to destroy immunocompetent T cells and to avoid GVHD in individuals with accompanying T-cell deficiencies. Administration of fresh frozen plasma is successful in individuals with WAS (IgM deficient), AT (IgA deficient), or complement component deficiencies.

Transplantation and Transfusion

Several primary immune deficiencies originate from defects in lymphoid stem cells that interfere with their development in the primary lymphoid organs. Some of these (e.g., SCID, WAS, leukocyte adhesion defect) have benefited from replacement of stem cells through transplantation of bone marrow, umbilical cord cells, or other cell populations that are rich in stem cells.

The source of donor cells, particularly bone marrow, may contain a mixed population of stem cells and more mature T lymphocytes. In order to avoid GVHD, the preferred donor would be matched with the recipient for HLA antigens. Several other diseases involving depletion of the bone marrow (i.e., aplastic anemia, leukemia requiring eradication of tumor cells in the marrow) also are treated by bone marrow transplantation. At least 75% of bone marrow transplants between individuals who are matched for HLA-A, HLA-B, HLA-C, and HLA-DR are accepted. In immunocompetent recipients, most rejections of HLA-matched transplants occur because of recognition of minor histocompatibility antigens by individuals who have received multiple blood transfusions and are, as a result, sensitized against those antigens, which are not evaluated in tissue typing. For stem cell transplants, differences in minor histocompatibility antigens may lead to GVHD. Because HLA antigens are inherited in a codominant fashion, the preferred donor would be a relative, especially a sibling. Although the donor is not tested for minor histocompatibility antigens, the use of a close relative also would minimize differences at those loci.

Chronic GVHD appears in 30% to 50% of transplants between HLA-matched siblings and 60% to 70% of transplants between unrelated donors. Symptoms may appear about 4 to 7 months after the transplant, but may begin much earlier or later. Depletion of T cells from bone marrow before transplantation significantly lowers the incidence of both acute and chronic GVHD. One method of doing this is to infuse the graft with monoclonal antibody against plasma membrane antigens found only on mature T cells. Another method is to use fetal tissue as the graft. For example, fetal liver, which contains stem

cells but not immunocompetent lymphocytes, is sometimes grafted in place of bone marrow if an HLA-matched donor cannot be found.

Steroids are commonly used to suppress GVHD in recipients of bone marrow transplants performed to treat certain malignancies or primary immune deficiencies. In cases where steroids are ineffective, promising new data support the use of **mesenchymal stem cells (MSCs)**.[44] Stem cells are relatively undifferentiated cells and can be obtained from a variety of sources (e.g., embryos, bone marrow, adult tissues). MSCs are present in all adult tissues. These particular stem cells undergo differentiation into other cell types and, more importantly, have potent immunosuppressive properties. Several recent clinical trials have demonstrated complete suppression of GVHD in a large number of recipients of MSCs.[45]

One therapy for deficiency diseases in which the individual lacks a thymus or thymic function (e.g., DiGeorge syndrome, ataxia-telangiectasia, or chronic mucocutaneous candidiasis) is reconstitution of thymic function. The procedure involves transplantation of fetal thymic tissue, which lacks immunocompetent T cells, or thymic epithelial cells (the cells that produce the thymic hormones) from which mature T cells have been removed. In some individuals transplantation increases the number of circulating mature T cells, but in most cases improvement is only temporary.

Enzymatic defects that cause SCID (e.g., adenosine deaminase deficiency) have been treated successfully with transfusions of glycerol frozen-packed erythrocytes. The donor erythrocytes contain the needed enzyme and can, at least temporarily, provide sufficient enzyme for normal lymphocyte function. An alternative method is administration of purified adenosine deaminase that has been stabilized with polyethylene glycol (PEG).

Treatment with Soluble Immune Modulators

The administration of soluble materials that affect lymphocyte function can restore T-cell function, especially in individuals with WAS or chronic mucocutaneous candidiasis. Successful for some individuals is the use of transfer factor, a low-molecular-weight nucleoprotein prepared from lymphocyte lysates, which can confer specific reactivity against certain antigens. Thymosin, a thymic hormone, also has been used, although with limited success. Cytokine therapy also has been effective in some cases of chronic granulomatous disease.

Gene Therapy

The first successful therapeutic replacement of defective genes was performed in two girls with SCID caused by an ADA deficiency.[46] The normal gene for ADA was cloned and inserted into a retroviral vector.[47] The gene for ADA replaced some retroviral genes, resulting in a virus that carried the normal human gene but did not cause disease. The virus was used to infect bone marrow stem cells from these children. The retrovirus inserted the normal ADA gene into the individuals' genetic material. The genetically altered stem cells were infused into the children, resulting in reconstitution of their immune systems. Gene therapy has now been used to successfully reconstitute the immune systems in individuals with ADA deficiency, X-linked SCID, and WAS.[48] However, the treatment trials have not been without some major complications, such as leukemia, that raise questions concerning the use of retroviral vectors for the insertion of new genes.

SUMMARY REVIEW

Hypersensitivity: Allergy, Autoimmunity, and Alloimmunity

1. Inappropriate immune responses are misdirected responses against the host's own tissues (autoimmunity); directed responses against beneficial foreign tissues, such as transfusions or transplants (alloimmunity); exaggerated responses against environmental antigens (allergy); or insufficient responses to protect the host (immune deficiency).
2. Allergy, autoimmunity, and alloimmunity are collectively known as hypersensitivity reactions.
3. Mechanisms of hypersensitivity are classified as type I (IgE-mediated) reactions, type II (tissue-specific) reactions, type III (immune complex–mediated) reactions, and type IV (cell-mediated) reactions.
4. Hypersensitivity reactions can be immediate (developing within minutes to a few hours) or delayed (developing within several hours or days).
5. Anaphylaxis, the most rapid immediate hypersensitivity reaction, is an explosive reaction that occurs within minutes of reexposure to the antigen and can lead to cardiovascular shock.
6. Allergens are antigens that cause allergic responses.
7. Type I (IgE-mediated) reactions are mediated through the binding of IgE to Fc receptors on mast cells and cross-linking of IgE by antigens that bind to the Fab portions of IgE. Cross-linking causes mast cell degranulation and the release of histamine (the most potent mediator) and other inflammatory substances.
8. Histamine enhances the chemotaxis of eosinophils into sites of type I allergic reactions.
9. Atopic individuals tend to produce higher quantities of IgE and to have more Fc receptors for IgE on their mast cells.
10. Type II (tissue-specific) reactions are caused by five possible mechanisms: complement-mediated lysis, opsonization and phagocytosis, neutrophil-mediated tissue damage, antibody-dependent cell-mediated cytotoxicity, and modulation of cellular function.
11. Type III (immune complex–mediated) reactions are caused by the formation of immune complexes that are deposited in target tissues, where they activate the complement cascade, generating chemotactic fragments that attract neutrophils into the inflammatory site. Neutrophils release lysosomal enzymes that result in tissue damage.

SUMMARY REVIEW—cont'd

12. Intermediate-sized immune complexes are the most likely to have severe pathologic consequences.
13. Immune complex disease can be a systemic reaction, such as serum sickness, or a localized response, such as the Arthus reaction.
14. Type IV (cell-mediated) reactions are caused by either cytotoxic T lymphocytes (Tc cells) or lymphokine-producing Th1 cells.
15. Typical allergens include pollen, molds and fungi, certain foods (milk, eggs, fish), animals, certain drugs, cigarette smoke, and house dust.
16. Clinical manifestations of allergic reactions usually are confined to the areas of initial intake or contact with the allergen. Ingested allergens induce gastrointestinal symptoms, airborne allergens induce respiratory tract or skin manifestations, and contact allergens induce allergic responses at the site of contact.
17. Autoimmunity is a breakdown of immunologic homeostasis, the immune system's tolerance of self-antigens. Central tolerance develops during the embryonic period. Peripheral tolerance is maintained in secondary lymphoid organs by regulatory T lymphocytes or antigen-presenting dendritic cells.
18. Autoimmune disease can be caused by the exposure of a previously sequestered antigen, the development of a neoantigen, the complications of infectious disease, the emergence of a forbidden clone of lymphocytes, or the consequence of ineffective peripheral tolerance.
19. Alloimmunity is the immune system's reaction against antigens on the tissues of other members of the same species.
20. Alloimmune disorders include transient neonatal disease, in which the maternal immune system becomes sensitized against antigens expressed by the fetus; transplant rejection; and transfusion reactions, in which the immune system of the recipient of an organ transplant or blood transfusion reacts against foreign antigens on the donor's cells.
21. SLE is a chronic, multisystem, inflammatory disease and is one of the most serious of the autoimmune disorders. SLE is characterized by the production of a large variety of autoantibodies.
22. Hyperacute graft rejection (preexisting antibody) is immediate and rare, acute rejection is cell mediated and occurs days to months after transplantation, and chronic rejection is caused by inflammatory damage to endothelial cells as a result of a weak cell-mediated reaction.
23. Red blood cell antigens may be the targets of autoimmune or alloimmune reactions. The most important of these, because they provoke the strongest humoral immune response, are the ABO and Rh systems.

Deficiencies in Immunity

1. Disorders resulting from immune deficiency are the clinical sequelae of impaired function of components of the immune or inflammatory response, phagocytes, or complement.
2. Immune deficiency is the failure of mechanisms of self-defense to function in their normal capacity.
3. Immune deficiencies are either congenital (primary) or acquired (secondary). Primary immune deficiencies are caused by genetic defects that disrupt lymphocyte development, whereas secondary immune deficiencies are secondary to disease or other physiologic alterations.
4. The clinical hallmark of immune deficiency is a propensity to unusual or recurrent severe infections. The type of infection usually reflects the immune system defect.
5. The most common infections in individuals with defects of the cell-mediated immune response are fungal and viral, whereas infections in individuals with defects of the humoral immune response or complement function are primarily bacterial.
6. Defects in B-cell function are diverse, ranging from a complete lack of the human bursal equivalent function, the lymphoid organs required for B-cell maturation (as in Bruton's agammaglobulinemia), to deficiencies in a single class of immunoglobulins (e.g., selective IgA deficiency).
7. DiGeorge syndrome (congenital thymic aplasia or hypoplasia) is characterized by complete or partial lack of the thymus (resulting in depressed T-cell immunity) and the parathyroid glands (resulting in hypocalcemia) and the presence of cardiac anomalies.
8. SCID is a total lack of T-cell function and a severe (either partial or total) lack of B-cell function. SCID can result from mutations in critical enzymes (ADA deficiency, PNP deficiency), in cytokine receptors (X-linked SCID, JAK3 deficiency, IL-7 receptor deficiency), or in antigen receptors (RAG-1/RAG-2 deficiencies, CD45 deficiency, CD3 deficiency, ZAP-70 deficiency). Other combined defects may result from deficiencies in antigen-presenting molecules (bare lymphocyte syndrome), cytoskeletal proteins (WAS), or DNA repair (ataxia-telangiectasia).
9. Almost any portion of the complement cascade may be defective. The most severe defect is C3 deficiency, which results in recurrent life-threatening bacterial infections. Defects in proteins of the membrane attack complex usually result in unusual disseminated infections with bacteria of the *Neisseria* spp.
10. Defects in phagocyte function, which include insufficient numbers of phagocytes or defects of chemotaxis, phagocytosis, or killing, can result in recurrent life-threatening infections such as septicemia and disseminated pyogenic lesions.
11. Acquired immunodeficiencies are caused by superimposed conditions, such as aging, malnutrition, infections, malignancies, physical or psychologic trauma, environmental factors, some medical treatments, or other diseases.
12. Deficiencies in immunity usually are treated by replacement therapy. Deficient antibody production is treated by replacement of missing immunoglobulins with commercial gamma-globulin preparations. Lymphocyte deficiencies are treated with the replacement of host lymphocytes with transplants of bone marrow, fetal liver, or fetal thymus from a donor.

CHAPTER OUTLINE

For most of human history infectious disease was the primary disease-related cause of death; bubonic/pneumonic plague (The Black Death) of the 14th century killed more than 50 million people worldwide, the Spanish influenza of 1918 to 1919 killed between 50 and 100 million people within 2 years, and it was not uncommon for frequent regional outbreaks of diseases such as smallpox or cholera to kill hundreds of thousands of people.[1] Modern health care has shown great progress in preventing and treating infectious diseases through the success of public health initiatives, vaccination programs, and the use of antibiotics. The greatest progress has occurred in developed countries where death from infections is most common among those with debilitating diseases, nutritional deficiencies, or immunosuppression. Death from influenza and pneumonia was the eighth leading cause of death in the United States in 2011.[2] As a result of these initiatives, smallpox has been eradicated from the globe (the last reported case was in 1975 in Somalia), measles is almost eradicated in the Western Hemisphere, and many diseases, such as tuberculosis and polio, are on the decline. Although the advent of sanitary living conditions, clean water, uncontaminated food, vaccinations, and antimicrobials had improved the health in many countries, infectious disease remains a significant threat to life in many parts of the world, including India, Africa, and Southeast Asia. The impact of differences in economic prosperity is significant.[2a] The leading causes of death in high-income countries were heart disease, stroke, and other cerebrovascular diseases; cancers of the respiratory tract; and Alzheimer disease and other dementias, with lower respiratory tract infections (influenza and pneumonia) the sole infectious cause in the top 10. In low-income countries, where the implementation of

TABLE 10-1 EXAMPLES OF EMERGENT INFECTIONS

YEAR	DISEASE	CAUSATIVE AGENT	SITE OF DISCOVERY
1955	Orally transmitted non-A, non-B infectious hepatitis	Hepatitis E virus	India
1967	Viral hemorrhagic fever	Marburg virus	Germany
1969	Lassa fever	Lassa virus	Nigeria
1976	Ebola hemorrhagic fever	Ebola virus	Zaire and Sudan
1976	Legionnaires disease	*Legionella pneumophila*	United States
1978	Toxic shock syndrome	Toxin-producing strains of *Staphylococcus* spp.	United States
1981	Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus	United States
1982	Lyme disease	*Borrelia burgdorferi*	Northeast United States
1982	Hemolytic-uremic syndrome, bloody diarrhea	*Escherichia coli* 0157:H7	United States, Japan
1983	Peptic ulcer disease	*Helicobacter pylori*	Australia
1986	Roseola	Human herpesvirus 6	United States
1989	Non-A, non-B infectious hepatitis, hepatocellular carcinoma	Hepatitis C virus	United States
1992	Cholera	*Vibrio cholerae* 0139	Indonesia
1993	Hemorrhagic fever with renal syndrome	Hantavirus	Korea
1994	Kaposi sarcoma	Human herpesvirus 8	United States
1994	Encephalitis transmitted from horses to humans	Hendra virus	Australia
1995	Bovine spongiform encephalopathy (BSE or "mad cow" disease)	Prion, variant of Creutzfeldt-Jakob disease agent	United Kingdom
1999	Encephalitis transmitted from pigs to humans	Nipah virus	Malaysia
2003	SARS (severe acute respiratory syndrome)	SARS-associated coronavirus	China
2006	Lymph node infection in individuals with chronic granulomatous disease	*Granulobacter bethesdensis*	United States
2007	New strain of Ebola hemorrhagic fever	*Bundidugyo ebolavirus*	Uganda
2007	Encephalitis and myocarditis	Saffold virus	United States
2013	Influenza A strain	Avian virus	China

programs to prevent infection has been less effective, 6 of the top 10 causes of death are caused by infection: lower respiratory tract infections (#1), diarrheal diseases (#2), HIV/AIDS (#3), malaria (#5), tuberculosis (#7), and neonatal infections (#10).

Despite the widespread implementation of progressive public health and immunization policies, infectious disease remains a significant cause of morbidity and mortality because of the emergence of previously unknown infections, the reemergence and spread of old infections that were thought to be under control, and the development of infectious agents that are resistant to multiple antibiotics. The causes for these occurrences are numerous and include the following:

- Vast and rapid urbanization in many areas of the world, resulting in a breakdown in public health programs and a more rapid spread of infection
- Poverty and social inequality
- War and famine
- Global travel, allowing more rapid spread of disease from isolated areas to virtually any point around the world in a few hours
- Globalization of the food supply
- Human encroachment into wilderness areas, resulting in contact with previously sequestered infectious agents
- Practice of prescribing antibiotics excessively or not taking antibiotics for a complete course of therapy, or, even when appropriately used, facilitates emergence of antibiotic-resistant microorganisms
- Decreases in federal research budgets to study infectious disease
- Denial of a problem by governments, allowing infections to spread in an uncontrolled way
- Diminished use of effective insecticides
- Increased global warming, allowing insect vectors to spread into and breed in areas that were previously too cool for them

EMERGING INFECTIONS

The emergence of previously unknown infections is not a new event in human history. However, the current rate may be unprecedented.[3] Within 1 generation, more than 40 previously unknown infections have arisen, and some examples are presented in Table 10-1. Several have extremely high mortality rates of more than 50% including severe acute respiratory syndrome (SARS) (in those older than 65 years), Ebola virus, Marburg virus, "mad cow" disease, Nipah virus (up to 75%), and acquired immunodeficiency syndrome (AIDS) (almost 100% in untreated persons). However, most either spread very slowly (e.g., AIDS) or initially appear in relatively isolated areas and are effectively controlled by quarantine (e.g., Ebola virus). Although none of these infections has developed into the worldwide scourges portrayed in the Hollywood movies *Andromeda Strain* and *I Am Legend*, the potential of reversion to more rapidly spreading variants is a concern of public health agencies worldwide.

Concurrently, the incidence and spread of at least 20 previously known infections are increasing. A new strain of cholera that arose in Indonesia in 1961 has spread to Africa and in 1991 to South America. Malaria, dengue fever, and yellow fever are reemerging in areas where they had been eliminated or were unknown. The incidence of tuberculosis is increasing in countries that had reported declines and has risen by almost 33% between the mid-1980s and early 1990s. Diphtheria has

reemerged as a major health issue in Russia. In 1994 plague was reported in India after being dormant for a generation. War has led to outbreaks of Marburg hemorrhagic fever during civil war in Angola during 1975 to 2002 and cholera in the Democratic Republic of the Congo among Rwandan refugees in 1994; about 50,000 refugees died from a combination of cholera and shigella dysentery. The spread of cholera, yellow fever, and epidemic meningococcal disease has rebounded. Decreased insect control programs that were previously successful have led to spread of vector-borne diseases: African trypanosomiasis, dengue hemorrhagic fever, and malaria. Although the United States is relatively free of most of these diseases, the effects of global warming and relaxed control of vectors may result in resurgence. It should not be forgotten that in 1793 a yellow fever outbreak in Philadelphia killed 2000 of the city's 55,000 inhabitants and forced the U.S. government to abandon the city until the outbreak ceased. To date, outbreaks of locally acquired malaria in the United States have been rare. However, West Nile Virus, also spread by mosquitoes, appeared initially in the Western Hemisphere in 1999 in the New York City area and has spread throughout the continental United States, Canada, and Mexico.[4]

Many common and reemerging infections have become antibiotic and drug resistant. *Streptococcus pneumoniae,* a common cause of otitis media, pneumonia, and bacteremia, has been treated routinely and successfully with penicillin. Now at least 25% of isolates are penicillin resistant, and some are resistant to multiple antibiotics. Multiple antibiotic-resistant forms of *Staphylococcus aureus,* a primary cause of infections of wounds, surgical incisions, and catheter insertion, are endemic in some hospitals. Some forms of this microorganism once were sensitive only to a single antibiotic, vancomycin, and now have become vancomycin-resistant. Antimicrobial resistance is now routinely observed in tuberculosis, diarrheal diseases, hospital-acquired infections, malaria, meningitis, respiratory tract infections, sexually transmitted infections (STIs), and human immunodeficiency virus (HIV).

Added to this collage of microbiologic dangers is the rising risk of bioterrorism. Agents such as smallpox, anthrax, and plague are continuing threats to public health and safety. All healthcare providers should have information about the characteristics and clinical manifestations of these biologic agents. The theoretical threat of bioterrorism became real in 2001 when letters containing anthrax were mailed; 22 individuals became infected and 5 died.

MICROORGANISMS AND HUMANS: A DYNAMIC RELATIONSHIP

For many microorganisms the human body is a hospitable site in which to grow and flourish because of its sufficient nutrients and appropriate conditions of temperature and humidity. In many cases a symbiotic relationship exists, in which both humans and microorganisms benefit (Box 10-1). These microorganisms make up the *normal microbiome*—the resident microorganisms found in different parts of the body, including the skin, mouth, gastrointestinal tract, respiratory tract, and genital tract[5] (see Chapter 7). For instance, the normal bacterial microbiome of the human gut is provided with nutrients from ingested food and in exchange produce enzymes that facilitate the digestion and use of many of the more complex molecules found in the human diet, produce antibacterial factors (e.g., bacteriocins, colicins) that prevent colonization by pathogenic microorganisms, and produce usable metabolites (e.g., vitamin K, B vitamins). This beneficial homeostasis is normally maintained through the physical integrity of the gut and other mechanisms that sequester these microorganisms on the mucosal surface.

BOX 10-1 THE MANY RELATIONSHIPS BETWEEN HUMANS AND MICROORGANISMS

Symbiosis: Benefits only the human; no harm to the microorganism
Mutualism: Benefits the human and the microorganism
Commensalism: Benefits only the microorganism; no harm to the human
Pathogenicity: Benefits the microorganism; harms the human
Opportunism: A situation in which benign microorganisms become pathogenic because of decreased human host resistance

MICROORGANISMS AND INFECTIONS

Process of Infection

The symbiotic relationship with the normal flora can be breached as a result of injury that compromises the physical protective barriers. Damage to the intestinal tract releases intestinal bacteria into the bloodstream, potentially leading to sepsis, shock, and death. Cuts in the skin may allow normally noninfectious bacteria (e.g., *S. aureus*) to cause local infections (e.g., abscesses, boils) and invade further and infect various organs. Symbiosis is also maintained by the immune and inflammatory systems. If those systems are compromised, many microorganisms will leave their normal sites and cause infection elsewhere in the body. Individuals with immune deficiencies easily become infected with *opportunistic microorganisms,* which normally would not cause disease but seize the opportunity to do so when a person's defensive systems are weakened or suppressed (see Chapter 9).

Unlike opportunistic infectious agents, *true pathogens* have devised means to circumvent the individual's defenses (discussed in Chapters 7 and 8) and directly cause infection. Successful infection with these agents is usually dependent on adequate numbers of microorganisms rather than compromise of the host's defenses.

From the perspective of the microorganisms that cause disease, the infectious process undergoes four separate stages of progression: colonization, invasion, multiplication, and spread.

Colonization

Infectious microorganisms usually exist in reservoirs, such as the environment (e.g., contaminated water, soil), animals, or another human who is infected or in a noninfectious state within the individual's normal microbiome. An individual may

obtain an infectious microorganism from a reservoir by several means.

Infections contracted from animal reservoirs (zoonotic infections) may be transmitted by direct contact (e.g., transmission of the rabies virus through bites) or indirectly by means of vectors (e.g., insects). Mechanical vectors (e.g., housefly) passively transfer microorganisms from a contaminated site to an individual. Biologic vectors (e.g., fleas, lice, mosquitoes, ticks) transmit infectious microorganisms through bites and stings. Individuals can also become infected by direct exposure to contaminated materials, such as fecal-oral transmission through food or water (e.g., salmonella food poisoning, cholera, hepatitis A infection, polio, rotavirus infection) or soil (e.g., tetanus).

Human-to-human transmission may occur through aerosolized microorganisms in droplets (e.g., produced by coughing or sneezing), which is the primary means of transmission for respiratory tract infections (e.g., agents that cause the common cold, influenza, streptococcal sore throat, bacterial meningitis). Other infectious agents require physical contact (e.g., sexual contact, blood transfusion, direct contact with contaminated clothes or bandages, entrance through wounds or openings in the skin). Direct contact is usually required for transmission of sexually transmitted infections (STIs), hepatitis B virus, cytomegalovirus (CMV), herpes simplex virus, or warts. Some microorganisms have the capacity to spread from mother to child across the placenta (e.g., *Treponema pallidum, Listeria monocytogenes,* CMV, *Toxoplasma gondii*), ascending the birth canal or during delivery (e.g., group B *Streptococcus, Escherichia coli, Chlamydia trachomatis, Neisseria gonorrhoeae,* hepatitis B virus, HIV, *Candida albicans*), or through the breast milk (e.g., *S. aureus*). This is classified as *vertical transmission*, whereas spread from one person to another is *horizontal transmission*. In a very few instances, the infectious agent may develop airborne transmission. Effective *airborne transmission* may occur by the prolonged presence of aerosolized droplets released by respiration, exercise, or other body activity and has been observed with SARS, tuberculosis, norovirus, and smallpox.

After deposition in receptive environments for colonization, the microorganism stabilizes the adherence to the tissue through specific surface receptors. For instance, infectious agents that cause respiratory tract infections specifically bind to molecules found on respiratory epithelium. Adherence helps protect the microorganism from removal by mechanical nonspecific forces, such as coughing of respiratory mucus. The specificity of adherence results in a particular microorganism being limited to the locations where infections can occur **(tissue tropism),** such as the confinement of common cold viruses to producing respiratory tract infections.

Invasion

Once colonization has occurred the infectious agent can invade the surrounding tissue and, in many cases, other sites in the individual. Successful infectious agents have developed mechanisms to penetrate the tissues and evade the host's nonspecific and specific defenses (inflammation and immunity). Many of these are discussed throughout this chapter.

Multiplication

Within the warm and nutrient-filled environment of human tissue, most microorganisms undergo rapid multiplication with production of many new infectious progeny. Viral pathogens replicate within infected cells, and some bacteria are intracellular pathogens and replicate in macrophages and other cells.

Spread

Many successful pathogens produce localized infections without spread to other regions of the body (e.g., *Vibrio cholerae*). Others, however, are highly invasive and may enter the lymphatics, blood, and internal organs. Successful spread relies on a variety of virulence factors, including adhesion molecules, toxins, and protection against the individual's inflammatory and immune systems. Fungi, in particular, are opportunistic. In an individual with an intact immune system, the microorganism remains localized, whereas the infection may rapidly spread if the individual's immune or inflammatory systems are compromised.

Clinical Infectious Disease

From the perspective of the individual who is infected, the clinical process occurs in the following four distinct stages:

- *Incubation period*—the period from initial exposure to the infectious agent and the onset of the first symptoms, during which the microorganism has entered the individual, undergone initial colonization, and begun multiplying, but is yet in insufficient numbers to cause symptoms; this period may last from several hours to years
- *Prodromal stage*—the occurrence of initial symptoms, which are often very mild and include a feeling of discomfort and tiredness
- *Invasion period*—the pathogen is multiplying rapidly, invading farther and affecting the tissues at the site of initial colonization as well as other areas; the immune and inflammatory responses are being triggered; development of symptoms specifically related to the pathogen and symptoms related to the ongoing protective inflammatory response
- *Convalescence*—in most instances, the individual's immune and inflammatory systems have successfully removed the infectious agent, and symptoms decline; alternatively, the disease may be fatal or may enter a latency phase with resolution of symptoms until reactivation at a later time

Clinical manifestations of infectious disease vary, depending on the pathogen, the organ system affected, and the severity. Effects of infection may be acute, chronic, secondary to the immune and inflammatory responses, or a consequence of bacterial toxins or viral injury. Manifestations can arise directly from the infecting microorganism or its products; however, the majority of manifestations result from the host's inflammatory and immune responses. Infectious diseases typically begin with the nonspecific or general symptoms of fatigue, malaise, weakness, and loss of concentration. Generalized aching and loss of appetite are common complaints. However, the hallmark of most infectious diseases is fever.

Fever is not failure of the body to regulate temperature; rather, body temperature is being regulated at a higher level than

TABLE 10-2 HISTORIC EXAMPLES OF PANDEMICS

YEAR	CAUSE	SITE	ESTIMATED DEATHS
1347-1352	Bubonic plague (black death) (70% mortality rate)	Europe (worldwide)	50 million (a third of Europe's population); up to 100 million worldwide
1775-1782	Smallpox (35% mortality rate)	North America	>150,000
1829-1851	Cholera	Europe	Several hundred thousands
1914-1918	Typhus *(Rickettsia prowazekii),* spread by body lice, 40% mortality rate	Europe during WWI	9 million
1916	Polio	United States	6000
1918-1919	Influenza (Spanish flu)	United States, became worldwide	20-40 million
1981-?	AIDS	Worldwide	>25 million
2009	Influenza H1N1	Worldwide	284,000

normal. Body temperature is regulated by nervous system feedback to the hypothalamus, which functions as a central thermostat (see Chapter 16). A large number of agents (pyrogens) can produce fever. In current classification, those pyrogens derived from outside the host are termed **exogenous pyrogens** and those produced by the individual are termed **endogenous pyrogens.** There is little evidence that exogenous pyrogens cause fever directly. Such pyrogens indirectly affect the hypothalamus through endogenous pyrogens released by cells of the host. A number of cytokines have been identified as endogenous pyrogens. They are interleukin-1 and interleukin-6 (IL-1 and IL-6, respectively), interferon (IFN), tumor necrosis factor (TNF), and others (see Figure 16-8). These cytokines seem to raise the thermoregulatory set point through stimulation of prostaglandin synthesis and turnover in both thermoregulatory (brain) and nonthermoregulatory (peripheral) tissue. Although it is generally believed that fever has a beneficial value in infection, the molecular mechanism behind the beneficial effects has not been established. Many investigators, however, consider fever as an adaptive host-defense response.

Several factors influence the capacity of a pathogen to cause disease.

- *Communicability:* The ability to spread from one individual to others and cause disease: measles and pertussis spread very easily; HIV is of lower communicability
- *Immunogenicity:* The ability of pathogens to induce an immune response
- *Infectivity:* The ability of the pathogen to invade and multiply in the host
- *Mechanism of action:* How the microorganism damages tissue
- *Pathogenicity:* The ability of an agent to produce disease—success depends on communicability, infectivity, extent of tissue damage, and virulence
- *Portal of entry:* The route by which a pathogenic microorganism infects the host: direct contact, inhalation, ingestion, or bites of an animal or insect
- *Toxigenicity:* The ability to produce soluble toxins or endotoxins, factors that greatly influence the pathogen's degree of virulence
- *Virulence:* The capacity of a pathogen to cause severe disease—for example, measles virus is of low virulence; rabies virus is highly virulent

Infectious diseases are also classified by their prevalence and spread within the community.

- *Endemic:* Diseases with relatively high, but constant, rates of infection in a particular population
- *Epidemic:* The number of new infections in a particular population greatly exceeds the number usually observed
- *Pandemic:* An epidemic that spreads over a large area, such as a continent or worldwide (Table 10-2)

Classes of Infectious Microorganisms

Infectious disease can be caused by microorganisms that range in size from 20 nm (poliovirus) to 10 m (tapeworm). Classes of pathogenic microorganisms and their characteristics are summarized in Table 10-3 and discussed in detail in the following sections.

Bacterial Infection

Bacteria are prokaryotic unicellular microorganisms with no nuclei, mitochondria, or membrane-bound organelles. They are generally divided into several groups.

- *"True bacteria"* divide by binary fission and may have a variety of morphologies, including cocci (spherical), bacilli (rod shaped), vibrios (comma-shaped rods), or spirilla (twisted, rod shaped). Most disease-causing bacteria fall into this classification.
- *Filamentous bacteria* may have branching, mycelium-like structures that resemble fungi. Examples include the mycobacteria *Mycobacterium tuberculosis* and *Mycobacterium leprae* that respectively cause tuberculosis and leprosy.
- *Spirochetes* are flexible spiral filaments that are motile. Most are anaerobic. Pertinent examples include *Borrelia recurrentis* (relapsing fever), *T. pallidum* (syphilis), and *Borrelia burgdorferi* (Lyme disease).
- *Mycoplasma* lack a rigid cell wall and are small and pleomorphic. They are the smallest and most simple members of the bacteria. *Mycoplasma pneumoniae* causes atypical pneumonia, and *Mycoplasma genitalium* is a suspected cause of urethritis and pelvic inflammatory disease.
- *Rickettsia* are strict intracellular parasites that can be rod-shaped, spherical, or pleomorphic. They are typically spread by insect vectors and cause Rocky Mountain spotted fever *(Rickettsia rickettsii)* and typhus *(Rickettsia prowazekii).*

TABLE 10-3 CLASSES OF ORGANISMS INFECTIOUS TO HUMANS

CLASS	SIZE	SITE OF REPRODUCTION	EXAMPLE
Virus	20-300 nm	Intracellular	Poliomyelitis
Chlamydiae	200-1000 nm	Intracellular	Urethritis
Rickettsiae	300-1200 nm	Intracellular	Rocky Mountain spotted fever
Mycoplasma	125-350 nm	Extracellular	Atypical pneumonia
Bacteria	0.8-15 mcg	Skin	Staphylococcal wound infection
		Mucous membranes	Cholera
		Extracellular	Streptococcal pneumonia
		Intracellular	Tuberculosis
Fungi	2-200 mcg	Skin	Tinea pedis (athlete's foot)
		Mucous membranes	Candida (e.g., thrush)
		Extracellular	Sporotrichosis
		Intracellular	Histoplasmosis
Protozoa	1-50 mm	Mucosal	Giardiasis
		Extracellular	Sleeping sickness
Helminths	3 mm to 10 m	Intracellular	Trichinosis
		Extracellular	Filariasis

- *Chlamydia* are also strict intracellular parasites, but with more complex intracellular life cycles. The primary chlamydial pathogen is *Chlamydia trachomatis,* which causes the most common bacterial sexually transmitted infection (pelvic inflammatory disease) and eye infections (conjunctivitis).

Bacteria are also categorized as gram-negative or gram-positive. Gram-negative bacteria do not retain crystal violet dye in the Gram-staining process whereas gram-positive bacteria do retain crystal violet dye. Gram-negative bacteria also have a lipopolysaccharide (LPS) coat in the outer membrane, which consists of lipid A, a core polysaccharide, and O antigen. The LPS coat is also known as endotoxin (see Figure 10-1 and further discussion on p. 306). Common bacterial pathogens are listed in Table 10-4.

Transmission and Colonization. Transmission of bacterial infections occurs through the same routes generally described previously. Many pathogenic bacteria normally reside in humans without causing disease, for instance, *Streptococcus pyogenes* (pharyngitis), *S. pneumoniae* (pneumonia, meningitis), *Neisseria meningitidis* (meningitis), and *Haemophilus influenzae* type b (meningitis). In most cases they either are present in inadequate numbers to cause disease or are effectively controlled by local protective mechanisms. Others reside in nature and cause infection after being ingested or entering wounds (e.g., *V. cholerae* [cholera] in contaminated water or *Clostridium tetani* [tetanus] in contaminated soil).

A large number require human-to-human contact, including several that are unstable on environmental surfaces (e.g., *Bordetella pertussis* [whooping cough], *N. gonorrhoeae* [gonorrhea], *T. pallidum* [syphilis]). Even the human-to-human spread of infectious bacteria contracted initially from environmental reservoirs can be facilitated by certain aspects of the disease (e.g., the explosive diarrhea of cholera). Chlamydia, which may be contracted as an STI, can spread from the mother to child during childbirth and may establish long-term intracellular persistence in the newborn.

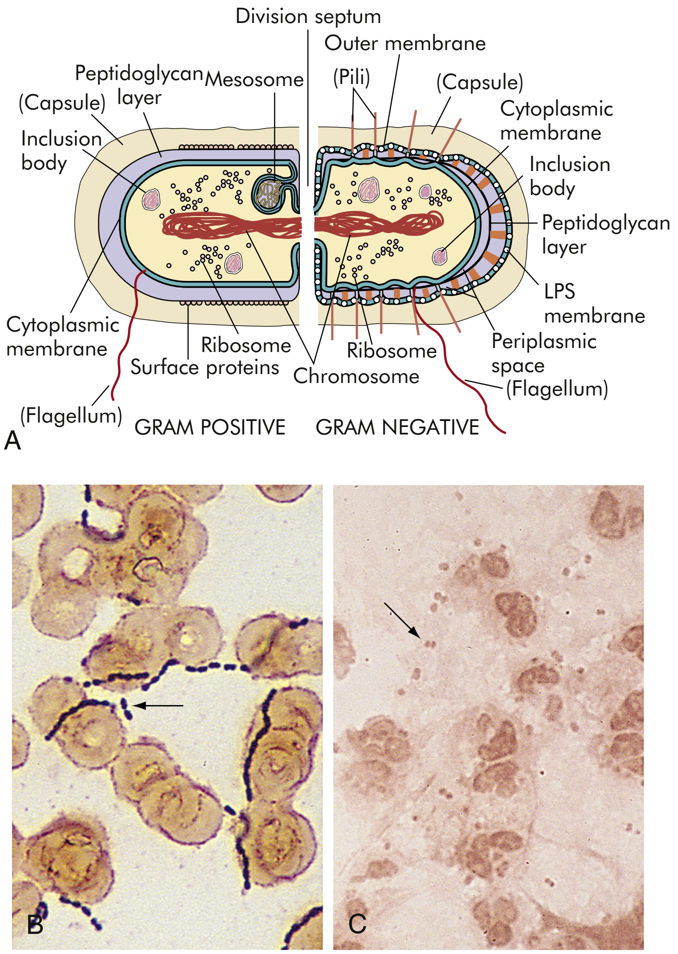

FIGURE 10-1 **Gram-Positive and Gram-Negative Bacteria. A,** The structure of the bacterial cell wall determines its staining characteristics with Gram stain. Gram-positive bacteria have a thick layer of peptidoglycan *(left).* Gram-negative bacteria have a thin peptidoglycan layer and an outer membrane of lipopolysaccharide (LPS) *(right).* **B,** Example of a gram-positive (darkly stained microorganisms, *arrow*) group A *Streptococcus.* This microorganism consists of cocci that frequently form chains. **C,** Example of a gram-negative (pink microorganisms, *arrow*) *Neisseria meningitidis* in cerebrospinal fluid. *Neisseria* form complexes of two cocci (diplococci).

TABLE 10-4 **COMMON BACTERIAL INFECTIONS**

MICROORGANISM	GRAM STAIN	RESPIRATORY PATHWAY	INTRACELLULAR OR EXTRACELLULAR
Respiratory Tract Infections			
Upper Respiratory Tract Infections			
Corynebacterium diphtheriae (diphtheria)	Gram +	Facultative anaerobic	Extracellular
Haemophilus influenzae	Gram –	Facultative anaerobic	Extracellular
Streptococcus pyogenes (group A)	Gram +	Facultative anaerobic	Extracellular
Otitis Media			
Haemophilus influenzae	Gram –	Facultative anaerobic	Extracellular
Moraxella catarrhalis	Gram –	Aerobic	Extracellular
Streptococcus pneumoniae	Gram +	Facultative anaerobic	Extracellular
Lower Respiratory Tract Infections			
Bacillus anthracis (pulmonary anthrax)	Gram +	Facultative anaerobic	Extracellular
Bordetella pertussis (whooping cough)	Gram –	Aerobic	Extracellular
Chlamydia pneumoniae	Not stainable	Aerobic	Obligate intracellular
Escherichia coli	Gram –	Facultative anaerobic	Extracellular
Haemophilus influenzae	Gram –	Facultative anaerobic	Extracellular
Klebsiella pneumoniae	Gram –	Facultative anaerobic	Extracellular
Legionella pneumophila	Gram –	Aerobic	Facultative intracellular
Mycobacterium tuberculosis	Weak gram +	Aerobic	Extracellular
Mycoplasma pneumoniae	Not stainable	Aerobic	Extracellular
Neisseria meningitidis (develops into meningitis)	Gram –	Aerobic	Extracellular
Pseudomonas aeruginosa	Gram –	Aerobic	Extracellular
Streptococcus agalactiae (group B; develops into meningitis)	Gram +	Facultative anaerobic	Extracellular
Streptococcus pneumoniae	Gram +	Facultative anaerobic	Extracellular
Yersinia pestis (plague)	Gram –	Facultative anaerobic	Extracellular
Gastrointestinal Tract Infections			
Inflammatory Gastrointestinal Tract Infections			
Bacillus anthracis (gastrointestinal anthrax)	Gram +	Facultative anaerobic	Extracellular
Clostridium difficile	Gram +	Anaerobic	Extracellular
Escherichia coli 0157:H7	Gram –	Facultative anaerobic	Extracellular
Vibrio cholerae	Gram –	Facultative anaerobic	Extracellular
Vibrio parahaemolyticus	Gram –	Facultative anaerobic	Extracellular
Invasive Gastrointestinal Tract Infections			
Brucella abortus (brucellosis, undulant fever leading to sepsis, heart infection)	Gram –	Aerobic	Intracellular
Campylobacter jejuni	Gram –	Microaerophilic	Extracellular
Francisella tularensis	Gram –	Strict anaerobic	Facultative intracellular
Helicobacter pylori (gastritis and peptic ulcers)	Gram –	Microaerophilic	Extracellular
Listeria monocytogenes (leading to sepsis and meningitis)	Gram +	Aerobic	Intracellular
Salmonella typhi (typhoid fever)	Gram –	Anaerobic	Extracellular
Shigella sonnei	Gram –	Facultative anaerobic	Extracellular
Food Poisoning			
Bacillus cereus	Gram +	Facultative anaerobic	Extracellular
Clostridium botulinum	Gram +	Anaerobic	Extracellular
Clostridium perfringens	Gram +	Anaerobic	Extracellular
Staphylococcus aureus	Gram +	Facultative anaerobic	Extracellular
Sexually Transmitted Infections			
Chlamydia trachomatis (pelvic inflammatory disease)	Not stainable	Aerobic	Intracellular
Neisseria gonorrhoeae (urethritis)	Gram –	Aerobic	Facultative intracellular
Treponema pallidum (spirochete; syphilis)	Gram –	Aerobic	Extracellular
Skin and Wound Infections			
Bacillus anthracis (cutaneous anthrax)	Gram +	Facultative anaerobic	Extracellular
Borrelia burgdorferi (Lyme disease; spirochete)	Gram –	Aerobic	Extracellular

TABLE 10-4 **COMMON BACTERIAL INFECTIONS—cont'd**

MICROORGANISM	GRAM STAIN	RESPIRATORY PATHWAY	INTRACELLULAR OR EXTRACELLULAR
Clostridium tetani (tetanus)	Gram +	Anaerobic	Extracellular
Clostridium perfringens (gas gangrene)	Gram +	Anaerobic	Extracellular
Mycobaterium leprae (leprosy)	Gram + (weakly)	Aerobic	Extracellular
Pseudomonas aeruginosa	Gram −	Aerobic	Extracellular
Rickettsia prowazekii (rickettsia; typhus)	Gram −	Aerobic	Obligate intracellular
Staphylococcus aureus	Gram +	Facultative anaerobic	Extracellular
Streptococcus pyogenes (group A)	Gram +	Facultative anaerobic	Extracellular
Eye Infections			
Chlamydia trachomatis (conjunctivitis)	Not stainable	Aerobic	Obligate intracellular
Haemophilus aegyptus (pink eye)	Gram −	Facultative anaerobic	Extracellular
Zoonotic Infections			
Bacillus anthracis (anthrax)	Gram +	Facultative anaerobic	Extracellular
Brucella abortus (brucellosis, also called undulant fever)	Gram −	Aerobic	Intracellular
Borrelia burgdorferi (spirochete; Lyme disease)	Gram −	Aerobic	Extracellular
Listeria monocytogenes	Gram +	Aerobic	Intracellular
Rickettsia rickettsii (rickettsia; Rocky Mountain spotted fever)	Gram −	Aerobic	Obligate intracellular
Rickettsia prowazekii (rickettsia; typhus)	Gram −	Aerobic	Obligate intracellular
Yersinia pestis (plague)	Gram −	Facultative anaerobic	Extracellular
Nosocomial Infections			
Enterococcus faecalis	Gram +	Facultative anaerobic	Extracellular
Enterococcus faecium	Gram +	Facultative anaerobic	Extracellular
Escherichia coli (cystitis)	Gram −	Facultative anaerobic	Extracellular
Pseudomonas aeruginosa	Gram −	Obligate anaerobic	Extracellular
Staphylococcus aureus	Gram +	Facultative anaerobic	Extracellular
Staphylococcus epidermidis	Gram +	Facultative anaerobic	Extracellular

The establishment of stable colonization requires adhesion. Many bacteria attach through **pili** (also called **fimbriae**), which are thin rod-like projections from the bacterial surface (see Figures 10-1 and 10-2). Pathogenic strains of *Escherichia coli* involved in urinary tract infections have a variety of different specific pili-associated adhesion molecules, including mannose-binding protein that binds with glycoproteins specifically expressed on the bladder epithelium and PapG (pyelonephritis-associated protein) adhesin that binds to galactoses of the human P blood group. PapG is a specific adhesion for urinary tract epithelium, but PapG variants are specific for other cell types so that the particular PapG expressed will determine the preferred site of infection with *E. coli*. The particular adhesin may vary depending on growth conditions under which bacteria may undergo a "phase change" and shift from one type to another.

Neisseria spp. bind to urinary tract epithelial cell membrane–associated cofactor protein (CD46), which is a receptor that regulates complement and protects cells by helping inactivate C3b and C4b. Several other microorganisms (e.g., *B. pertussis, Legionella pneumophila, Mycobacterium tuberculosis*) bind to the CR3 complement receptor (a receptor for C3b and C3b breakdown products) on the surface of monocytes/macrophages. *B. pertussis* expresses a surface hemagglutinin that recognizes CR3, whereas *L. pneumophila* and *M. tuberculosis* initially absorb inactivated C3b (C3bi) for use as an adhesin for CR3.

A variety of proteins and carbohydrates not associated with pili function as adhesion molecules. Flagella (used for motion) act as adhesions in *V. cholerae*. Hemagglutinins on *B. pertussis, Salmonella* spp., and *Helicobacter pylori* bind to erythrocyte surface molecules. Fibronectin is a common component of mucosal cell surfaces and is frequently used as a receptor. Several bacteria *(S. pyogenes, S. aureus, T. pallidum)* have developed specific adhesion molecules that recognize a particular amino acid sequence (Arg-Gly-Asp) in fibronectin. Many other bacteria have developed adhesion molecules that bind to collagen, laminin, and vitronectin, which are plentiful in connective tissue. A surface polysaccharide (poly-*N*-acetylglucosamine) is on nonencapsulated *Staphylococcus* spp., *E. coli* that infect the urinary system. *Yersinia pestis,* which causes plague, mediates adherence to the material in catheters and prosthetic devices, thus increasing the risk of infection of joint replacements and other implanted materials.

Although discussions of infectious diseases generally focus on single microorganisms that can be isolated and identified as part of the diagnostic workup, the microorganism frequently exists in the individual as part of complex multicellular masses called **biofilms.**[6] Biofilms consist of mixed species of microorganisms, including bacteria, fungi, and viruses.[7] Growth of bacteria in biofilms offers survival advantage by protection from the host's protective responses and exposure to antibiotics.[8] These structures are associated with chronic and recurrent infections

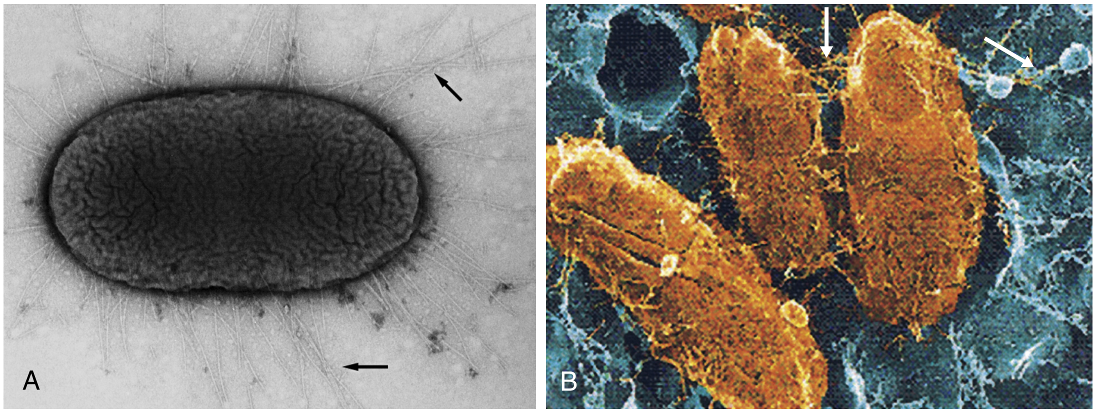

FIGURE 10-2 Attachment of *Escherichia coli* Through Pili. **A,** Transmission electron micrograph showing pili *(arrows)* of pathogenic *E. coli.* **B,** Scanning electron micrograph of *E. coli (orange)* attached by pili *(arrows)* to bladder epithelium *(blue).* (**A** courtesy Eric Buckles and Paula J. Fernandes; **B** modified from Wein A et al: *Campbell-Walsh urology,* ed 9, Philadelphia, 2007, Saunders.)

associated with persistent nasopharyngeal colonization with staphylococci; otitis media; urinary tract infections secondary to indwelling catheters; foot ulcers in diabetic persons; infected burn wounds; vaginitis; osteomyelitis; pneumonia secondary to cystic fibrosis; and diseases of the oral cavity related to dental plaque, such as dental caries and periodontitis.[9,10]

Invasion and Evasion. Invasion results in direct confrontation with the individual's primary defense mechanisms against bacteria, which include the complement system, antibodies, and phagocytes, such as neutrophils and macrophages (see Chapters 7, 8, and 9). Bacterial survival and growth depend on the effectiveness of the body's defenses and on the bacterium's capacity to resist those defenses and obtain nutrients and multiply. Evasion of the body's defense mechanisms may result in infectious microorganisms being transported in the blood (**bacteremia**) to infect other organs or even multiplying in the blood **(sepsis).**

Efficient pathogens produce a variety of toxic molecules that may kill the individual's cells, disrupt the tissue, and protect against inflammation. **Exotoxins** are proteins released during bacterial growth. They are usually enzymes and have highly specific effects; they include cytotoxins, neurotoxins, pneumotoxins, enterotoxins, and hemolysins. Exotoxins can damage cell membranes, activate second messengers, and inhibit protein synthesis. For instance, a key component of invasion by *N. meningitidis* is a toxin that weakens intercellular adhesion between epithelial cells, thus allowing penetration into the underlying tissue. Pathogenic strains of streptococci and staphylococci produce hyaluronidase, lipases, and hemolysins that break down cells and intercellular matrix. Exotoxins are immunogenic and elicit the production of antibodies known as **antitoxins.** Consequently, vaccines are available for many of the exotoxins (i.e., tetanus, diphtheria, and pertussis).

Endotoxins are **lipopolysaccharides (LPSs)** contained in the cell walls of gram-negative bacteria and released during lysis (or destruction) of the bacteria (see Figure 10-1). The innermost part of the lipopolysaccharide, *lipid A,* is made of polysaccharides and fatty acids and is responsible for the substance's toxic effects. Bacteria that produce endotoxins are called *pyrogenic bacteria* because they stimulate the release of inflammatory mediators and produce fever and the local and systemic effects of inflammation including septic shock and damage to multiple organs (Figure 10-3).[11] Endotoxin also may be released from the membrane of the bacteria, either during bacterial growth or during treatment with antibiotics. Therefore, antibiotics cannot prevent the toxic effects of the endotoxin. Evasion of the individual's immune and inflammatory systems is multifaceted, and the most successful pathogens incorporate several mechanisms (Table 10-5).[12]

Rapid Division. Because the primary immune response may take 3 to 5 days to reach protective levels, some pathogens proliferate at rates that surpass the development of the immune system. Cholera causes severe vomiting and watery diarrhea, has a 60% mortality rate, and develops within 2 to 3 days of ingestion of the bacteria. Some strains of toxin-producing group A streptococci cause destructive skin infections and pneumonia that may kill an individual within 2 days. Group B streptococci from the maternal vagina may ascend the birth canal, penetrate fetal membranes, and infect the fluid surrounding the fetus. This microorganism may have already established an active infection of the child's lungs by the time of birth, resulting in a pneumonia (50% mortality rate in newborns) that is too advanced to be treated successfully by antibiotics.

Intracellular Survival. Bacteria may hide from the immune response by growth in sites that are relatively poorly protected by immune cells, for example, *V. cholerae* in the gastrointestinal (GI) tract and *Salmonella typhi* in the intestinal tract and biliary tract (gallbladder). Even asymptomatic people may undergo prolonged local colonization and shed infectious microorganisms in urine and feces, thus creating a *carrier state.*

Survival within cells *(intracellular bacteria)* affords a distinct advantage to some bacteria. Many intracellular bacteria can survive and even multiply in macrophages *(Brucella, Listeria, M. leprae, M. tuberculosis)* or in other cells *(Yersinia, Shigella, Listeria, E. coli).*[13] Normally a macrophage would efficiently kill bacteria by fusing lysosomal granules with the phagosome to produce a phagolysosome and using oxygen-dependent and oxygen-independent mechanisms. Successful

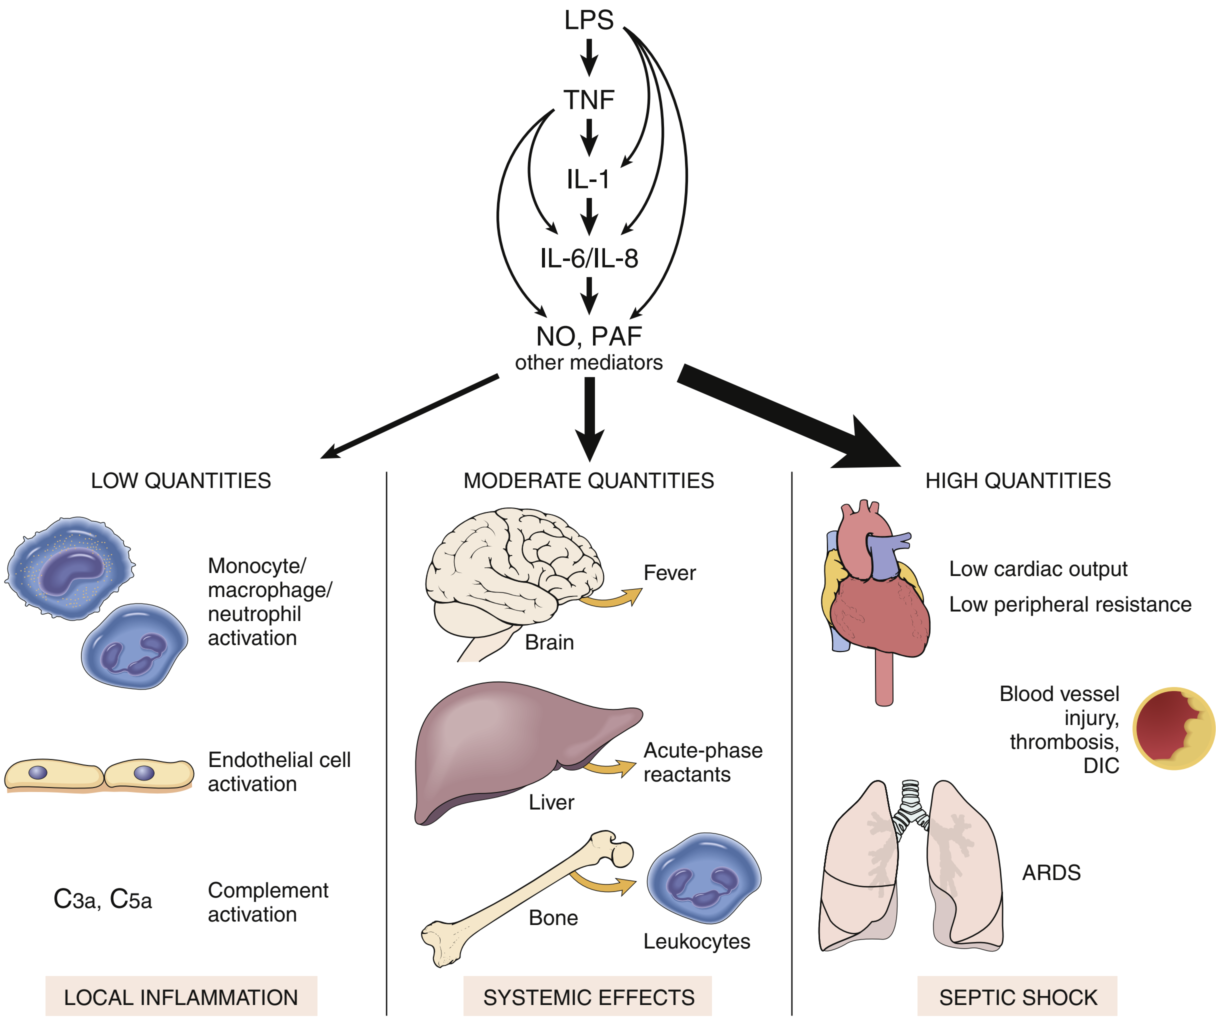

FIGURE 10-3 **The Many Activities of Lipopolysaccharide (LPS).** Bacterial endotoxin *(LPS)* activates almost every aspect of inflammation. The release of LPS from gram-negative bacteria triggers successive waves of cytokine production, including tumor necrosis factor *(TNF),* interleukin-1 *(IL-1),* interleukin-6 *(IL-6),* and interleukin-8 *(IL-8),* and secondary mediators of inflammation, such as nitric oxide *(NO)* and platelet-activating factor *(PAF).* At low levels of LPS the effect is local. Moderate levels of LPS cause more systemic inflammatory responses. High levels of LPS may lead to septic shock and death. *ARDS,* Acute respiratory distress syndrome; *DIC,* disseminated intravascular coagulation. (From Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders; Modified from Abbas AK et al: *Cellular and molecular immunology,* ed 4, Philadelphia, 2000, WB Saunders.)

intracellular bacteria may block killing in several ways. Several microorganisms are resistant to killing and survive in the phagolysosome.

Species of *Salmonella* secrete products that alter the environment of the phagolysosome. Production of catalase and superoxide dismutase *(N. gonorrhoeae, Brucella abortus, S. aureus)* destroys toxic oxygen products produced by the hexose-monophosphate shunt.[14] *S. aureus* also produces a cell-bound pigment (carotenoid) that "quenches" singlet oxygen. A second means of avoiding killing is escape from the phagosome. Several bacteria secrete lysins (e.g., hemolysin of *Shigella*, listeriolysin O and phospholipase C of *L. monocytogenes*, phospholipase A of *Rickettsia* spp.) that break down the phagosome membrane, and the bacteria are released into the cytoplasm, where they multiply.[15] A third means of avoiding killing is by prevention of phagosome-lysosome fusion. *M. tuberculosis* and *T. gondii* produce toxins that prevent fusion so that the environment in the phagosome remains relatively nontoxic.

Protection Against Phagocytosis. Bacteria produce a large variety of toxins and extracellular enzymes, some of which kill phagocytic cells (e.g., *Pseudomonas aeruginosa* exotoxin A). Staphylococcal hemolysins and toxins from *Bacillus anthracis* and *B. pertussis* decrease phagocytic and chemotactic activities and may be toxic. Streptococcal products, such as streptolysin O, bind to cholesterol in the phagocyte's plasma membrane and initiate destruction through the internal release of enzymes in lysosomal granules.

Antiphagocytic **capsules** are expressed by most bacterial pathogens involved in pneumonia and meningitis (Figure 10-4). Capsules are mostly polysaccharide, although some very important proteins may be capsular components, which inhibit complement activation and phagocytosis. Such coatings inhibit

TABLE 10-5 MECHANISMS USED BY MICROORGANISMS TO DEFEND AGAINST INFLAMMATION AND IMMUNITY

STRATEGY	BACTERIAL MECHANISM	FUNGAL MECHANISM	PARASITE/PROTOZOAL MECHANISM	VIRAL MECHANISM
Rapid division	Initial proliferation in protective environment	NA	NA	Rapid proliferation of viruses with small genomes
Intracellular survival	Intracellular bacteria block granule fusion, survive in phagolysosomes, enter and multiply in cytoplasm	Multiplication in phagosomes, inhibition of lysosomal enzymes	Resistance to lysosomal enzymes, block granule fusion, enter and multiply in cytoplasm	Obligative intracellular life cycle, latency (e.g., herpes simplex virus in dorsal root ganglia)
Protection against phagocytosis	Capsules with antiphagocytic and anticomplement activities, toxins to kill phagocytes (e.g., α-toxin and leukocidin)	Polysaccharide capsule, toxins that inhibit phagocytosis	Glycocalyx, toxins that inhibit phagocytosis	NA
Coating with self	Adsorption of fibronectin or IgG (e.g., protein A), sialic acid capsule	NA	Adsorption of IgG by Fc receptor	Enveloped viruses with plasma membrane
Antigenic variation	Large diversity of surface molecules, phase changes in pili or membrane proteins, strain-to-strain serotype differences	Changes in surface antigens	Changing morphologic forms during life cycle, antigen switching	Viral enzymes that produce translational errors, antigen shift and drift, diversity of serotypes
Degrade immune molecules	Proteases for IgA and IgG, degrade complement, defensins, and cathelicidins	NA	IgG and IgA proteases	
Neutralization of immune molecules	Shedding of surface antigens	NA	Shedding of surface antigens	Secretion of viral proteins to neutralize antibody, molecules to neutralize cytokines
Complement evasion	Proteases degrade complement (e.g., C3b, C5a), capsules that prevent complement deposition, inhibitors of complement components and convertases	NA	Degrade or inactivate C3b, C3a, and C5a; break down C3 convertase	Cellular complement inhibitors in envelope
Immune suppression	Induction of anergy, direct suppression of Th cell development	Stimulation of anti-inflammatory cytokines, inhibition of proinflammatory cytokines	Release of soluble antigens that induce "tolerance," polyclonal B-cell activation, induction of anti-inflammatory cytokines, cytotoxic molecules	Infect and kill immune cells, inhibit Tc and natural killer (NK) recognition of major histocompatibility complex (MHC), inhibit antigen presentation

NA, Not applicable.

phagocytosis and include the thick polysaccharide covering of the pneumococcus *(S. pneumoniae)*, the waxy capsule surrounding the tubercle bacillus *(M. tuberculosis)*, the polysaccharide "slime" capsule of *P. aeruginosa*, and the M protein of *S. pyogenes*. The M protein binds fibrinogen and fibrin and functions as an adhesin.

Coating with Self-Protein. Some bacterial surface proteins (e.g., protein G of *S. pyogenes*) bind the Fc portion of the individual's antibody, thus forming a protective coat of "self" protein. Binding through the Fc holds the antibody in an orientation that does not allow complement activation or phagocytosis. *T. pallidum* coats itself with fibronectin. Capsules are produced that contain sialic acid (*E. coli* K-12), which closely resembles the sialic acid on the surface of most human cells, and hyaluronic acid (group A streptococci), which is the basic substance in connective tissue.

Antigenic Variation. **Antigenic variation** allows the pathogen to alter surface molecules that express antigens that are the targets of protective immune responses. Thus as the individual develops protective levels of antibodies, the pathogen responds by changing antigens and becoming resistant. The three primary mechanisms of antigenic variation are *mutation*, *recombination*, and *gene switching*. Antigenic variation can occur during the course of an infection in the host or during the spread of infection through the environment.

Neisseria use pili to adhere to epithelium, and antibody against these antigens can abrogate adherence. *Neisseria* undergoes *phase shifts* during which pilar antigens are changed by progressive silencing of 1 set of 10 or 11 available pili genes and activation of others that express different antigens. The spirochete *B. recurrentis* (relapsing fever) repeatedly relapses with spiking fevers as a result of as many as 10 episodes of antigenic changes over weeks or months. Many other bacteria have a large number of different antigenic types (serotypes) across the species. At least 80 different strains of group A *S. pyogenes* express different serotypes of the capsular M protein. *S. pneumoniae* has

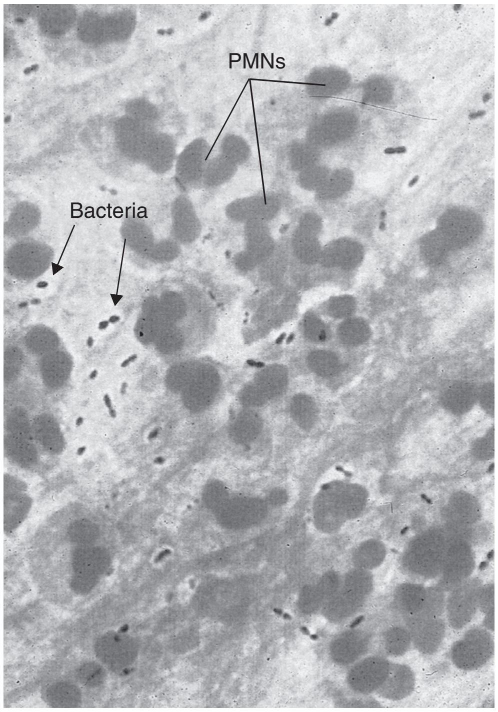

FIGURE 10-4 Bacterial Capsule. Gram stain of a sputum sample from an individual with pneumococcal pneumonia (× 1000 magnification). The sputum is rich in polymorphonuclear *(PMN)* cells and slightly elongated, gram-negative cocci *(Streptococcus pneumoniae).* Clear areas *(arrows)* around the bacteria indicate capsules. (Modified from Mandell G, Bennett J, Dolin R: *Principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

at least 100 different serotypes based on capsular polysaccharides. Multiple serotypes are also found in *V. cholerae, S. aureus, E. coli, N. gonorrhoeae,* and others. Although the particular serotype is stable on that bacterium, an immune response against one serotype will result in increased growth of a different serotype. Some gram-negative bacteria can revert to "rough" forms in which serotype-specific carbohydrates are deleted, thus becoming resistant to antibody and activation of complement.

Degradation of Immune Molecules. Protection is afforded by the breakdown of molecules of the immune or inflammatory system. An **IgA protease** produced by meningitis-causing microorganisms and other related bacteria *(N. gonorrhoeae, N. meningitidis, H. influenzae, S. pneumoniae)* cleaves IgA at the hinge region into ineffective Fc and Fab'_2 regions.[16] A staphylokinase produced by *Staphylococcus* spp. activates plasmin (resulting in the breakdown of clots) and degrades IgG and C3b of the complement system. *Pseudomonas* produces elastase (breakdown C3 of the complement system) and a 56-kDa protease (breaks down C5a).

*Salmonell*a membrane protease degrades nonspecific antimicrobial molecules like defensins and cathelicidins. *Salmonella* can also alter surface lipid A by changing its fatty acid content to become resistant to small-molecular-weight antimicrobials.

Neutralization of Immune Molecules. Bacteria may spontaneously release surface molecules that bind to and neutralize antibody. These include endotoxin from gram-negative bacteria, capsular antigens from *S. pneumoniae* and *N. meningitidis,* and protein A from *S. aureus*. During infection the blood may contain high levels of complexes between antibody and bacterial antigen. At certain antigen/antibody ratios the complexes will deposit in the kidney, joints, and other target organs and initiate type III hypersensitivity reactions (see Chapter 9).

Complement Evasion. Complement is a major component of the defense against bacterial infection through production of opsonin (C3b) and chemotactic factors (C3a, C5a) for neutrophils. Teichoic acid in the Gram-positive cell wall provides resistance against complement-mediated lysis. Bacterial regulatory proteins (e.g., *Borrelia* complement-regulator-acquiring protein, *Neisseria* porins, and members of the *Streptococcus* M protein family) affect complement activation, including destabilization of the C3 convertase complex or degradation of the opsonin C3b.[17]

Immune Suppression. Although more prominent in viral infections, some bacterial pathogens can broadly suppress immune responses against their own antigens as well as other antigens unrelated to the infectious agent. Chronic bacterial infections, like leprosy *(M. leprae)* and tuberculosis *(M. tuberculosis),* induce anergy (suppressed response to multiple antigens) in infected hosts. *H. pylori* can release LPS that binds to dendritic cells and blocks development of Th1 cells, as well as produce toxins that block the T-cell IL-2 receptor signaling pathway, thus inhibiting maturation of Th cells. *N. gonorrhoeae* pili antigens bind to adhesion molecules on CD4+ cells and prevent their activation.

Tissue Damage. Bacterial infections damage tissue either directly by means of bacterial products or indirectly as a result of inflammation. Many toxins break down tissue directly. These include a large variety of proteases, lipases, hyaluronidases, hemolysins, and many others discussed previously. Some bacterial diseases arise completely from the systemic effects of toxins. Diphtheria is a respiratory tract infection *(Corynebacterium diphtheriae)* with systemic complications caused by toxin that inhibits messenger ribonucleic acid (mRNA) translation and causes low blood pressure, necrosis in the heart and liver, degeneration of myelin sheaths, and death. Gastrointestinal pathogens *(V. cholerae, Salmonella, Shigella, E. coli)* may produce enterotoxins that are cytotoxic and alter the permeability of intestinal cells leading to diarrheal diseases.

Necrotizing fasciitis, commonly called flesh-eating disease, is an unusual rapidly progressing bacterial infection of the soft tissue. Group A *Streptococcus* is the primary cause of this disease, although mixed infections with other bacterial microorganisms may cause similar soft tissue damage. The microorganisms usually invade the subcutaneous tissue from a minor wound infection. Severe and rapid tissue destruction proceeds from the combined effects of bacterial toxins and enzymes released from damaged cells. Rapid surgical débridement is absolutely necessary to limit morbidity and prevent the individual's death.

Clostridia are anaerobic bacteria that produce some of the most powerful toxins known. One type of food poisoning is caused by *Clostridium botulinum* that produces a paralytic neurotoxin (botulinum toxin) that blocks the release of acetylcholine at nerve-muscle synapses and results in flaccid paralysis. Infection of deep wounds with *C. tetani* results in release of a

neurotoxin that causes severe muscle spasms, spastic paralysis of the voluntary muscles, and potentially death. *C. perfringens* produces multiple toxins that cause gas gangrene. One of these, alpha toxin, is a lecithinase that destroys the infected tissue by digesting cellular plasma membranes. Infection of the colon with *Clostridium difficile* results in watery diarrhea from toxins that damage the mucosa.

Bacterial superantigens are toxins that increase the adherence between major histocompatibility complex (MHC) class II proteins on antigen-presenting cells and the T-cell receptor. Because the effect is independent of antigen, a large population of T cells is activated and overproduces proinflammatory cytokines, such as IL-1, IL-6, and TNF-α. Superantigens are responsible for several diseases, including food poisoning (enterotoxins of *S. aureus* and *C. perfringens*), toxic shock syndrome (toxic shock syndrome toxin [TSST] of *S. aureus*), and scarlet fever (erythrogenic toxin of *S. pyogenes*).

Inflammation is the body's initial response to the presence of the bacteria. Vascular permeability is increased, allowing blood-borne substances (e.g., the complement system) involved in bacterial destruction to access the site of infection. The release of anaphylatoxins (C5a and C3a) of the complement cascade may increase the inflammatory response and lead to an increase in capillary permeability sufficient to permit the escape of large volumes of plasma, contributing to hypotension and, in severe cases, cardiovascular shock (see Chapter 48). Many persistent bacterial infections (e.g., *M. tuberculosis*) may lead to formation of *granulomas,* which diminishes the function of the affected organ (e.g., the lung).

The release of a sufficient amount of endotoxin can lead to fatal **endotoxic shock (septic shock),** which is one of the leading causes of death in intensive care units. The usual cause is proliferation of gram-negative bacteria, although shock may be caused by a few gram-positive bacteria and fungi. Once in the blood, endotoxins cause the release of vasoactive peptides and cytokines that affect blood vessels, producing vasodilation, which reduces blood pressure, causes decreased oxygen delivery, and produces subsequent cardiovascular shock (see Figure 10-3 and Chapter 48). Endotoxin can activate the coagulation cascade, leading to the syndrome of disseminated (or diffuse) intravascular coagulation (see Chapter 27). Additionally, endotoxin induces the release of TNF-α (cachectin) by macrophages. TNF is a potent proinflammatory cytokine that is also called *cachectin* because of its role in promoting cachexia in individuals with cancer. (Cachexia is discussed in Chapter 12; cytokines are discussed in Chapters 7 and 8.)

Example of Bacterial Pathogenesis. *S. aureus* has become a major cause of hospital-acquired (nosocomial) infections. This microorganism is a common commensal inhabitant of normal skin and nasal passages (about 30% of individuals are nasal carriers) and can be transmitted by direct skin-to-skin contact or by contact with shared items or surfaces that have become contaminated from another person's infection (e.g., towels, used bandages).[9]

Skin infections may occur at sites of trauma, such as cuts and abrasions, and at areas of the body covered by hair (e.g., back of neck, groin, buttock, armpit, beard area of men). Most infections are relatively mild and localized, appearing as red and swollen pustules on the skin, containing pus or other drainage (Figure 10-5). They can develop into abscesses, boils, carbuncles, cellulitis, or furunculosis. Invasive disease may originate from wound infections (e.g., trauma, surgical wounds, indwelling medical devices, prosthetic joints) and lead to fatal septicemia and abscesses in internal organs (e.g., lungs, kidney, bones, skeletal muscle, meninges, or heart).[18]

Adherence to tissue is mediated by surface proteins that attach to connective tissue (laminin, fibrin, fibronectin) and endothelium. Attachment to collagen occurs in osteomyelitis and septic arthritis–causing strains, and capsular polysaccharide mediates attachment to prosthetic devices.

Staphylococci also produce very effective polysaccharide capsules that protect against phagocytosis as well as surface protein A that binds IgG by the Fc portion and a surface coagulase that induces fibrin clotting on the bacterial surface; both processes mask bacterial antigens under a surface of self-proteins. Staphylococcal protein A, as well as a protein called staphylococcal binder of immunoglobulin, is also secreted and binds and neutralizes IgG.[19] *Staphylococcus* produces proteins that inhibit complement activity, including C3 and C5 convertases, C5, C2, and the C5a receptor that mediates complement-induced chemotaxis.[20] Many pathogenic strains have increased resistance to intracellular oxidative killing when engulfed by a phagocyte.

Invasion is mediated by a variety of toxins, including membrane-damaging toxins (α-toxin, which forms pores in membranes; hemolysin, which destroys erythrocytes; β-toxin, which is a sphingomyelinase; δ-toxin, a detergent-like toxin; leukocidin, which lyses phagocytes), coagulase (causes clots), staphylokinase (breaks down clots), exfoliative toxins (causes separation of epidermis resulting in scalded skin syndrome), lipase (degrades lipids on skin surface; facilitates abscess formation), and a variety of enterotoxins. Many of the enterotoxins are superantigens that are responsible for staphylococcal food poisoning with diarrhea and vomiting and toxic shock syndrome. Each infectious strain of *S. aureus* produces a few of these toxins so that strains may differ in their capacities to cause particular diseases; thus, different strains can cause purulent dermal infections, food poisoning, or toxic shock syndrome.

Antibiotic resistance has become a major problem with *S. aureus*. For several decades pathogenic strains have commonly produced **β-lactamase,** an enzyme that destroys penicillin. More recently staphylococci have developed resistance (methicillin-resistant *Staphylococcus aureus* [MRSA]) to broad-spectrum antibiotics, including methicillin-like antibiotics, which were widely used to treat penicillin-resistant microorganisms.

Fungal Infections

Fungi are eukaryotic microorganisms with thick rigid cell walls and the capacity to form a variety of complex structures (Figure 10-6). Fungi may grow as a **mold** with branched filaments or as a meshwork mycelium structure (e.g., *Aspergillus* spp., causing aspergillosis), **yeast** with ovoid or spherical shapes (*C. albicans*, which causes candidiasis), or **dimorphic** with a yeastlike

appearance in tissue and mycelium in culture (e.g., *Histoplasma capsulatum*, which causes histoplasmosis, a systemic respiratory disease). The cell wall is composed of polysaccharides that differ from the peptidoglycans of bacteria and are thus are resistant to bacterial cell wall inhibitors such as penicillin and cephalosporin. In contrast to bacteria, the cytosol of fungi contains organelles: mitochondria, Golgi apparatus, microtubules, microvesicles, endoplasmic reticulum, and nuclei. Molds are aerobic, and yeasts are facultative anaerobes. Common pathologic fungi are summarized in Table 10-6.

Fungi are diagnosed by microscopic observation of specimens treated with potassium hydroxide and stained to enhance visualization of spheres and filaments. Specimens also can be cultured. Skin tests are available for species of *Aspergillus*. Many of the antifungal drugs (e.g., amphotericin B, ketoconazole, fluconazole) used to treat deep or systemic infections are toxic to the host because the fungal cell composition is similar to the human cell.

Transmission and Colonization. Infection with a fungus is called **mycosis.** Most pathogenic fungi (e.g., *H. capsulatum*, *Coccidioides immitis*, *Blastomyces dermatitidis*) grow as saprophytes in the environment and are transmitted by inhalation or contamination of wounds. The majority of medically relevant fungi either exist as human commensals or cause relatively mild infections (superficial mycoses) of the skin, nails, hair, and mucous membranes of the mouth and vagina. These include dermatophytes (e.g., tineas, which refers to several skin mycoses including ringworm, athlete's foot, and others) and yeasts (e.g., *Candida*, *Aspergillus*, *Cryptococcus*).

Human-to-human transmission is only a concern with dermatophyte infections. Systemic mycosis caused by pathogenic fungi generally results from inhalation of spores present in a

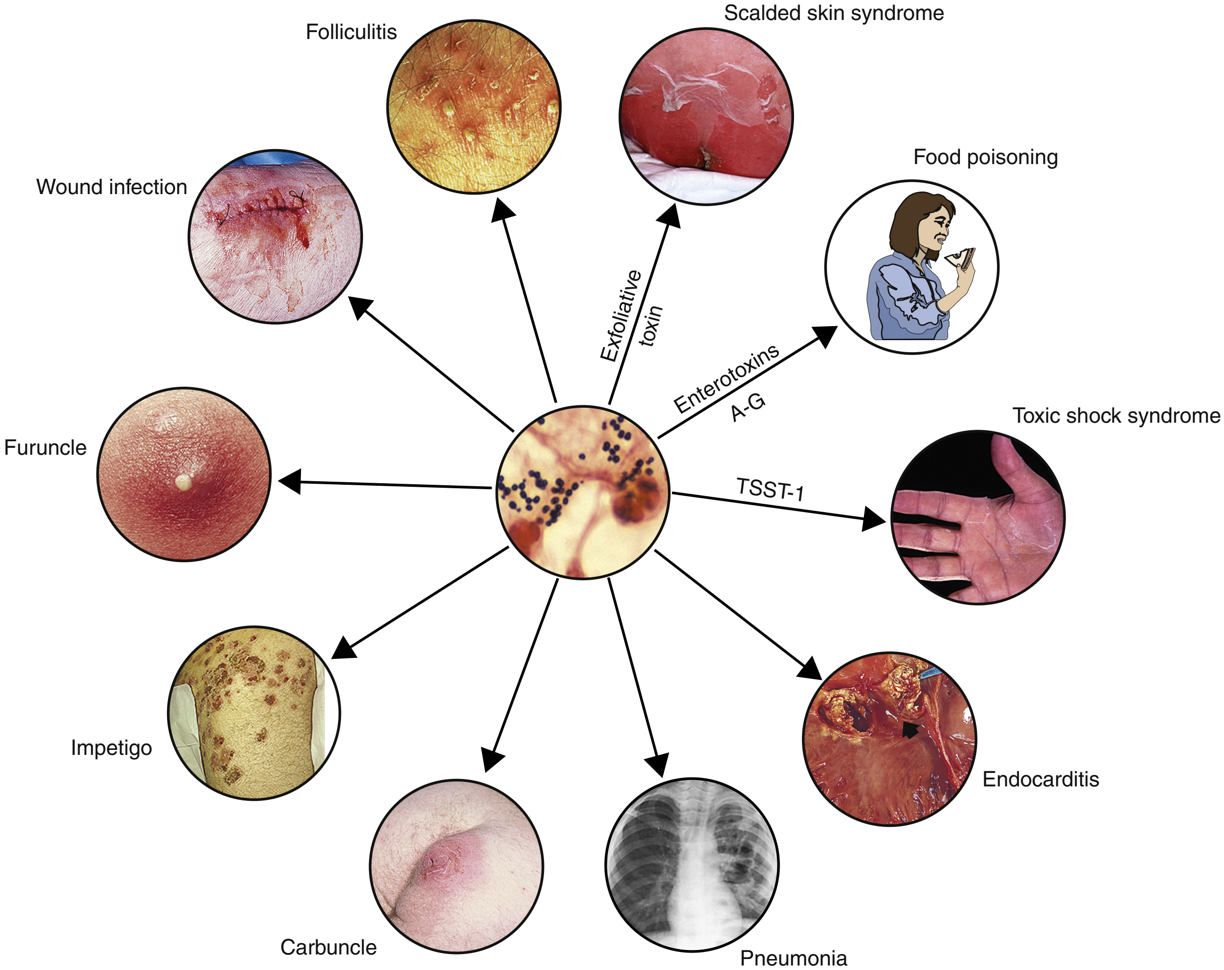

FIGURE 10-5 ***Staphylococcus aureus*** **Infections.** Different strains of *S. aureus* (gram-positive cocci in sputum from an individual with pneumonia *[center photograph]*) cause a variety of infections. The particular infection may depend on the toxin produced: exfoliative toxin (scalded skin syndrome), enterotoxins A-G (food poisoning), or toxic shock syndrome toxin-1 *(TSST-1)*. (Toxic shock syndrome, carbuncle, impetigo, and wound infection photos from Cohen J, Powderly WG: *Infectious diseases,* ed 3, St Louis, 2010, Mosby. Folliculitis photo from Goldman L, Ausiello D: *Cecil medicine,* ed 24, Philadelphia, 2012, Saunders. Center photo and photos of food poisoning and endocarditis from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders. Furuncle photo from Long S et al: *Principles and practice of pediatric infectious diseases,* ed 4, Philadelphia, 2012, Saunders. Scalded skin syndrome and pneumonia photos from Mandell G et al: *Principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

contaminated environment and initially presents as a pulmonary infection. Infection that disseminates to other organs can be life threatening. Systemic mycosis caused by opportunistic fungi is usually secondary to immunosuppression caused by genetic defects, infections such as HIV, cancer, and drugs used to prevent transplant rejection.

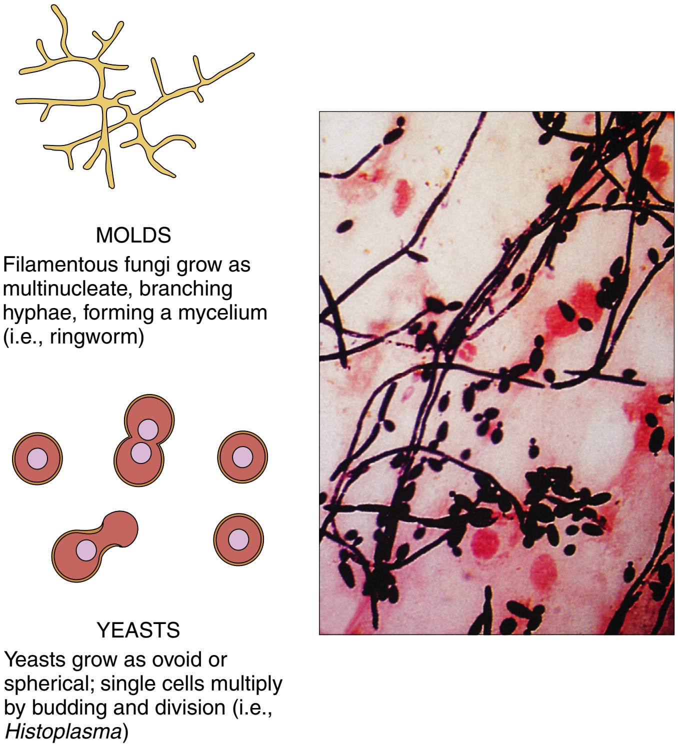

FIGURE 10-6 **Morphology of Fungi.** Fungi may be either mold or yeast forms, or dimorphic. The photograph shows *Candida albicans* with both the mycelial and the yeast forms. (From Goering R et al: *Mims' medical microbiology,* ed 5, London, 2013, Saunders.)

Specific adherence to the epithelium is provided by several polysaccharides on the fungal surface. Glucan, mannan, glycoprotein, and chitin molecules adhere with host receptors, including Toll-like receptors (TLRs), mannose receptors, dectin-1, and cadherins, respectively. A cell wall adhesion molecule, agglutinin-like sequence 3 (ALS3), on several fungi (e.g., *C. albicans*) promotes adherence to epithelial cells as well as silicone, thus facilitating infection of implants and other medical devices.

In 2006 the opportunist pathogen *Pneumocystis carinii* was reclassified as a fungus, and the specific variant that infects humans was renamed *Pneumocystis jiroveci*.[21] Despite the official change in nomenclature, much of the literature will continue to use *P. carinii* for some time. As with many fungi and protozoa, *Pneumocystis* has two life-cycle forms: a trophic form and the cyst form. Two surface proteins, glycoprotein A (gpA) and major surface glycoprotein (MSG), mediate attachment to alveolar epithelial cells.

Invasion and Evasion. The host defense against fungal infection includes the fungistatic properties of neutrophils and macrophages. T lymphocytes are crucial in limiting the extent of infection and producing cytokines to further activate macrophages. Human host defense against the inhaled spores begins with the mucous layer and the ciliary action in the respiratory tract, which then remove the fungus or facilitate phagocytosis by local macrophages. Pathogenic fungi have developed means to circumvent these mechanisms (see Table 10-5).[22]

Intracellular Survival. Fungal virulence and resistance to the individual's protective mechanisms is a complex process that requires the expression of multiple genes at different stages and different sites of infection. Pathologic fungi are generally dimorphic (e.g., *H. capsulatum, B. dermatitidis, C. immitis*) and readily adapt to the host environment, responding to temperature variations, low oxygen environment, more alkaline pH, and other conditions in the host tissue by undergoing changes

TABLE 10-6 COMMON PATHOGENIC FUNGI

PRIMARY SITE OF INFECTION	FUNGUS	DISEASE (PRIMARY)	SYMPTOMS
Superficial (no tissue invasion, little inflammation)	*Malassezia furfur*	Tinea versicolor, seborrheic dermatitis, dandruff	Red rash on body
Cutaneous (no tissue invasion, inflammatory response)	Dermatophytes		
	Trichophyton mentagrophytes	Tinea pedis (athlete's foot)	Scaling, fissures, itching
	Trichophyton rubrum	Tinea cruris (jock itch)	Rash, itching
	Microsporum canis	Tinea corporis (ringworm)	Lesion, raised border, scaling
	Candida albicans	Cutaneous candidiasis	Lesions in most areas of skin, mucous membranes, thrush, vaginal infection
Subcutaneous (tissue invasion)	*Sporothrix schenckii*	Sporotrichosis	Ulcers or abscesses on skin and other organ systems
Systemic (dimorphic; causes disease in healthy individuals)	*Stachybotrys chartarum* or "black mold"	Black mold disease	Rash, headaches, nausea, pains
	Coccidioides immitis	Coccidioidomycosis	Valley fever, flulike symptoms
	Histoplasma capsulatum	Histoplasmosis	Lung, flulike symptoms, disseminates to multiple organs, eye
	Blastomyces dermatitidis	Blastomycosis	Flulike symptoms, chest pains
Systemic (opportunistic)	*Aspergillus fumigatus, Aspergillus flavus*	Aspergillosis	Invasive to lungs and other organs
	Pneumocystis jiroveci	Pneumocystis pneumonia (PCP)	Pneumonia
	Cryptococcus neoformans	Cryptococcosis	Pneumonia-like illness, skin lesions, disseminates to brain, meningitis
	Candidia albicans	Systemic candidiasis	Sepsis, endocarditis, meningitis

in morphology and switching from avirulent mold forms to virulent yeast forms. Similar conditions also trigger yeasts (e.g., *C. albicans*) to switch from the yeast form to its more virulent hyphal form.

The more virulent morphologies allow fungi to survive in macrophages after phagocytosis. After phagocytosis by macrophages, the yeast form of *Histoplasma* replicates in phagosomes and phagolysosomes. Some yeast may produce proteins that inhibit the activity of lysosomal proteases. The macrophage either may be destroyed as a result of membrane modification by the fungus or, in the case of fungi like *Histoplasma,* may harbor the fungus in granulomas. Breakdown of the granulomas over time may result in release of viable fungi and recurrence of the infection.

Protection Against Phagocytosis. Encapsulated yeast cells (e.g., *Cryptococcus neoformans*) are more resistant to phagocytosis than unencapsulated yeast. The cryptococcal polysaccharide capsule is antiphagocytic by blocking recognition by macrophages and may also be immunosuppressive by inhibiting migration of leukocytes into the site of fungal infection. *Aspergillus fumigatus* and many other fungi produce toxic metabolites (e.g., gliotoxin) that inhibit macrophage and neutrophil phagocytosis. Molecules like gliotoxin may also be immunosuppressive, including suppression of mast cell activation, degranulation, and secretion of leukotrienes and cytokines.

Antigenic Variation. Altered antigen expression affords protection against the developing immune responses, although this defense strategy is rarely used by fungal pathogens. *Pneumocystis* contains approximately 80 different gpA and MSG genes, only 1 of which is expressed at a time. Modulation of these antigens may provide resistance against immune destruction.

Immune Suppression. Several yeasts stimulate the production of immunosuppressive cytokines, resulting in downregulation of some aspects of the host's immune response. The yeast *C. neoformans* suppresses inflammation by inhibiting production of the proinflammatory cytokines TNF-α and IL-12 and inducing production of the anti-inflammatory cytokine IL-10. The overall result is suppression of macrophage function and protection against killing.

Tissue Damage. Fungal infections damage tissue directly by secretion of enzymes and indirectly by initiation of an inflammatory response. Secreted enzymes, such as proteases, phospholipases, and elastases, damage cells and intercellular matrix, leading to necrosis. Many molds secrete mycotoxins when grown in environmental locations, such as on nuts, beans, and grains. Ingestion of this toxin affects muscle coordination, causes tremors, and may be fatal. Some fungal toxins may cause cancer; aflatoxins produced by some *Aspergillus* are especially carcinogenic.

The typical immune and inflammatory reaction against fungal infections involves a cell-mediated response with infiltration of T cells and macrophages, as well as neutrophils. The inflammatory site is rich in proinflammatory cytokines. Fungal infections can be very difficult for these systems to eradicate, leading to progressively increasing production of cytokines. Thus, as the host's response increases so do the destructive effects on surrounding healthy tissue. In cases of persistent infection, granulomas form and compromise the normal function of the infected tissue.

Example of Fungal Pathogenesis. *Candida albicans* is the most common cause of fungal infections in humans. It is an opportunistic yeast that is a commensal in the normal microbiome of many healthy individuals, residing in the skin, gastrointestinal tract, mouth (30% to 55% of healthy individuals), and vagina (20% of healthy women) and normally under the control of local defense mechanisms, including members of the bacterial microbiome that produce antifungal agents. In healthy individuals, particularly those whose normal microbiome has been disturbed by antibiotic therapy (e.g., diminished levels of *Lactobacillus* in the vaginal microbiome), *Candida* overgrowth may occur resulting in vaginitis or oropharyngeal infection (thrush). In those with an intact immune system the infection remains localized.

In immunocompromised individuals, particularly those with diminished levels of neutrophils (neutropenia), disseminated infection may occur. *Candida* is the most common fungal infection in people with cancer (particularly acute leukemia and other hematologic cancers), transplantation (bone marrow and solid organ), and HIV/AIDS. Almost 90% of people with AIDS have *Candida* at least one time during the disease, although infection is usually contained locally (thrush or vaginitis) because of adequate numbers of neutrophils (Figure 10-7). Invasive candidiasis may also be secondary to indwelling

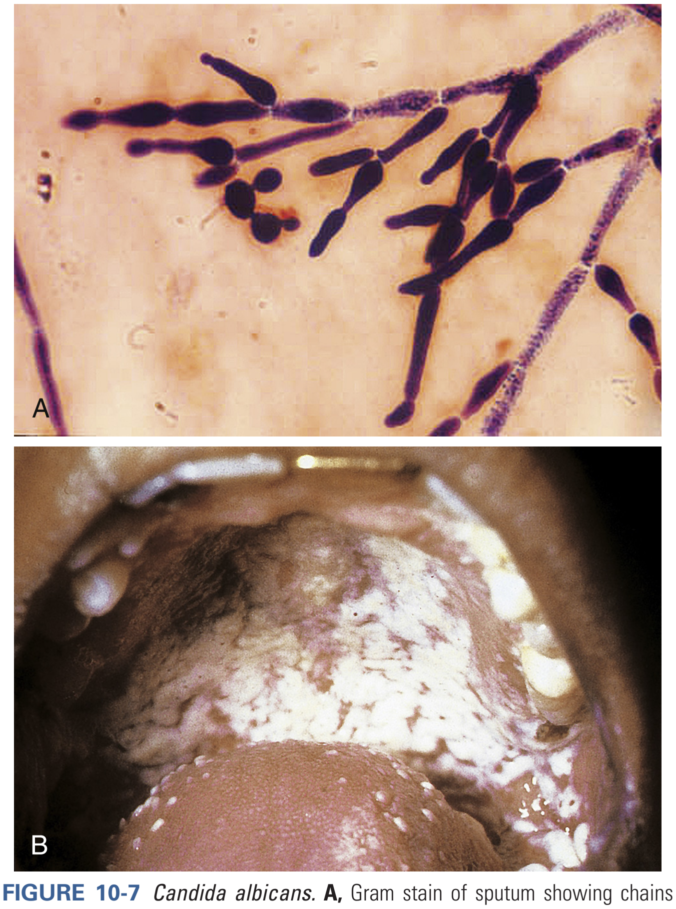

FIGURE 10-7 *Candida albicans.* **A,** Gram stain of sputum showing chains of elongated budding yeasts of *C. albicans* producing pseudohyphae (×1000). **B,** Oral candidiasis (thrush). (**A** from McPherson R, Pincus M: *Henry's clinical diagnosis and management by laboratory methods,* ed 22, Philadelphia, 2012, Saunders; **B** courtesy Dr. Stephen Raffanti.)

catheters, intravenous lines, or peritoneal dialysis, which provides direct entrance into the blood.

Disseminated candidiasis may involve several internal organs, including abscesses in the kidney, brain, liver, and heart, and is characterized by persistent or recurrent fever, gram-negative shock-like symptoms (hypotension, tachycardia), disseminated intravascular coagulation (DIC), and death. The mortality rates of sepsis or disseminated candidiasis are in the range of 30% to 40%.[23]

Like most pathogenic yeasts, *Candida* undergoes morphologic changes from unicellular yeast to filamentous hyphal forms under conditions of neutral to alkaline pH, elevated temperature, and changes in host serum factors. Switching of morphology results in altered profiles of surface antigens and increased resistance to immunologic destruction as well as altered tissue adhesion specificity.[24] *Candida* expresses diverse surface adhesion molecules that permit adherence to materials in implants, epithelium, extracellular matrix (fibronectin, laminin, collagen), and leukocytes and facilitate invasion into tissue. One surface adherence molecule is a glycoprotein, INT1p (integrator complex subunit 1), which specifically binds to integrins. EAP1 (enhanced adhesion to plastic) is a glycoprotein that permits *Candida* to bind to epithelial cells and a variety of synthetic materials found in implants.

Candida secretes several enzymes that function as virulence factors and contribute to tissue destruction. Acid proteases and phospholipases damage the cell membrane and enhance invasive capacity. Secreted aspartic proteinases (Saps) increase the virulence of *Candida* by destroying cell membranes and removing surface molecules, including from cells of the immune and inflammatory systems.

Candida may suppress the host's immune system. Production of the cytokine granulocyte-monocyte colony-stimulating factor (GM-CSF) suppresses monocyte/macrophage function, including the production of components of the complement cascade. Decreased production of C3 results in less opsonization (C3b) and production of chemotactic activity (C3a) for phagocytes.

Parasitic and Protozoal Infections

Parasitic organisms establish symbiosis with another species in which the parasite benefits at the expense of the other species. Parasites range from unicellular protozoal to large worms. Parasitic worms (helminths) include intestinal and tissue nematodes (e.g., hookworm, roundworm), flukes (e.g., liver fluke, lung fluke), and tapeworms. A protozoan is a eukaryotic, unicellular microorganism with a nucleus and cytoplasm. Pathogenic protozoa include malaria *(Plasmodium)*, amoebae (e.g., *Entamoeba histolytica,* which causes amoebic dysentery), and flagellates (e.g., *Giardia lamblia,* which causes diarrhea; *Trypanosoma*, which causes sleeping sickness). Although less common in the United States, parasites and protozoa are common causes of infections worldwide, with a significant effect on the mortality and morbidity of individuals in developing countries. Important parasites of humans are listed in Table 10-7.

Transmission and Colonization. Parasitic and protozoal infections are rarely transmitted from human to human. The predominant means is through vectors in which the organism

TABLE 10-7 PARASITES THAT ARE IMPORTANT IN HUMANS

CATEGORY	SUBGROUP	SPECIES	DISEASE	ORGANS AFFECTED/SYMPTOMS
Protozoa	Amoeboid	*Entamoeba histolytica*	Amebiasis	Dysentery, liver abscess
	Flagellate	*Giardia lamblia*	Giardiasis*	Diarrhea
		Leishmania donovani, L. tropica	Leishmaniasis	Sores on skin, progression to liver, spleen
		Trichomonas vaginalis	Trichomoniasis	Inflammation of reproductive organs
		Trypanosoma cruzi, T. brucei	Chagas disease: African sleeping sickness	Generalized, blood, lymph nodes, progressing to cardiac and central nervous system (CNS)
	Ciliate	*Balantidium coli*	Balantidiasis	Small intestines, invasion of colon, diarrhea
	Sporozoa (nonmotile)	*Cryptosporidium parvum, C. hominis*	Cryptosporidiosis*	Intestine, diarrhea
		Plasmodium spp.	Malaria	Blood, liver
		Toxoplasma gondii	Toxoplasmosis*	Intestine, eyes, blood, heart, liver
Helminths	Flukes (trematodes)	*Fasciola hepatica*	Fasciolosis	Liver destruction
		Paragonimus westermani	Lung fluke disease	Granuloma in lung, spinal cord
		Schistosoma mansoni	Schistosomiasis	Blood, diarrhea, bladder, generalized symptoms
	Tapeworms (cestodes)	*Taenia solium*	Pork tapeworm	Encysts in muscle, brain, liver
	Roundworms (nematodes)	*Ascaris lumbricoides*	Ascariasis	Intestinal obstruction, bile duct obstruction
		Necator americanus (hookworm)	Hookworm disease	Intestinal parasite
		Trichuris trichiura (whipworm)	Trichuriasis	Diarrhea
		Trichinella spiralis	Trichinosis*	Intestine, diarrhea, muscle, CNS, death
		Wuchereria bancrofti	Filariasis, elephantiasis	Lymphatics
		Enterobius vermicularis (pinworm)	Pinworm infection	Intestines
		Strongyloides stercoralis (threadworm)	Strongyloidiasis	Intestinal parasite, skin infection
		Onchocerca volvulus	Onchocerciasis	Blindness, dermatitis

*Most common in the United States.

spends part of its life cycle. Examples include the transmission of malaria (*Plasmodium* spp.) by mosquitoes, trypanosomes (*Trypanosoma cruzi*, which causes Chagas disease in South America; *Trypanosoma brucei*, which causes sleeping sickness in Africa) by the tsetse fly, and *Leishmania* spp. by sand fleas. Many of the protozoal infectious agents (e.g., *E. histolytica, G. lamblia*) are encountered in contaminated water or food and transmission is by ingestion.

The initial attachment depends on whether the microorganism is injected into the bloodstream by a vector or whether entrance is through the gastrointestinal tract. Microorganisms in the bloodstream frequently have surface lectins that react with carbohydrates on specific cells. Malarial parasites attach to erythrocytes that express Duffy blood group antigens. Thus Duffy-negative individuals are resistant to malaria. *T. cruzi* can infect both CD4-negative and CD8-positive T cells through a T-cell surface receptor. Several parasites express surface glycoproteins that facilitate preferential entrance into monocytes/macrophages using various receptors, including the receptors for complement component C3b (*Leishmania* spp.). *Leishmania* expresses a surface glycoprotein (gp63) that is necessary for its entrance into macrophages. The gp63 molecule binds complement components (C3b, C3bi) and uses the macrophage complement receptors. *E. histolytica* expresses two surface proteins that react with the disaccharide galactose/*N*-acetylgalactosamine on epithelium.

Invasion and Evasion. An effective immune response varies depending on the particular parasite or protozoa. Intercellular pathogens are susceptible to cell-mediated immunity and activation of macrophages by T cells. Other organisms are more sensitive to antibody, particularly used in antibody-dependent cell-mediated cytotoxicity (ADCC) by macrophages and natural killer (NK) cells. Many helminth infections are sensitive to damage by eosinophils, which are attracted by IgE-mediated mast cell degranulation and release of eosinophil chemotactic factor of anaphylaxis (ECF-A). Evasion of the individual's defenses is accomplished by several means (see Table 10-5).[25]

Intracellular Survival. *Leishmania* spp. are obligative intracellular parasites of monocytes/macrophages. They are protected from being killed in the phagosome and phagolysosome in which they multiply. Protection may be afforded by a surface protein that inhibits fusion of lysosomes to the phagosome, thus decreasing the amount of degradative enzymes within the phagolysosome. *Toxoplasma* spp. may be protected by entrance into a variety of cells, including macrophages. The probability of survival is increased by inhibiting fusion of lysosomes with the phagosome. Many of the intracellular organisms are sensitive to macrophage activation by T cells. *T. cruzi* bypasses the effects of macrophage activation by escaping from the phagosome and growing in the macrophage cytoplasm.

Protection Against Phagocytosis. Because many unicellular parasites survive within macrophages, the development of antiphagocytic capsules does not seem to be a major protective strategy. In some cases, a surface glycocalyx may function in a similar fashion as capsules to mask surface antigens from binding antibody. Some organisms produce toxins to protect themselves against phagocytosis; *E. histolytica* releases phospholipase and pore-forming proteins that disrupt the phagocyte's plasma membrane.

Coating with Self-Proteins. Pathogens that coat themselves with human proteins may be disguised and "fool" the immune system. Schistosomes and trypanosomes mask their antigens by absorbing IgG by the Fc portion of the molecule.

Antigenic Variation. In general, those organisms that undergo part of their life cycle in humans or may assume multiple morphologic forms will also undergo antigenic changes related to the stage in the life cycle or morphology. Some protozoa have developed very complex alterations in surface antigens using **gene switching.** Infection with African trypanosomes may lead to fatal neurologic disease. During infection protective antibody is produced against surface antigens called variable surface glycoproteins (VSGs). The parasite remains extracellular and an IgG or IgM response will successfully kill most of the microorganisms. However, a small percentage will undergo a gene shift that results in a change in VSG.[26] The existing antibodies will not recognize the new VSG, and the level of schistosomes will rebound, causing recurrent disease. The schistosome has genetic information (about 10% of the genome) for hundreds of variations in VSG, which are expressed one at a time. Thus the organism undergoes periodic shifts in VSG expression, resulting in periodicity of parasites in the blood. A similar process occurs in some helminths *(Trichinella spiralis).*

Degradation of Immune Molecules. If a microorganism is sensitive to a particular component of the immune or inflammatory system, a survival advantage is obtained by production of enzymes that specifically degrade that component. Schistosomes secrete an enzyme that diminishes the effectiveness of IgG by specifically removing a critical peptide. *E. histolytica* secretes a protease that can degrade IgG and IgA.

Neutralization of Immune Molecules. Large parasitic organisms may release a large amount of soluble antigen to neutralize antibody.

Complement Evasion. Complement activation is effective against several parasites. Some parasites (e.g., *Echinococcus* spp., *Leishmania* spp.) produce complement regulatory proteins that affect complement function by destabilizing C3 convertase or promoting degradation of C3b. Trypanosomes produce complement regulatory factors, including a surface gp63-like molecule, that confer resistance to complement. *E. histolytica* produces complement regulatory factors that inactivate C3a and C5a, thus inhibiting phagocyte chemotaxis activity.

Immune Suppression. Parasites may produce both pathogen-specific and nonspecific immune suppression. The release of large amounts of soluble antigen may induce specific tolerance to the pathogen as well as induce dysfunctional macrophage antigen processing. The function of immune cells is directly blocked by secretion of cytotoxic molecules *(T. spiralis),* selective inhibitors of T-cell function (schistosomes), or inducers of polyclonal B-cell activation (B-cell mitogen released by trypanosomes).

E. histolytica induces T-cell hyporesponsiveness by induction of IL-4 and IL-10 that down-regulate maturation of Th cells. The VSG molecules of African trypanosomes stimulate macrophages to overproduce TNF-α and CD8-positive cells to

secrete high levels of interferon-gamma (IFN-γ), which impairs T-cell responses.[27] *Leishmania* has developed an interesting approach to circumventing antigen processing by macrophages. This pathogen adsorbs IgG, which binds to the macrophage Fc receptor, resulting in the hyperproduction of IL-10 and suppression of IL-12 from infected macrophages. IL-10 prevents macrophage responses to IFN-γ, allowing the parasites to survive even in the immunologically intact individual.

Tissue Damage. Tissue damage may result directly by parasitic infestation in the tissue or be secondary to the individual's immune and inflammatory responses. The particular process depends a great deal on burden of parasites infesting the site and sensitivity of the particular site to damage. Large infestations may lead to physical loss of function in a tissue or organ. For instance, a large number of intestinal parasites (e.g., the roundworm *Ascaris lumbricoides,* tapeworms, *Giardia* spp.) compete for and prevent uptake of nutrients, leading to various forms of malabsorption, blocked uptake of fats, or anemia from malabsorption of B_{12} or from large amounts of blood loss. Filarial parasites (e.g., *Wuchereria bancrofti* and *Brugia malayi,* which causes elephantiasis) block the lymphatics and cause accumulation of lymph in tissues. The larvae of tapeworms (e.g., *Taenia solium*) encyst in and prevent normal function of organs (e.g., muscle, liver, eye), which is particularly dangerous in the human brain.

Toxins released from parasites may cause significant irreversible organ damage. Proteolytic enzymes from *E. histolytica* are very cytolytic, leading to ulceration of intestinal walls, bloody diarrhea, amoebic dysentery, dehydration, and death in infants and young children. *T. cruzi* (causes Chagas disease) secretes proteases and phospholipases that damage the myocardium and intestinal smooth muscle and secretes a small-molecular –weight neurotoxin that affects the anatomic nervous system and causes fever.

The infected individual's immune and inflammatory responses result in considerable histopathology. Schistosomiasis results in the deposition of eggs in organs (e.g., the liver), which leads to formation of granulomas and tissue destruction through fibrosis. Some parasitic products (*T. brucei,* malarial parasites) activate macrophages to overproduce cytokines, which leads to exacerbated inflammation. The IgE produced against parasitic worms is protective, but can also stimulate excessive degranulation of mast cells and even anaphylactic shock. Polyclonal B-cell activation leads to the production of a broad spectrum of autoantibodies that may precipitate autoimmune diseases. Overproduction of antigens by some pathogens (e.g., malaria, trypanosomiasis, schistosomiasis) may lead to excessive levels of pathogenic circulating immune complexes and initiation of type III hypersensitivity reactions (see Chapter 9) in the kidneys and vasculature.

Example of Parasitic Pathogenesis. Malaria is one of the most common infections worldwide. The World Health Organization (WHO) estimated in 2010 that there were 219 million cases of malaria worldwide and that malaria accounted for an estimated 666,000 deaths, 90% of which are in Africa, mostly among children.[28] Malaria is caused by four species of *Plasmodium* parasites that infect humans: *Plasmodium falciparum* (accounts for most fatalities), *Plasmodium vivax and Plasmodium ovale* (both of which are more benign), and *Plasmodium malariae*. The four strains differ in disease severity and incidence of fever. Infection with *P. falciparum,* the most severe form, results in severe chills, high fever, sweating, headache, muscle pains, vomiting, severe anemia, pulmonary edema, and many other complications. Neurologic complications may result from infected red blood cells (RBCs) adhering to endothelium in capillaries of the brain. The individual may develop cardiovascular collapse, shock, coma, and death.

Transmission is through the bite of an infected female *Anopheles* mosquito, where the microorganism grows in the salivary gland. The infectious form enters the bloodstream, survives in the liver, and invades parenchymal cells. After several rounds of division, the liver cell ruptures, and several thousand parasites enter the blood, where they infect red blood cells (Figure 10-8). Multiplication occurs in RBCs, resulting in the release of daughter parasites that reinfect other erythrocytes.

P. vivax and *P. ovale* malaria can remain dormant in the liver for years, protected from the immune system by intracellular residence. The parasite in the blood avoids destruction by phagocytes in the spleen by expressing adhesion proteins that cause adherence and sequestration along the walls of the small vessels. Additionally, *P. falciparum* undergoes gene switching among about 60 different antigenic variants of antigens expressed on the surface of infected erythrocytes (*P. falciparum*

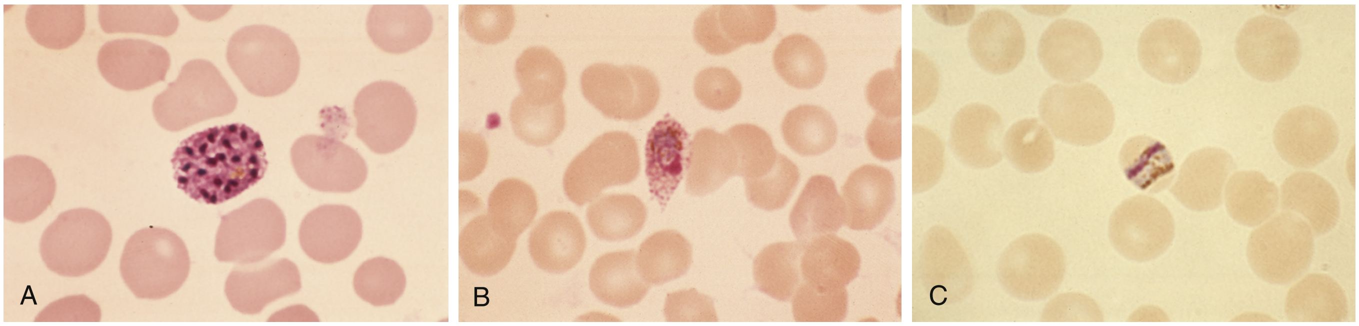

FIGURE 10-8 Malaria. Giemsa-stained smears. **A,** *Plasmodium vivax* schizont. **B,** *Plasmodium ovale* trophozoite. **C,** Characteristic band from trophozoite of *Plasmodium malariae* containing intracellular pigment hemozoin. (From Kliegman R et al: *Nelson textbook of pediatrics,* ed 19, St Louis, 2011, Saunders.)

erythrocyte membrane protein, *Pf*EMP). Malaria induces a form of immune suppression. Numbers of CD4 and CD8 T cells are diminished and lymphocytes from individuals infected with *P. falciparum* do not proliferate in the presence of *Pf*EMP antigen in vitro.

Malarial parasites have developed broad drug resistance including chloroquine, the previous mainstay of the preventive and therapeutic arsenal of antimalarial drugs.[29] Most resistance originates from mutations in the target genes (antigenic variation). Resistance to drugs that cause cellular damage appear to result from increased activity, or even novel development, of drug transporters that eliminate the drugs from the parasitic organism.

Viral Infection and Injury

Viruses are extremely simple microorganisms and do not possess any of the metabolic organelles found in prokaryotes (e.g., bacteria) or eukaryotes (e.g., human cells). The basic viral structure (virion) consists of nucleic acid protected by a protein shell, the capsid. The capsid may take many characteristic shapes: helical, icosahedral, or large pleiomorphic (poxvirus) (Figure 10-9). Some viruses also have a protective envelope surrounding the capsid, which consists of the plasma membrane from the previously infected cell.

Viruses are classified by the format of nucleic acid in the virion, which may be RNA or deoxyribonucleic acid (DNA) and either single-stranded (ss) or double-stranded (ds), and by whether the virus uses the enzyme reverse transcriptase (RT) for replication. Thus seven classifications are used: dsDNA (e.g., herpesvirus, smallpox virus), ssDNA (parvovirus), dsRNA (rotavirus), ssRNA +sense (+sense functions as mRNA) (e.g., hepatitis A and C viruses, SARS virus, poliovirus, rhinovirus), ssRNA−sense (e.g., Ebola virus, Marburg virus, Nipah virus, influenza virus, and viruses that cause measles, mumps, and rabies, hantavirus, Lassa virus), ssRNA +sense with RT (e.g., HIV), and dsDNA with RT (e.g., hepatitis B virus).

Viral diseases are the most common afflictions of humans and include the common cold, the "cold sore" of herpes simplex virus, several forms of hepatitis, HIV, and several types of cancer. Examples of human diseases caused by specific viruses are listed in Table 10-8.

Transmission and Colonization. Viruses are obligatory intracellular parasites; thus transmission is usually from one infected individual to an uninfected individual or from an animal reservoir **(zoonotic infection).** Transmission may be direct or through a vector, such as mosquitoes. Human-to-human transmission may take many forms, including aerosols of respiratory fluids, contact with infected blood, or sexual contact.

The viral life cycle is completely intracellular and involves several steps: *attachment* to the target cell (determines host range and tropism), *penetration* (by endocytosis or membrane

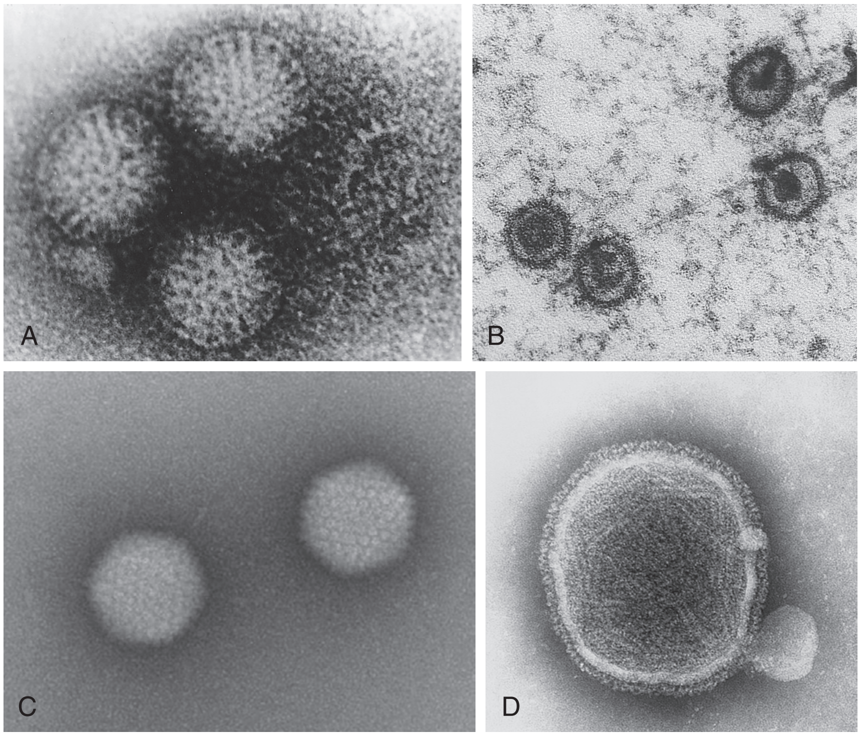

FIGURE 10-9 **Electron Micrographs of Representative Viral Structures. A,** Rotavirus: particles with a double shell and a characteristic "wheel-and-spoke" appearance. **B,** Epstein-Barr virus: icosahedral enveloped DNA virus. **C,** Adenovirus: particles with characteristic icosahedral structures. **D,** Paramyxovirus: spherical enveloped RNA virus. RNA is seen spilling out of the disrupted virus. (**A** from Long S, Pickering L, Prober C: *Principles and practice of pediatric infectious diseases,* ed 3, Philadelphia, 2005, Saunders; **B** and **D** photos courtesy Science Source; © Photo Researchers, Inc., New York, NY; **C** from Mandell GL, Bennett JE, Dolin R: *Mandell, Douglas, and Bennett's principles and practice of infectious diseases,* ed 7, Philadelphia, 2010, Churchill Livingstone.)

fusion), *uncoating* (release of viral nucleic acid from the viral capsid by viral or host enzymes), *replication* (synthesis of viral proteins and mRNA), *assembly* (formation of new virions), and *release* (by lysis, budding) (Figure 10-10).

Attachment involves specific interactions between surface proteins on the virus and receptors on the cell to be infected. The specificity of the virus for these receptors and the distribution of receptors throughout the individual's tissues dictate the range of host cells that a particular virus can infect. For example, HIV has a glycoprotein (gp120) that attaches to the CD4 molecule expressed on helper T cells, monocytes, and microglia. Rotavirus recognizes sialic acid and other constituents of epithelial junctions. Epstein-Barr virus (EBV, which causes mononucleosis) binds to complement receptor 2 (CR2) on B lymphocytes.

Once bound, the virion penetrates the plasma membrane by receptor-mediated endocytosis, by envelope fusion with the plasma membrane, or by directly crossing the plasma membrane. Within the cytoplasm the virus uncoats the protective

TABLE 10-8 HUMAN DISEASES CAUSED BY SPECIFIC VIRUSES

BALTIMORE CLASSIFICATION	FAMILY	VIRUS	ENVELOPE	MAIN ROUTE OF TRANSMISSION	DISEASE
dsDNA	Adenoviruses	Adenovirus	No	Droplet contact	Acute febrile pharyngitis
	Herpesviruses	Herpes simplex type 1 (HSV-1)	Yes	Direct contact with saliva or lesions	Lesions in mouth, pharynx, conjunctivitis
		Herpes simplex type 2 (HSV-2)	Yes	Sexually, contact with lesions during birth	Sores on labia, meningitis in children
		Herpes simplex type 8 (HSV-8)	Yes	Sexually?, body fluids	Kaposi sarcoma
		Epstein-Barr virus (EBV)	Yes	Saliva	Mononucleosis, Burkitt lymphoma
		Cytomegalovirus (CMV)	Yes	Body fluids, mother's milk, transplacental	Mononucleosis, congenital infection
		Varicella-zoster virus (VZV)	Yes	Droplet contact	Chickenpox, shingles
ssDNA	Papovaviruses	Papillomavirus	No	Direct contact	Warts, cervical carcinoma
dsRNA	Reoviruses	Rotavirus	No	Fecal-oral	Severe diarrhea
ssRNA+	Picornaviruses	Coxsackievirus	No	Fecal-oral, droplet contact	Nonspecific febrile illness, conjunctivitis, meningitis
		Hepatitis A virus	No	Fecal-oral	Acute hepatitis
		Poliovirus	No	Fecal-oral	Poliomyelitis
		Rhinovirus	No	Droplet contact	Common cold
	Flaviviruses	Hepatitis C virus	Yes	Blood, sexually	Acute or chronic hepatitis, hepatocellular carcinoma
		Yellow fever virus	Yes	Mosquito vector	Yellow fever
		Dengue virus	Yes	Mosquito vector	Dengue fever
		West Nile virus	Yes	Mosquito vector	Meningitis, encephalitis
	Togaviruses	Rubella virus	Yes	Droplet contact, transplacental	Acute or congenital rubella
	Coronaviruses	SARS	Yes	Droplets in aerosol or direct contact	Severe respiratory disease
	Caliciviruses	Norovirus	No	Fecal-oral	Gastroenteritis
ssRNA–	Orthomyxoviruses	Influenza virus	Yes	Droplet contact	Influenza
	Paramyxoviruses	Measles virus	Yes	Droplet contact	Measles
		Mumps virus	Yes	Droplet contact	Mumps
		Parainfluenza virus	Yes	Droplet contact	Croup, pneumonia, common cold
		Respiratory syncytial virus (RSV)	Yes	Droplet contact, hand-to-mouth	Pneumonia, influenza-like syndrome
	Rhabdoviruses	Rabies virus	Yes	Animal bite, droplet contact	Rabies
	Bunyaviruses	Hantavirus	Yes	Aerosolized animal fecal material	Viral hemorrhagic fever
	Filoviruses	Ebola virus	Yes	Direct contact with body fluids	Viral hemorrhagic fever

nucleocapsid and releases viral genetic information. Most RNA viruses directly produce mRNA, which is translated into viral proteins, and genomic RNA, which is eventually packaged into new viruses. One particular family of viruses, retroviruses (e.g., HIV), carries the enzyme *reverse transcriptase* that creates a double-stranded DNA version of the virus. The DNA "provirus" enters the cell's nucleus, where it becomes integrated into the host cell's chromosomal DNA. DNA viruses also enter the nucleus and are transcribed into mRNA before protein translation. Some DNA viruses also may integrate into the infected cell's chromosomal DNA.

The translation of viral-specific mRNA results in viral proteins that self-assemble. New virions are released from the cell for transmission of the viral infection to neighboring uninfected cells. Enveloped viruses are released through *budding,* in which shed viral particles are enveloped in the plasma membrane from the surface of the infected cell. Nonenveloped viruses commonly are released in large numbers concurrent with the destruction of the cell. Viral DNA that has become integrated with host DNA is transmitted to the daughter cells during mitosis. By this process, viral genes can become part of the genetic information of the cell and its progeny.

Invasion and Evasion. The primary defense mechanisms against viruses include antibody that prevents viral entrance into a cell and cellular immunity that recognizes antigenic changes on the surface of infected cells. Nonspecific defense includes production of α- and β-interferons that block intracellular viral replication. However, many viruses are highly successful pathogens and have developed a variety of mechanisms for bypassing immune rejection (see Table 10-5, p. 308).

Rapid Division. Some viruses, particularly those with small genomes, rapidly proliferate after the initial infection and by doing so produce a large number of virions more quickly than the immune system can develop. Norovirus and rotavirus (causes of severe diarrhea and vomiting) and Ebola virus, Marburg virus, and hantavirus (causes of hemorrhagic fever) have very short incubation periods. By the development of an effective adaptive immune response in 4 or 5 days, the virus has spread and caused severe clinical disease.

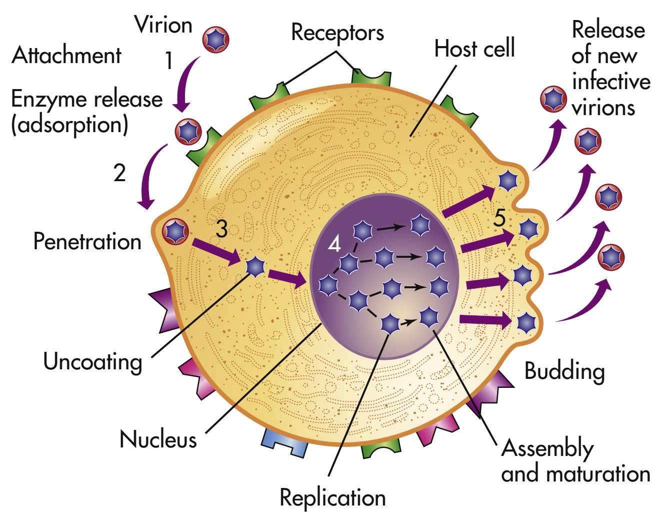

FIGURE 10-10 Stages of Viral Infection of an Infected Cell.

Intracellular Survival. As obligative intracellular pathogens, viruses hide within cells and away from normal inflammatory or immune responses. Viral agents that spread from cell to cell after the initial infection must encounter the immune response, which in most cases cures the infection. Thus most viral infections are self-limiting.

If a symbiotic relationship is maintained between the cell and the virus, persistent unapparent infection may result (latency). The infected cell will be functional, and the virus persists until it is activated to replicate (e.g., the recurrent coldsores of herpes simplex virus infection).[30] Latent viruses usually possess latency-associated transcript (LAT) genes that control persistence indefinitely. Reactivation usually results from expression of lytic genes that lead to increased viral expression and destruction of the infected cell. Latency is characteristic of several chronic viral infections (e.g., HIV, hepatitis B and C viruses).

The interferon response is particularly effective against many viral infections, and viral survival mechanisms have evolved to mitigate the antiviral effects of interferon. The V and P proteins of the measles virus may function as regulators of transcription and prevent the synthesis of interferon, as well as the induction of protective genes by interferon.[31] In a similar fashion, the influenza virus produces a family of viral proteins that inhibit the pathways leading to the production of interferon and to activation of interferon-activated protective genes.[32]

Coat with Self-Proteins. Enveloped viruses are the prime examples of how this mechanism may succeed. The viral capsid is completely surrounded by a cellular plasma membrane that is highly similar to that of an uninfected cell. Only a few critical differences exist. In order to infect another cell the viron expresses envelope proteins (SU and TM proteins) that are critical for the intercellular fusion process. These proteins are virus-specific and targets for protective immune responses. Other viruses, such as the hepatitis C virus, bind on their surface normal proteins from the infected host, such as lipoproteins, that mask the viral epitopes from circulating antibody.[33]

Antigenic Variation. One of the classic examples of antigenic variation is influenza. This virus undergoes frequent antigen shifts and drifts, which are described in detail within the following section titled Example of Viral Pathogenesis. Other viruses (e.g., HIV) add antigenic diversity by incorporating frequent functional translational errors. Some viral enzymes are designed to create small errors in reading mRNA leading to minor changes in the viral proteins. These changes are not at functionally critical sites, but may provide resistance to specific and nonspecific defense mechanisms.

In a manner similar to bacteria, some viruses have multiple stable antigenic serotypes. A person who recovers from an infection with one serotype may not have protective immunity against other serotypes of the same virus. At least 100 serotypes of rhinovirus can cause the "common cold," which explains why individuals can catch many colds throughout their lives. HIV and hepatitis C virus also have multiple serotypes.

Neutralization of Immune Molecules. As with other pathogens, the secretion of large amounts of soluble viral antigen may lead to neutralization of antibody and formation of immune complexes. With infections such as hepatitis B significant levels

of circulating immune complexes may form and be deposited in target tissues, such as the kidneys.

Some viruses also have the capacity to neutralize cytokines, such as IL-1 and TNF-α. Cells infected with vaccinia virus produce a protein that can bind to IL-1. These molecules are frequently called cytokine decoys.

Complement Evasion. Several viruses induce expression of regulators of complement activation. Cellular complement inhibitors are incorporated into the envelope of some viruses (e.g., HIV-1, vaccinia). Cytomegalovirus (CMV) induces complement inhibitors on the surface of infected cells. Herpes simplex virus expresses a cell surface protein (glycoprotein C-1) that binds and inhibits C3b, as well blocks the membrane attack complex.

Immune Suppression. HIV and other viruses have developed the capacity to infect and kill immune cells, thus protecting themselves, but also leading to a broad immunosuppression against other antigens. This process is discussed more thoroughly in the section on AIDS.

Some viruses have developed mechanisms for interfering with antigen processing and presentation by major histocompatibility complex (MHC) class I molecules. Endogenous antigens, such as viral antigens, are normally degraded by proteasomes, transported by transporters with antigen processing (TAP) proteins into the endoplasmic reticulum, and complexed with MHC class I molecules for expression on the cell surface and presentation to appropriate cells of the immune response (see Chapter 8). Many of the herpesviruses and retroviruses prevent steps in this process. For instance, Epstein-Barr virus inhibits degradation by the proteasomes. Herpes simplex virus can prevent binding of the antigenic peptide to MHC class I. Inhibition of antigen presentation by MHC class I prevents the generation of effective T-cell immune responses.

Human CMV has developed a unique modification of affecting MHC processing. NK cells are the principal defenders against tumor cells or virally infected cells that have down-regulated MHC expression and are therefore not recognized by T-cytotoxic cells. NK cell function is suppressed by targets with surface class I MHC molecules. CMV is capable of preventing antigen presentation by MHC class I and stimulates the expression of a MHC-like molecule that cannot present antigen but is recognized as a suppression signal by NK cells. Thus CMV-infected cells are protected from both T-cytotoxic cells and NK cell killing.

Tissue Damage. Once inside the infected cell, viruses may have many harmful effects, including the following:

- Cytopathic effects resulting from inhibition of cellular DNA, RNA, or protein synthesis, disruption of lysosomal membranes, resulting in release of "digestive" lysosomal enzymes that can kill the cell (cell lysis)
- Promotion of apoptosis of the cell
- Fusion of infected, adjacent cells, thereby producing **multinucleated giant cells** (herpesviruses and paramyxoviruses [measles virus, mumps virus, respiratory syncytial virus])
- Transformation of infected cell into cancerous cells, resulting in uninhibited and unregulated growth
- Alteration of the antigenic properties, or "identity," of the infected cell, causing the immune system to attack the cell as if it were foreign

Example of Viral Pathogenesis. Influenza is an ssRNA (−strand) with a segmented genome (seven or eight pieces of ssRNA) (Figure 10-11). It is transmitted through aerosols or body fluids and is highly infectious. The virions attach to respiratory epithelial cells and enter by endocytosis. Symptoms begin 1 to 4 days after infection and may include chills, fever, sore throat, muscle aches, severe headaches, coughing, weakness, generalized discomfort, nausea, and vomiting, and may lead to pneumonia; it can be fatal, particularly in young children and older adults. The normal rate of infectivity is about 5% to 15%, with a mortality rate of about 0.1%, and in most cases recovery occurs in 1 to 2 weeks. Yearly seasonal influenza outbreaks result in about 250,000 to 500,000 deaths worldwide.

The influenza virion expresses two surface proteins that are essential to virulence. The hemagglutinin (HA) protein is a glycoprotein that is necessary for entrance into cells by binding to glycan receptors, which are richly expressed on the surface of respiratory epithelium.[34] The surface neuraminidase (NA) is an enzyme that is necessary for release of new virions from infected cells by cleaving cellular sialic acids (a common component of mammalian cell membranes).

Antibodies against the HA and NA antigens are responsible for protection against influenza infection. Infections are seasonal and protection gained from 1 year's infection does not totally protect against influenza in the following year because the HA and NA antigens undergo yearly change. Usually antigenic variation is relatively minor **(antigenic drift)** and results from **mutations.** Individuals frequently have partial protection resulting from the previous year's infection, which lessens the effects of the disease. Two groups of influenza virus, influenza A and influenza B, infect humans, and the yearly vaccine against influenza virus is a trivalent mixture of inactivated proteins from two influenza A subtypes and one influenza B subtype. Influenza B almost exclusively infects humans, mutates at a much lower rate than influenza A, and has reduced rate of antigenic change. Influenza B, however, has antigenically distinct subtypes based on HA (16 forms) and NA (9 forms) antigens and is infectious to birds and mammals. Currently subtypes H1N1, H1N2, and H3N2 are the primary causes of influenza worldwide. Information regarding subtype H5N1 (avian influenza) is summarized in What's New? Avian Influenza.

Periodically influenza A undergoes major antigenic changes **(antigenic shifts)** (see Figure 10-11). Shifts occur in animals coinfected by a human and an avian strain of influenza.[35] Because the genome is segmented, the segments can undergo **recombination** during which the human virus obtains a new HA or NA antigen. When such changes occur, previous protection may not exist, resulting in a major pandemic and much more severe disease. In 1918 an antigenic shift occurred in the western United States (first reported in Fort Riley, Kansas) resulting in an influenza A virus with an H1N1 serotype (called Spanish flu). The virus spread worldwide throughout 1918 and 1919. Symptoms were unusually severe, resulted from excessive production of cytokines, and included deaths from secondary bacterial pneumonia, massive hemorrhages, and pulmonary edema. Spanish flu possessed an extremely high rate of infectivity (up to 50%) and mortality (killed 20% or more of those

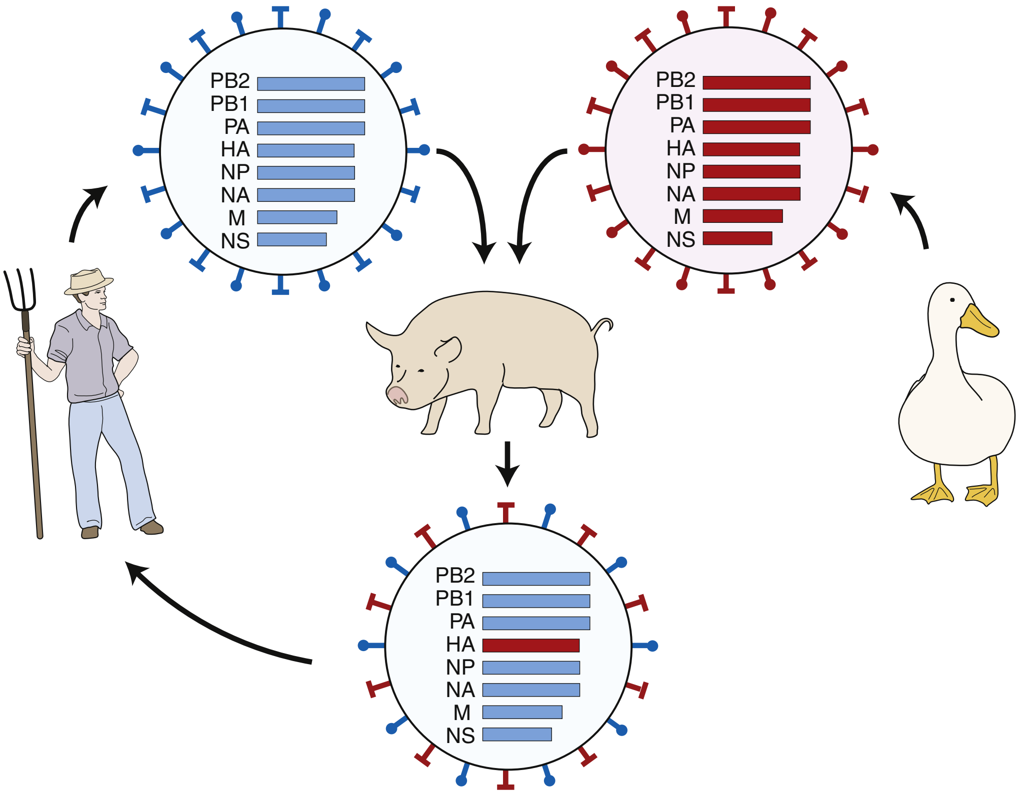

FIGURE 10-11 Antigenic Shifts in Influenza Virus. One theory proposes that antigenic shifts occur when a human influenza virus *(blue)* and an avian influenza virus *(red)* coinfect a species that is permissive for both. The eight ssRNA strands are co-expressed in the same infected cell, resulting in mixing of the strands so that a hybrid virus can be produced. The hybrid virus indicated here contains all the genetic information of the original virus that infected humans, but contains a new hemagglutinin *(HA)*-containing stand from the avian virus. This virus expresses a new HA antigen and will be less susceptible to residual immunity that normally provides partial protection against yearly influenza infections.

WHAT'S NEW?

Avian Influenza

Influenza viruses infect a wide variety of species, including humans, different strains of birds, and swine. The species specificity of a particular variant of influenza is determined by the amino acid sequence of the hemagglutinin (HA) molecule on the viral surface. Influenza viruses have a relatively high mutation rate that can result in minor changes in the HA and change the species specificity. As a result, an influenza virus strain that primarily infects birds may, after a mutation, become efficiently infectious for humans.

Various strains of a highly pathogenic avian influenza A (H5N1) have arisen in the past few years. These strains were first reported in 1996 in China. The most pathogenic variants have a near 100% mortality rate in domestic poultry and have spread globally, killing tens of millions of birds. The global spread may be a result of collateral nonfatal infection of wild migrating birds, such as ducks and geese.

In 1997, the first human infections with the H5N1 avian virus were reported in Hong Kong involving 18 cases, 6 of whom died. From 2003 through 2012, the WHO has reported a total of 608 confirmed H5N1 cases and 359 deaths across 15 countries worldwide. So far, human infections occur primarily in those individuals who have been in close contact with infected birds (especially those who have handled sick, dead, or frozen poultry). Human-to-human transmission is rare. No cases have been identified among short-term travelers visiting countries affected by outbreaks. The H5N1 strain infects the lungs and targets type 2 alveolar pneumocytes and macrophages. It also passes throughout the body to the gastrointestinal tract, brain, liver, and blood cells and can be transmitted transplacentally from the mother to the fetus. Symptoms include fever, cough, sore throat, muscle aches, eye infections (conjunctivitis), pneumonia, acute respiratory distress, and other severe and life-threatening complications. Diagnosis is made by detection of viral ribonucleic acid (RNA) obtained through throat swabs. The mortality rate in human infections is about 60%. Host immunogenic variation may play a role in the outcome of the immune response.

The concern is that further mutations may lead to a strain that spreads and infects humans more efficiently, resulting in a rapid pandemic. These concerns are not unfounded. Highly pathogenic H5N1 strains have undergone continued evolution and expansion of host range with increasing mortality rates among wild birds and infectivity for other mammals, including dogs and cats. In 2007, a H5N1 strain was clearly transmitted from an infected individual to six other members of the same Indonesian family group. The virus was further transmitted from one of those six, an infected child, to the child's caregiver. Seven of the eight individuals died.

Whether highly pathogenic variants of H5N1 avian influenza virus eventually mutate into a major human pathogen remains to be seen. Prevention efforts rely on the development, distribution, and use of vaccines. Antiviral agents are used for active infection and prophylaxis of those who have been exposed to the virus. Candidate genes influencing susceptibility are being identified.

infected) and resulted in an estimated 40 million deaths worldwide. A unique aspect of this influenza pandemic concerned the age of the most susceptible populations.[36] Most mortalities secondary to influenza generally occur in the very young or very old. Although those two age groups were at risk, a startling high mortality rate was observed in adults between ages 20 and 39. Strain variations caused by antigenic drift occur within both HA and NA, and some may further affect virulence of that virus. The 1918 H1N1 serotype also possessed several mutations in the HA that resulted in a far greater virulence than the currently circulating H1N1 type. Studies have demonstrated that survivors of the 1918 pandemic still have protective levels of antibodies against that particular virus, confirming that protection against a particular influenza strain may be lifelong.

ACQUIRED IMMUNODEFICIENCY SYNDROME (AIDS)

The most notable form of secondary or acquired immune deficiency caused by an infectious agent is **acquired immunodeficiency syndrome (AIDS).** AIDS is a viral disease caused by the **human immunodeficiency virus (HIV).** HIV infects and depletes a portion of the immune system (Th cells), making individuals extremely susceptible to life-threatening infections and malignancies.

Despite major efforts by healthcare agencies around the world, HIV/AIDS remains the major cause of worldwide morbidity and mortality. Although aggressive antiretroviral therapy and public health campaigns have stabilized the number of new cases and deaths in the United States from HIV/AIDS, the number of cases and deaths continues to increase rapidly worldwide. Surveillance reports from the Centers for Disease Control and Prevention (CDC) estimates that more than a million (1,148,200) adults and adolescents were living with HIV infection in the United States in 2010, of whom 18% were undiagnosed, and that approximately 50,000 new HIV infections occur yearly.[37] Most new infections (61%) occurred in gay or bisexual men. The number of new AIDS diagnoses in the United States increases by more than 30,000 per year (estimated at about 35,000 in 2011). The estimated number of AIDS-related deaths in 2010 was 15,529. Cumulatively since 1981 more than a million individuals (1,155,792) have been diagnosed with AIDS in the United States, of which almost 636,000 have died as a result, and more than 490,000 are still living with AIDS. In the United States, AIDS is predominantly related to a history of male-to-male sexual contact: about 50% of the newly diagnosed cases were attributed to male-to-male sexual contact, 30% to high-risk heterosexual contact, and 14% to injected drug abuse. About 25% of new cases were diagnosed in females, primarily (74%) contracted through high-risk heterosexual contact.

Sub-Saharan Africa is still the epicenter of the AIDS pandemic. In 2009, the World Health Organization (WHO) estimated that 22.5 million people living with HIV infection (68% of the global total) resided in sub-Saharan Africa. South Africa continues to have the largest estimated number of infected individuals (5.6 million), and Swaziland has the highest adult prevalence (26%) of HIV infection in the world.[38] Women remain at greatest risk of infection: of all women infected with HIV globally, 76% of them reside in sub-Saharan Africa. Throughout the region, women, especially those aged 15 to 19, are the majority of HIV-infected individuals. HIV infection among women aged 20 to 24 in South Africa is approximately 21%, compared to 7% in age-matched men. It is estimated that the incidence of new HIV infections in women in the region exceeds those in men by 1.3 times. It is estimated that AIDS is responsible for almost 50% of all deaths in South Africa and 71% of deaths among individuals in the 15- to 40-year age group. It is the leading cause of maternal deaths and is responsible for 35% of deaths in children younger than 5 years of age. As a result, the average life expectancy is now 54 years, whereas it would be at least 64 without AIDS. More than half of the current 15-year-olds are not expected to live to age 60.

The outlook for the future is not all bleak. Through the work of the WHO and other groups, as well as the implementation of aggressive AIDS awareness programs and greatly increased access to antiretroviral therapy in many sub-Saharan African countries, the incidence of HIV infection and death caused by AIDS is falling across the region. The HIV infection rate in the total region fell by more than 25% between 2001 and 2009. Between 2004 and 2009, the number of AIDS-related deaths decreased by 20%.

Transmission

HIV is a blood-borne pathogen present in body fluids (e.g., blood, vaginal fluid, semen, breast milk) with the typical routes of transmission: blood or blood products, intravenous drug abuse, heterosexual and homosexual activity, and maternal-child transmission before or during birth. As of 2009, an estimated 8640 children in the United States developed AIDS after contracting HIV infection from their mothers across the placenta, through contact with infected blood during delivery, or through the milk during breast-feeding. Without treatment, symptoms usually develop within 6 months of life, and life expectancy is generally less than 3 years. However, adequate use of prenatal antiviral therapy has reduced maternal-child transmission dramatically; only 12 new cases were reported in 2009.

As with all blood-borne infections, healthcare providers are at increased risk of contracting the infection from an individual's blood.[39] The first reported case of occupational HIV infection was an emergency department nurse who became infected in 1986. The route of infection was probably through cuts in her hand that came into contact with contaminated blood through a gauze pad she was holding on a person's open wound. The infectivity of HIV is relatively low compared to other major blood-borne contaminants; from a single needle stick of contaminated blood the probability of acquiring an HIV infection is 0.3%, compared to 3% for hepatitis C and 30% for hepatitis B.[40] Tens of thousands of healthcare workers have become infected with HIV, but as of May 2011, only 57 cases of confirmed HIV infection and 143 possible cases were contracted by occupational exposure, and no new cases of occupational HIV infection have been identified since 1999.[41] Since initiation of widespread educational programs on universal precautions published by the

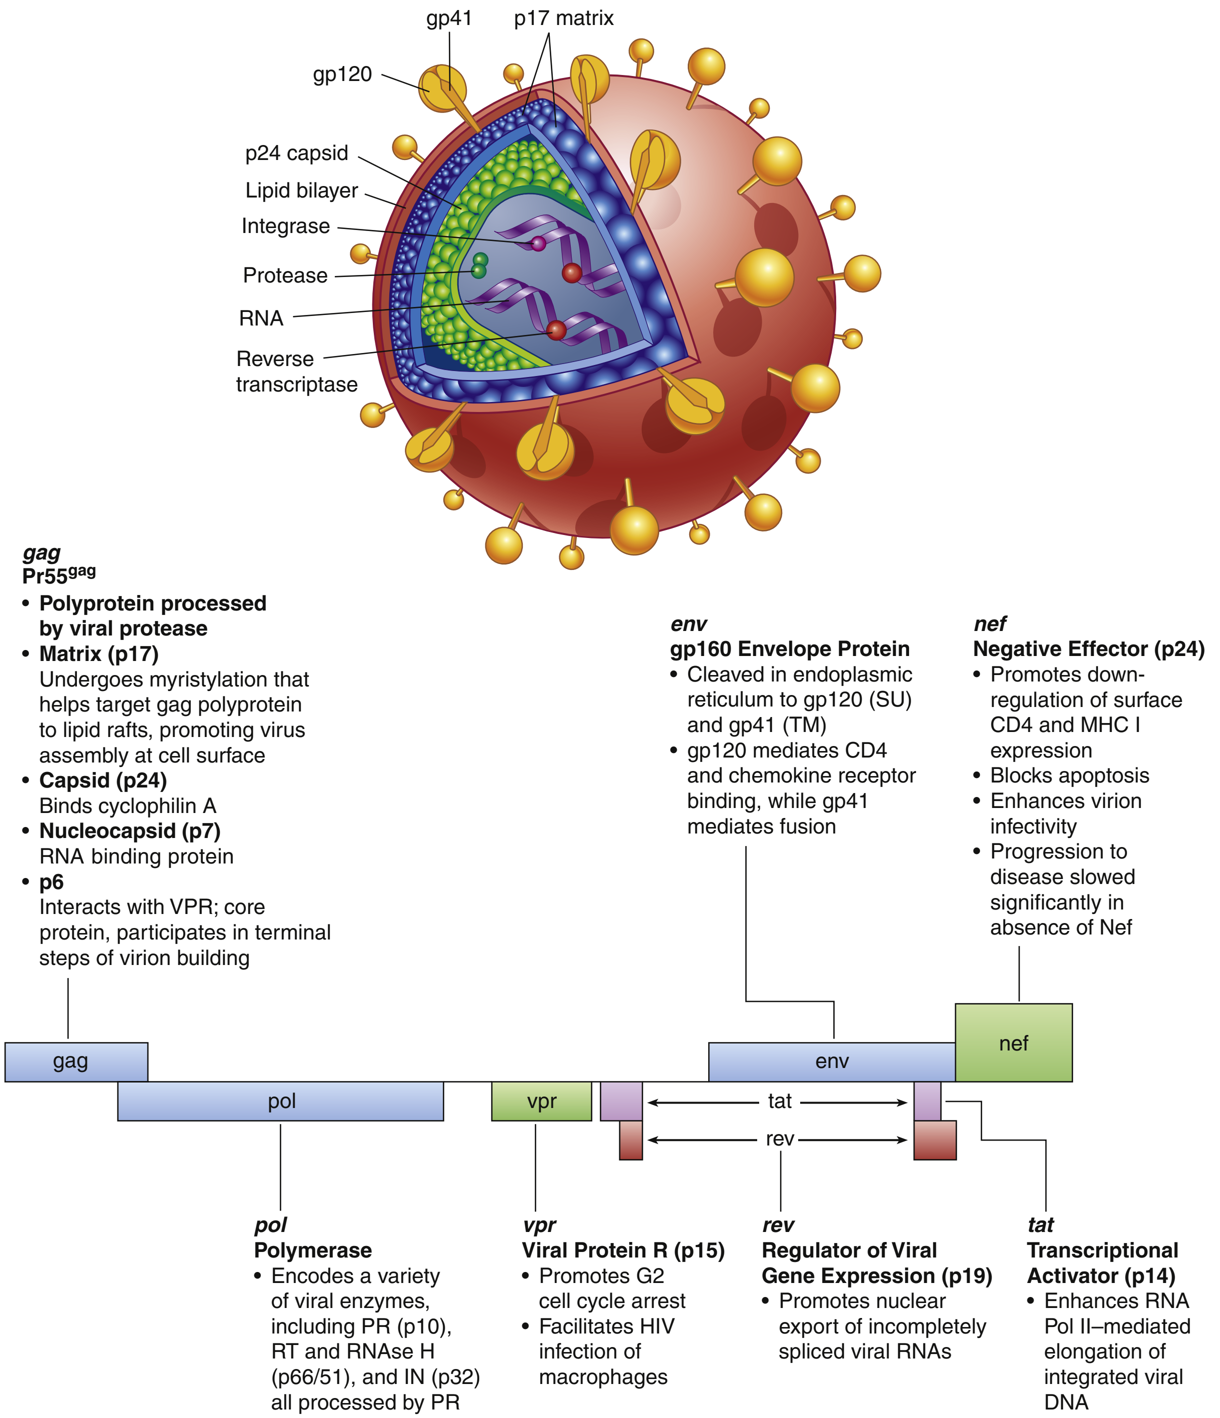

FIGURE 10-12 The Structure and Genetic Map of HIV-1. The HIV-1 virion consists of a core of two identical strands of viral RNA molecules of viral enzymes (reverse transcriptase [RT], protease [PR], integrase [IN]) encoated in a core capsid structure consisting primarily of the structural viral protein p24. The capsid is further encased in a matrix consisting primarily of a viral protein, p17. The outer surface is an envelope consisting of the plasma membrane of the cell from which the virus budded (lipid bilayer) and two viral glycoproteins: a transmembrane gp41 and a noncovalently attached surface protein, gp120. The HIV-1 genome contains regions that encode the structural proteins *(gag),* the viral enzymes *(pol),* and the envelope proteins *(env).* The *gag* region is translated into a large precursor (Pr55^{gag}) that is cut by the HIV protease into smaller proteins that construct the capsid and matrix. The *env* region is translated into a gp160 precursor protein that is cut by a host-cell protease into the gp120 and gp41 envelope proteins. The genome of complex retroviruses, like HIV-1, often contains a variety of small regions that regulate expression of the virus. (Modified from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

CDC only 3 new cases have been reported. Nurses (42% of total cases) and clinical laboratory technicians (28% of cases) are by far the most commonly exposed healthcare workers. In the event of occupational exposure to HIV-contaminated specimens, post-exposure prophylaxis with antiretroviral medications may be appropriate.[42,43]

Pathogenesis

HIV-1 was initially isolated by researchers at the Pasteur Institute as the lymphadenopathy/AIDS virus (LAV), a discovery for which they received the 2008 Nobel Prize in Medicine.[44] A second major and less virulent variant, HIV-2, was identified later and is found mostly in western Africa. HIV is a member of the retrovirus family, which carries genetic information in the form of two copies of RNA (Figure 10-12). Retroviruses use a viral enzyme, **reverse transcriptase,** to convert RNA into double-stranded DNA (Figure 10-13). Using a second viral enzyme, an **integrase,** the new DNA is inserted into the infected cell's genetic material, where it may remain dormant. If the cell is activated, translation of the viral information may be initiated, resulting in the formation of new virions, lysis and death of the infected cell, and shedding of infectious HIV particles. If, however, the cell remains relatively dormant, the viral genetic material may remain latent for years, and is probably present for the life of the individual.

The primary surface receptor on HIV is the envelope glycoprotein gp120, which binds to the molecule CD4, found primarily on the surface of helper T cells (see Figure 10-13).[45] Several other necessary co-receptors have been identified on the target cells,

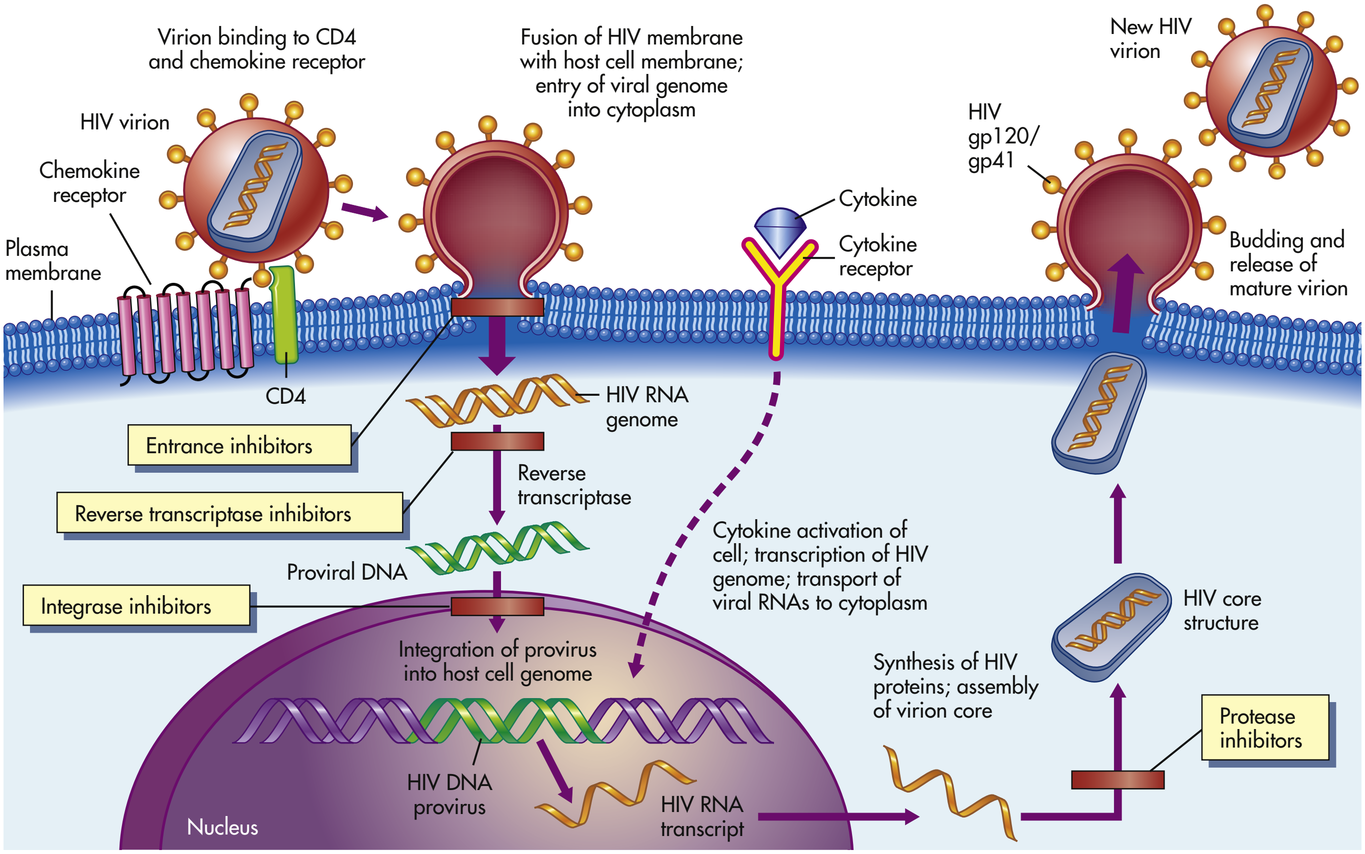

FIGURE 10-13 Life Cycle and Possible Sites of Therapeutic Intervention of HIV-1. HIV infection begins when a virion, or virus particle, binds to CD4 and chemokine co-receptors on a susceptible cell. The HIV virion has viral proteins gp41 and gp120 on its surface (envelope), which interact with CD4 and the CCR5 co-receptor and initiate fusion between the viral envelope and the plasma membrane, resulting in the core of the virus being injected into the cytoplasm. Uncoating occurs in the cytoplasm, during which the core proteins are removed, and the viral RNA is released into the infected cell's cytoplasm. The viral RNA is converted to a double-stranded DNA provirus by the action of the viral reverse transcriptase. The provirus migrates into the nucleus and is integrated into the cell's own DNA. The provirus may remain latent. If the infected cell is activated (e.g., by cytokines), the provirus may be transcribed and translated into viral protein precursors. The precursor proteins are modified by viral (gag proteins) and cellular (env proteins) proteases into smaller proteins that are used to package the viral RNA into new virions that bud from the cell. The HIV-1 life cycle is susceptible to blockage at several sites. Some agents could block the attachment and entrance of the virus (entrance inhibitors). Reverse transcriptase inhibitors (e.g., azidothymidine [AZT]) prevent the reverse transcription of viral RNA into DNA. Drugs also may be able to inhibit the viral integrase (integrase inhibitors) and prevent insertion of the provirus into the host's chromosomes. Protease inhibitors specifically inhibit the viral protease and prevent the processing of the gp160 into viral capsid and matrix proteins. (Modified from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 7, Philadelphia, 2005, Saunders.)

particularly the chemokine receptors CXCR4 and CCR5. Different strains of HIV-1 are selective for the CXCR4 or CCR5 co-receptors, which influences the tropism for different target cells. Strains that prefer the CXCR4 co-receptor tend to be T-cell tropic, usually found later in an infection, and cause infected cells to fuse and form a multinucleate **syncytium.** Strains that react better with the co-receptor CCR5 are macrophage-tropic, usually cause the primary HIV infection, and do not cause syncytium formation.

The primary cellular targets for HIV include the following:

- CD4-positive Th cells
- Dendritic cells (depending on the level of chemokine receptors the cell expresses)
- Macrophages (express low levels of CD4, but high amounts of heparin sulfate proteoglycans [syndecan] and other molecules [CCR5] that bind to gp120 and adsorb HIV)
- CD8-positive Tc cells (low rate of infection, but CD4 can be expressed by activated CD8-positive Tc cells)
- Double positive thymic cells (express CD4 and CD8 simultaneously)
- NK cells (some are CD4+, CCR5+)
- Neural cells of monocyte origin (macrophages and microglial cells)

Initially, the lymphoid areas of the mucosal surfaces are the primary sites of infection (Figure 10-14). Dendritic cells and mucosal T cells probably spread the infection to other peripheral lymphoid organs (especially follicular dendritic cells in the lymph nodes, which infect T cells).[46] Infection also may involve the thymus and bone marrow, including the bone marrow stromal cells. Cells in the central nervous system (e.g., astrocytes and monocytes), the gastrointestinal tract (particularly in the rectum and ileum), and other anatomic sites act as reservoirs in which HIV can be relatively protected from antiviral drugs.[47] The virus is also found in T cells and macrophages in semen and in the renal epithelium.

The major immunologic finding in AIDS is the striking decrease in the number of CD4+ Th cells (Figure 10-15). Individuals who are not HIV infected typically have 800 to 1000 CD4+ cells/μL of blood, with a range from 600 to 1200/μL. Numbers of CD8+ Tc cells are usually normal or slightly elevated. The decrease in CD4+ cell numbers results in a reversal of the normal CD4/CD8 T-cell ratio (normally about 1.9) to lower than 0.9 and often near zero.

HIV causes destruction of Th cells by a variety of means. Production of new HIV virions can be directly cytopathic to the infected cell, causing lysis (breakdown of the cell) or inducing

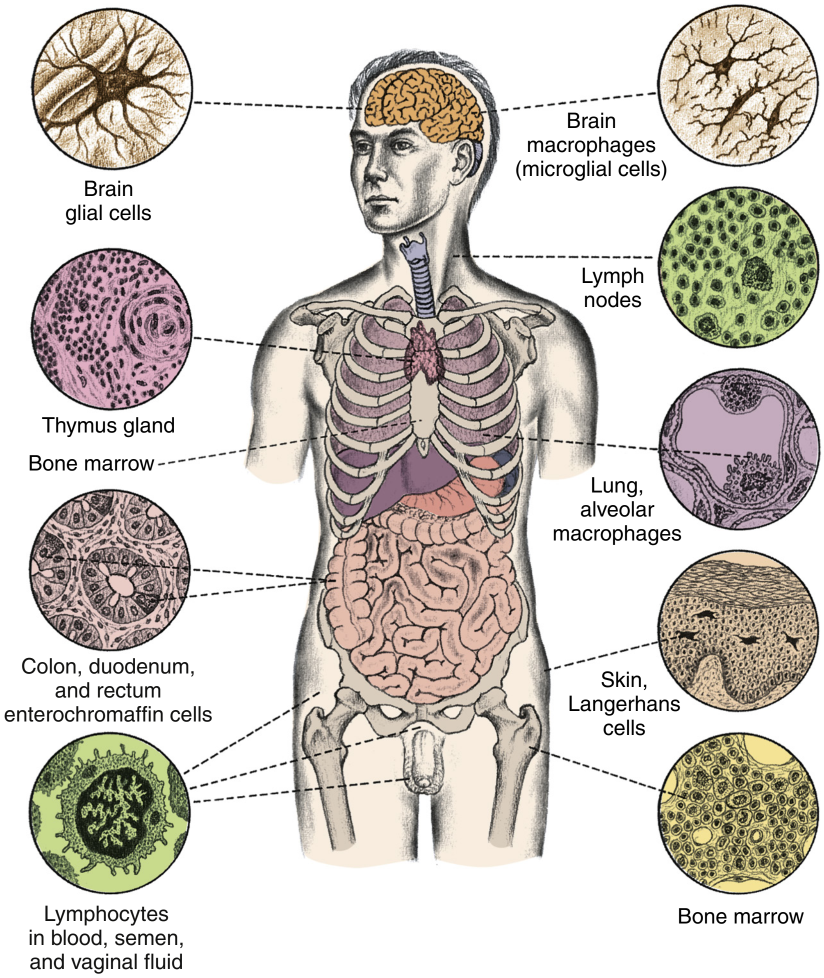

FIGURE 10-14 **Distribution of Tissues That Can Be Infected by HIV.** Infection is closely linked to the presence of CD4 receptors or chemokine co-receptors on host tissue, particularly T cells and macrophages. (Modified from Weber JN, Weiss RA: *HIV infection: the cellular picture, in the science of AIDS: readings from Scientific American,* New York, 1989, Freeman.)

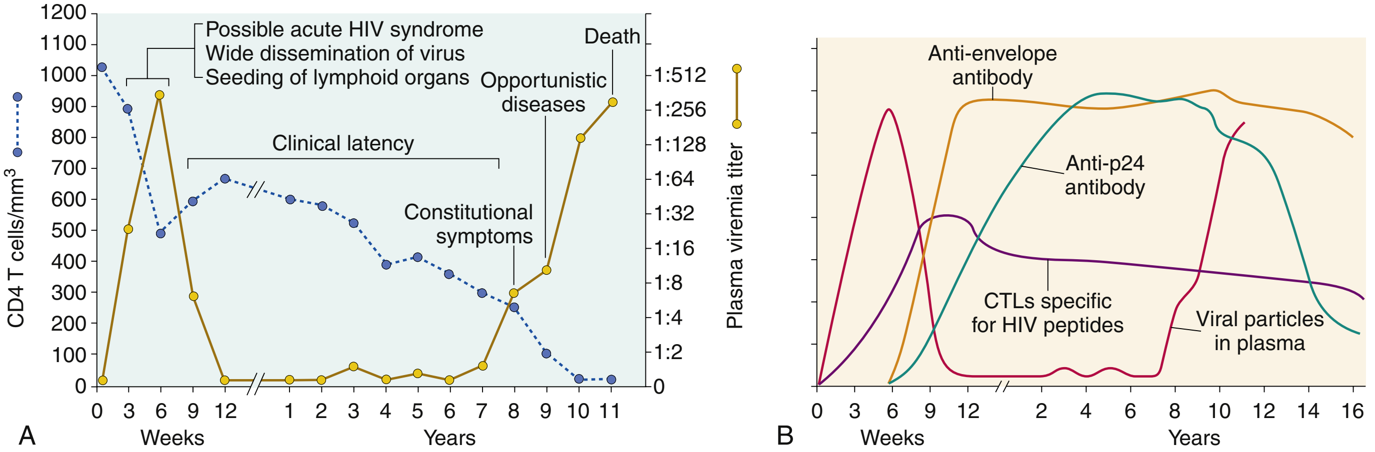

FIGURE 10-15 Typical Course of Progression from HIV Infection to AIDS in Untreated Persons. **A,** Within weeks after infection, the person may experience symptoms of acute HIV syndrome. During this early period the virus progressively infects mucosal T cells and dendritic cells, propagates, and spreads to the lymphoid organs, with a sharp decrease in the number of circulating CD4+ Th cells. The resulting immune response usually induces a period of clinical latency, during which viral replication and T-cell destruction continue in the lymph nodes, although the individual is generally asymptomatic. As the disease progresses, the person may develop HIV-related disease (constitutional symptoms)—a variety of symptoms of acute viral infection that do not involve opportunistic infections or malignancies. When the number of CD4+ cells is critically suppressed, the person becomes susceptible to a variety of opportunistic infections and cancers. The length of time for progression from HIV infection to AIDS may vary considerably from person to person. **B,** Antibody and Tc cell (cytotoxic T lymphocytes [CTLs]) levels change during the progression to AIDS. During the initial phase antibodies against HIV-1 are not yet detectable (window period), but viral products, including p24 antigen, viral RNA, and infectious virus, may be detectable in the blood a few weeks after infection. Most antibodies produced against envelope proteins in the early phase are absorbed onto viral particles in the blood and are not detectable by most routine assays. During the latent phase of infection antibody levels against p24 and other viral proteins, as well as HIV-specific CTLs, generally increase, then remain constant until the development of AIDS. As the immune system becomes severely depressed and excess viral antigen is released into the blood, measurable antibody levels decrease. Disease progression usually ends in the death of the untreated individual. (**A** redrawn from Fauci AS, Lane HC: Human immunodeficiency virus disease: AIDS and related conditions. In Fauci AS et al, editors: *Harrison's principles of internal medicine,* ed 14, New York, 1997, McGraw-Hill; **B** from Kumar V, Abbas A, Fausto N: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.)

apoptosis. Additionally, HIV-infected cells express new surface antigens and are targets for Tc-mediated lysis.

However, it is not unusual for a large majority (>98%) of peripheral CD4+ Th cells to *not* be infected with HIV-1, although a significant amount (10% to 50%) show signs of apoptosis. Therefore, HIV-1 killing is probably an indirect rather than direct effect. HIV-infected cells shed soluble viral envelope protein, gp120, which can induce apoptotic cell death of uninfected T lymphocytes, neurons, and monocytes through interaction with cell surface receptors. The interaction between viral envelope protein on the surface of infected cells and its receptors on neighboring uninfected cells also can result in intercellular fusion and syncytium formation. The syncytia undergo apoptosis after a phase of latency. Envelope protein present on the surface of HIV-1–infected cells also can create partial fusion (hemifusion, membrane damage) that results in death of the uninfected cell. The presence of HIV virions and soluble viral antigen can result in a chronic activation of uninfected T cells with HIV-specific T-cell receptors (TCRs). Because activated T cells more efficiently support HIV replication, the most susceptible cells are those with TCRs against HIV, which undergo antigen-driven activation and infection. This observation may not bode well for successful vaccine development if the induced and supposedly protective CD4+ cells are also the most susceptible targets for HIV.

As a result of these processes the level of T cells decreases (particularly T-memory cells, which seem more susceptible to HIV infection), thymic production of new T cells is decreased, and the secondary lymphoid organs (particularly the lymph nodes) are damaged.

Clinical Manifestations

Depletion of CD4+ cells has a profound effect on the immune system, causing a severely diminished response to a wide array of infectious pathogens and malignant tumors (Box 10-2).

At the time of diagnosis, the individual may manifest one of several different conditions: serologically negative (no detectable antibody), serologically positive (positive for antibody against HIV) but asymptomatic, early stages of HIV disease, or AIDS (see Figure 10-15).

The presence of circulating antibody against the HIV indicates infection by the virus, although many of these individuals are asymptomatic. Antibody appears rather rapidly after infection through blood products, usually within 4 to 7 weeks. After sexual transmission, however, the individual can be infected yet seronegative for 6 to 14 months or, in at least one case, for years. In addition, in the late stages of the disease, some individuals become seronegative because of a deficient immune system.

BOX 10-2 AIDS-DEFINING OPPORTUNISTIC INFECTIONS AND NEOPLASMS FOUND IN INDIVIDUALS WITH HIV INFECTION

Protozoal and Helminthic Infections
Cryptosporidiosis or isosporiasis (enteritis)
Toxoplasmosis (pneumonia or central nervous system [CNS] infection)

Fungal Infections
Pneumocystosis (pneumonia or disseminated infection)
Candidiasis (esophageal, tracheal, or pulmonary)
Cryptococcosis (CNS infection)
Coccidioidomycosis (disseminated)
Histoplasmosis (disseminated)

Bacterial Infections
Mycobacteriosis (atypical, e.g., *Mycobacterium avium-intracellulare,* disseminated or extrapulmonary; *Mycobacterium tuberculosis,* pulmonary or extrapulmonary)
Nocardiosis (pneumonia, meningitis, disseminated)
Salmonella infections (disseminated)

Viral infections
Cytomegalovirus (pulmonary, intestinal, retinitis, or CNS infections)
Herpes simplex virus (localized or disseminated)
Varicella-zoster virus (localized or disseminated)
Progressive multifocal (leukoencephalopathy)

Neoplasms
Kaposi sarcoma
B-cell non-Hodgkin lymphomas
Primary lymphoma of the brain
Invasive cancer of the uterine cervix

Adapted from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, Philadelphia, 2010, Saunders.

The period between infection and the appearance of antibody is referred to as the **window period** (see Figure 10-15). Although the individual may not have antibody, he or she may have virus growing, have virus in the blood and body fluids, and be infectious to others. Early symptoms are relatively nonspecific to HIV and include fatigue, fever, muscle aches, and headaches.

Those with the early stages of HIV disease *(early stage disease* or *clinical latency)* are usually asymptomatic. The early stage may last as long as 10 years in untreated people, during which viral load increases and numbers of CD4+ cells progressively decrease. Some estimates are that approximately 99% of untreated HIV-infected individuals would eventually progress to AIDS.

The currently accepted definition of AIDS relies on both laboratory tests and clinical symptoms. The most common laboratory test is for antibodies against HIV proteins (particularly p24). If the individual is seropositive, the diagnosis of AIDS is made in association with various clinical symptoms (see Box 10-2). The symptoms include atypical or opportunistic infections and cancers, as well as indications of debilitating chronic disease (e.g., wasting syndrome, recurrent fevers) (Figure 10-16). Most commonly, new cases of AIDS are diagnosed initially by decreased CD4+ T-cell numbers at or below 200 cells/μL.

Treatment and Prevention

The current regimen of **antiretroviral therapy (ART)** for treatment of HIV infection is a combination of drugs.[48] As of 2012, more than 20 antiretroviral drugs that fell into 6 different mechanisms were available for ART. Classes of antiretroviral agents included inhibitors of the enzyme reverse transcriptase (nucleoside reverse transcriptase inhibitors [NRTIs] and non-nucleoside reverse transcriptase inhibitors [NNRTIs]), inhibitors of the viral protease (protease inhibitors [PIs]), inhibitors of fusion between HIV and the cell membrane (fusion inhibitors), inhibitors of HIV binding to CCR3 (CCR5 antagonists), and inhibitors of the viral integrase enzyme (integrase strand transfer inhibitors [INSTIs]). Several preferred and alternative therapeutic regimens are recommended, depending on the particular individual. In general, the combination includes at least three drugs: two NRTIs and one from another class (NNRTI, PI, INSTI, or CCR5 antagonist) (see Figure 10-13). Death from AIDS-related diseases has been reduced significantly since the introduction of ART; without treatment an individual may live only 9 to 10 months after diagnosis of AIDS, whereas those who respond well to ART may survive for several decades. However, many people do not respond to ART therapy, those who do respond are not "cured," and resistant variants to these drugs have been identified. Many individuals who initiate antiretroviral therapy will still have a shortened life expectancy secondary to HIV-associated persistent immune activation. Although the capacity of the immune system to respond to specific pathogens is greatly diminished, HIV infection nonspecifically activates T cells and monocytes resulting in greatly increased production of inflammatory cytokines and an increased risk for developing chronic and potentially fatal morbidities, such as cardiovascular disease, renal disease, diabetes, and liver disease.[49]

Drug therapy for AIDS is difficult because, like most retroviruses, the AIDS virus incorporates into the genetic material of the host and may never be removed by antimicrobial therapy. Therefore, drug administration to control the virus may have to continue for the lifetime of the individual. Additionally, HIV may persist in regions where the antiviral drugs are not as effective, such as the central nervous system (CNS).

To date, the development of an effective vaccine is the only hope for preventing the spread of HIV infection. Most common antiviral vaccines (e.g., rubella, mumps, influenza) induce protective antibodies that block the initial infection. Only one vaccine (rabies) is used after the infection has occurred. That approach is successful because the rabies virus proliferates and spreads very slowly. Whether an HIV vaccine would be effective in either preventing or treating HIV infection is problematic, and the results of recent vaccine trials have for the moment dampened enthusiasm. The USPSTF recommends that clinicians screen adolescents and adults aged 15 to 65 years for HIV infection. Those younger or older who are at increased risk should also be screened.[49a]

Pediatric AIDS and Central Nervous System Involvement

The clinical diagnosis of HIV in children is very often a difficult task (Box 10-3). The presence of passive maternal antibody limits the use of HIV antibody testing in infants in the high-risk

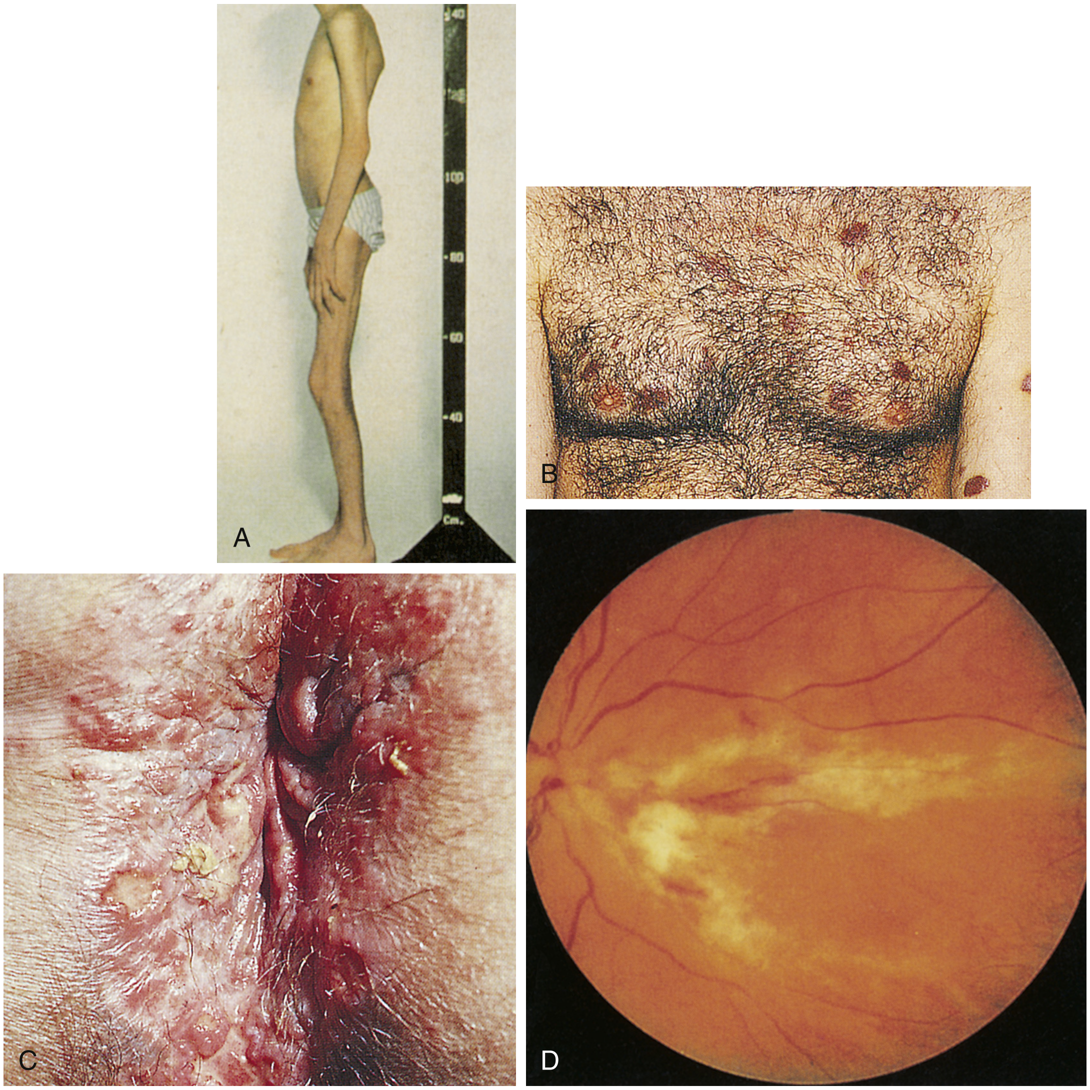

FIGURE 10-16 Clinical Symptoms of AIDS. **A,** Severe weight loss and anorexia. **B,** Biopsy-proven Kaposi sarcoma lesions. **C,** Perianal vesicular and ulcerative lesions of herpes simplex infection. **D,** Deterioration of vision from cytomegalovirus retinitis leading to areas of infection; unless treated the progressive impairment will lead to blindness. (**A** and **D** from Taylor PK: *Diagnostic picture tests in sexually transmitted diseases,* London, 1995, Mosby; **B** and **C** from Morse SA, Holmes KK, Ballard RC, editors: *Atlas of sexually transmitted diseases and AIDS,* ed 4, London, 2011, Saunders.)

category up to 18 months of age. In this age group, diagnosis of HIV infection must be made by assays to measure viral DNA or RNA in the blood. For children older than 18 months, the diagnosis of HIV infection is confirmed by the presence of specific antibodies to the virus.

HIV directly invades most major organ systems, including the CNS. Therefore, the clinical manifestations vary greatly from child to child. The initial signs and symptoms may be nonspecific and subtle, and they may progress slowly or rapidly to an acute, life-threatening condition. A definite diagnosis of HIV is made by obtaining a personal history, performing virologic testing, and assessing clinical manifestations. Monitoring CD8+ T lymphocytes and monocytes, in addition to CD4+ Th lymphocytes, has been suggested for predicting risk for progressive encephalopathy. Decreases in the number of CD8+ Tc lymphocytes diminish defenses against viral infection and facilitate infected monocytes to cross the blood-brain barrier.

A particularly vulnerable site of HIV infection in infants and children is the CNS. HIV encephalopathy is more common in the advanced stages. Because survival of children with HIV has been prolonged with effective treatment, the incidence of progressive encephalopathy has increased. The 1994 classification from the CDC requires one of the following progressing findings to be present for at least 2 months, in the absence of a concurrent illness other than HIV that could explain the following findings:

- Failure to attain or loss of developmental milestones, or loss of intellectual ability, verified by standard developmental scale or neuropsychologic tests
- Impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy demonstrated by computed tomography (CT) or magnetic resonance imaging (MRI) with serial imaging required in children less than 2 years of age

BOX 10-3 PEDIATRIC HUMAN IMMUNODEFICIENCY VIRUS (HIV) CLASSIFICATION

IMMUNOLOGIC CATEGORIES	N: NO SIGNS/ SYMPTOMS	A: MILD SIGNS/ SYMPTOMS	B: MODERATE SIGNS/ SYMPTOMS	C: SEVERE SIGNS/ SYMPTOMS
1. No evidence	N1	A1	B1	C1
2. Evidence of moderate suppression	N2	A2	B2	C2
3. Severe suppression	N3	A3	B3	C3

Clinical Categories for Children with HIV Infection

Category N: Not symptomatic

Children who have no signs or symptoms considered to be the result of HIV infection or who have only one of the conditions listed in Category A

Category A: Mildly symptomatic

Children with two or more of the conditions listed below but none of the conditions listed in Category B or C:

Lymphadenopathy
Hepatomegaly
Splenomegaly
Dermatitis
Parotitis
Recurrent or persistent upper respiratory tract infection, sinusitis, or otitis media

Category B: Moderately symptomatic

Children who have symptomatic conditions other than those listed for Category A or C that are attributed to HIV infection; examples of conditions in clinical Category B include but are not limited to:

Anemia (≤8 g/dl), neutropenia (≤1000 mm^3), or thrombocytopenia (≤100,000 mm^3) persisting ≥30 days
Bacterial meningitis, pneumonia, or sepsis (single episode)
Candidiasis or oropharyngeal infection (thrush) persisting (≥2 months) in children ≥6 months of age
Cardiomyopathy
Cytomegalovirus infection with onset before 1 month of age
Diarrhea, recurrent or chronic
Hepatitis
Herpes simplex virus (HSV), recurrent stomatitis (more than two episodes within 1 year)
HSV bronchitis, pneumonitis, or esophagitis with onset before 1 month of age
Herpes zoster (shingles) involving at least two distinct episodes or more than 1 dermatome
Leiomyosarcoma
Lymphoid interstitial pneumonia (LIP) or pulmonary lymphoid hyperplasia complex
Neuropathy
Nocardiosis
Persistent fever (lasting ≥1 month)
Toxoplasmosis, onset before 1 month of age
Varicella, disseminated (complicated chickenpox)

Category C: Severely symptomatic

Children who have any condition listed in the 1987 surveillance case definition of acquired immunodeficiency with the exception of LIP

Data from Centers for Disease Control and Prevention: *MMWR Morb Mortal Wkly Rep* 43(12):1, 1994.

- Acquired symmetric motor deficits manifested by affecting a child 1 month of age or older
- The onset of progressive encephalopathy may be a prognostic indicator of a poor outcome.

It may be difficult to completely differentiate the effect of HIV infection on the CNS from the effect of prenatal and perinatal exposure. In addition, other insults may accompany HIV in a young child and affect growth and development, such as drug exposure, prematurity, chronic illness, and a chaotic social atmosphere. The pathogenesis of HIV encephalopathy in children is poorly understood, but the presence of inflammatory mediators may be a contributing factor.

A growing number of investigational protocols are available for treatment of children with HIV. In general, treatment is focused on the preservation and maintenance of the immune system, aggressive response to opportunistic infections, and support and relief of symptomatic occurrences and administration of ART.[50]

COUNTERMEASURES AGAINST PATHOGENS

An extremely effective means of countering infectious microorganisms is rigorous use of environmental infection control measures, including control of insect vector populations, establishment of modern sanitation facilities, provision of clean water and uncontaminated food supplies, and other measures. Additionally, prophylactic or interventive procedures have been developed to prevent pathogens from initiating disease (vaccines) or to subdue the pathogen once the disease process has started (antimicrobials). Vaccine development has focused successfully on preventing the most severe and common infections (Table 10-9). With the initial success of antibiotic therapy, there was no perceived need for vaccination against many common and non–life-threatening infections. The increasing problem of antibiotic-resistant pathogens, however, forced a reappraisal of that strategy, and a greater emphasis is being placed on the development of new vaccines.

Infection Control Measures

Although effective means of safeguarding populations from exposure to infectious disease are well-known, lack of implementation or breakdowns in application of these initiatives has led to the reemergence of some infectious diseases.

John Snow, a British physician, is considered the "father of epidemiology."[51] Industrialization in England in the nineteenth century resulted in rapid expansion of London's population that outgrew city services. An outbreak of cholera in the Soho area of London in 1854 resulted in more than 600 deaths. Snow discovered that the outbreak centered around one particular public water pump, which got water from a well that had been

TABLE 10-9 REDUCTION IN VACCINE-PREVENTABLE DISEASES IN THE UNITED STATES

DISEASE	BASELINE 20TH CENTURY ANNUAL CASES*	2008 CASES	% REDUCTION
Diphtheria	175,885	0	100.0
Measles	503,282	55	99.9
Mumps	152,209	454	95.7
Pertussis	147,271	10,735	92.7
Smallpox	48,164	0	100.0
Polio	16,316	0	100.0
Rubella	47,745	11	99.9
Tetanus	1,314	19	98.6
Haemophilus influenzae type b, invasive	20,000	30	99.9

From National Institute of Allergy and Infectious Disease, National Institutes of Health: Vaccine, Vaccine Benefits, Updated May 11, 2010 available at http://www.niaid.nih.gov/topics/vaccines/understanding/pages/vaccinebenefits.aspx. Accessed February 25, 2013.

*Average number of reported cases over multiple years before initiation of vaccine (Centers for Disease Control and Prevention: *MMWR Morb Mortal Wkly Rep* 48[12]:243–248, 1999, *Morb Mortal Wkly Rep* 57[11]:289–291, 2008).

dug 3 feet from a cesspool (open sewage was common in London at that time). After the pump was closed, the rate of new cholera cases rapidly diminished. Snow's observation stimulated the development of the construction of clean water supplies and sewers throughout the city.

Sewage removal and other public health initiatives (e.g., routine trash collection, disposal of garbage by incineration or in landfills) are now the expected norm in developed countries. The quality of water and food, as well as disposal of human and animal waste, remains poor in many developing countries. Rapid urbanization as well as other problems (e.g., poverty, overcrowding, mass relocation of people because of war, rapid destruction of forests) has put pressure on already inadequate systems.[52] A 1991 outbreak of cholera in Peru resulted in an estimated 10,000 deaths and was attributed to inadequate sanitation.

Additionally, previously successful programs designed to control the breeding of insect vectors have been reversed. Despite an international emphasis on draining standing water that provides breeding grounds for mosquitoes, large unmanaged areas still abound. A very successful international mosquito eradication program resulted in decreasing incidence of mosquito-borne diseases. Some regions were declared "free" of mosquito-borne diseases. However, since the international ban on DDT (dichlorodiphenyltrichloroethane) for agricultural work and limitation of its use for control of disease vectors, mosquitoes and mosquito-related diseases have rebounded in previously disease-free areas. In northern India, heavy rains in the 1990s resulted in an increase in standing water that was not drained because of the lack of government-provided public health information and inadequate insecticides to control mosquitoes. Since 1996, recurrent and increasingly severe outbreaks of dengue fever (caused by dengue virus, which is related to yellow fever virus and West Nile virus) have occurred in this region. In the 2006 outbreak 10,344 cases were reported, with 162 deaths. This problem is exacerbated by the development of insecticide-resistant mosquitoes.

Antimicrobials

Since the first use of penicillin during World War II, antibiotics have had the greatest effect on controlling infection. Antibiotics are natural products of fungi, bacteria, and related microorganisms and kill or inhibit the growth of other microorganisms. Numerous chemicals or antimicrobials have been identified that either prevent the growth of microorganisms or directly destroy them. Antibiotics generally act by preventing the function of enzymes or cell structures that are unique to the infecting agent. Because viruses use the enzymes of the host's cells, there has been far less success in developing antiviral antibiotics.

Immediately after antibiotics became widely used, antibiotic-resistant microorganisms were observed.[53] By 1944 an adequate supply of penicillin allowed its widespread use to treat infections. In 1946 a hospital in Britain reported that 14% of all *S. aureus* infections were penicillin resistant. By 1950 the same hospital reported an increase to 59% and to greater than 89% in the 1990s. Over the past few decades healthcare providers have observed increasing incidences of drug-resistant malaria, tuberculosis, gonorrhea, salmonellosis, shigellosis, and staphylococcal infections (see What's New? Drug-Resistant Tuberculosis). *S. pneumoniae,* which causes pneumonia, meningitis, and acute otitis media (ear infections), was once routinely susceptible to penicillin. Since the 1980s, however, the incidence of penicillin-resistant microorganisms has risen to greater than 30% in some populations.

The goal of antibiotic therapy is elimination of the pathogenic microorganism. Some antibacterial antibiotics are **bactericidal** (kill the organism), whereas others are **bacteriostatic** (inhibit growth until the organism is destroyed by the individual's own protective mechanisms). The mechanisms of action of most antibiotics are (1) inhibition of the function or production of the cell wall, (2) prevention of protein synthesis, (3) blockage of DNA replication, or (4) interference with folic acid metabolism.

Antibiotic resistance is usually a result of one of four general mechanisms resulting from genetic mutations that can be transmitted directly to neighboring microorganisms by plasmid exchange.[54] One mechanism microorganisms commonly develop is the capacity to inactivate antibiotics. For example, resistance to penicillin, cephalosporins, and other β-lactam-containing antibiotics results from the production of an enzyme (β-lactamase) that breaks down the structure of the antibiotic.[55] Other forms of resistance result from modification of the target molecule. Azidothymidine (AZT) is a family of antivirals that suppresses the enzymatic activity of reverse transcriptase, a viral-specific enzyme responsible for the replication of viral RNA and the production of a DNA copy. HIV frequently mutates and produces an AZT-resistant reverse transcriptase. Some bacteria have gained the capacity to produce penicillin-binding proteins

WHAT'S NEW?

Drug-Resistant Tuberculosis

Tuberculosis (TB) is one of the oldest known human diseases. Evidence of molecular biomarkers of infection with the etiologic agent of TB, the bacterium *Mycobacterium tuberculosis,* dates to the earliest Egyptian dynastic period (about 3500-2650 BCE) and even earlier. *M. tuberculosis* was not discovered as the cause of TB until 1882 by Robert Koch, who won the 1905 Nobel Prize for his work.

The bacterium primarily attacks the lungs and spreads from person to person through droplets, released into the air during coughing or sneezing. Few individuals (approximately 10%) with adequate immune responses develop overt disease; however, most will not completely destroy the microorganisms and will develop a chronic asymptomatic infection that can be activated if the immune system is suppressed, such as associated with aging, progressive genetic immunodeficiency, immunosuppressive medication, HIV infection, and other conditions. If the individual is immunocompromised upon initial exposure to *M. tuberculosis,* the probability of developing clinical, rather than chronic, TB is near 50%.

For centuries TB was a major cause of death throughout the world. The spread of the disease was limited by the recognition in the 19th century that TB was caused by a contagion, which led to separation of infected individuals in isolation wards and sanatoriums. The advent of antibiotic use after World War II increased optimism that TB could be controlled. The rapid spread of AIDS in the 1980s, however, resulted in a rebound in the incidence of TB. The World Health Organization (WHO) estimated that in 2010 8.8 million individuals (1.1 million of whom were HIV-infected) contracted TB and 1.4 million (350,000 of whom were HIV-infected) died of TB. Most deaths from TB occurred in Southeast Asia, Africa, and the Western Pacific.

In 1993, the WHO declared a TB "global emergency" and initiated a global TB control program. Although the number of new cases of TB has declined slowly, the global incidence decreased by 1% to 3% annually since 2002; since 1990, deaths fell by 40% globally; and record low rates of TB have been achieved in the United States and most of Western Europe. However, the goals of the program will not be met. *M. tuberculosis* developed resistance to the limited battery of available anti-tuberculosis drugs. Development of drug resistance has been increased in many countries by provision of incomplete or erratic therapy by poorly trained physicians, substandard quality of real or counterfeit medications, lack of expert testing for drug-resistant strains, and other inadequacies in healthcare systems.

Drug resistance has been classified as multidrug-resistant (MDR) TB and extensively drug-resistant (XDR) TB. MDR TB is defined as resistance to the two first-line drugs isoniazid and rifampicin. XDR TB is defined as MDR TB that is also resistant to second-line drugs, including all fluoroquinolones and at least one of three injectable drugs (capreomycin, kanamycin, or amikacin). Both classes of drug resistance occur in individuals with untreated TB who were infected from others with a drug-resistant strain or those who were poorly treated initially and developed recurrence with a drug-resistant strain. In most countries, accurate estimates of drug resistance are difficult to obtain because of inadequate laboratory testing facilities. In Azerbaijan, a careful study reported that 22.3% of new and 55.8% of previously treated TB cases were MDR. A recent study from China, where an estimated 1 million new cases of TB occur yearly, estimated that 1 in 10 infected persons have MDR TB and 1 in 120 have XDR TB. Drug-resistant TB is difficult to treat because anti-tuberculosis drugs are expensive and have several side effects and because MDR TB may require up to 2 years of treatment with success rates of 70% or less; XDR TB may be incurable in many individuals.

The situation has become worse. Reports from India of 12 individuals with TB that is resistant to all approved first- and second-line drugs have sparked concern in both the medical and lay communities. These reports are not the first of such cases; earlier reports of similar broadly resistant TB had occurred in 15 cases in Iran in 2009 and in two cases in Italy in 2007. The term *totally drug-resistant (TDR) TB* has been used unofficially to describe this disease. Will TDR TB become a predominant form in the future, and how will it be contained? Many new anti-tuberculosis drugs are in the developmental pipeline, but efficacy, side effects, cost, and other important considerations remain unknown. An effective vaccine would be the ideal solution, but only one vaccine is currently available. The bacille Calmette-Guérin (BCG) vaccine was developed a century ago using an attenuated strain of the bovine form of TB *(Mycobacterium bovis)* and is administered to children in many countries. Although it protects against disseminated infection and death in children, there is no protection against chronic infection or pulmonary TB in adults. At least a dozen new vaccines are in development, but will take years to be approved, even if one is found to be effective.

Data from Arya SC, Agarwal N: *Int J Tuberc Lung Dis* 16(6):852, 2012; Brennan MJ, Thole J: *Tuberculosis* 92(Suppl 1):S6–S13, 2012; Chaisson RE, Nuermberger EL: *N Engl J Med* 366(23):2223–2224, 2012; Donoghue HD: *Clin Microbiol Infect* 17(6):821–829, 2011; Loewenberg S: *Lancet* 379(9812):205, 2012; Migliori GB et al: *Clin Infect Dis* 54(9):1379–1380, 2012; Rappuoli R, Aderem A: *Nature* 473(7348):463–469, 2011; Raviglione M et al: *Lancet* 379(9829):1902–1913, 2012; Udwadia ZF et al: *Clin Infect Dis* 54(4):579–581, 2012; Zumla A et al: *J Infect Dis* 205(Suppl 2):S228–S240, 2012; Zumia A et al: *Nat Rev Drug Disc* 11(3):171–172, 2012.

that block penicillin from binding to sites in the bacterial cell wall, and other bacteria have modified antibiotic-sensitive binding sites on the ribosomes and developed resistance to antibiotics that interfere with protein synthesis. A third mechanism of resistance results from alteration of metabolic pathways that may be sensitive to antibiotics to alternative, more antibiotic-resistant pathways. Some bacteria have gained resistance to sulfonamide by converting from use of environmental *para*-aminobenzoic acid for conversion to folic acid, which is an antibiotic-sensitive step in nucleic acid synthesis, to the direct use of environmental folic acid. A fourth mechanism is mediated by multidrug transporters in the microorganism's membrane. These transporters affect the rate of intracellular accumulation of the antimicrobial by preventing entrance or, more commonly, increasing active efflux of the antibiotic. Antibiotic-resistant strains of *M. tuberculosis* are protected from aminoglycosides and tetracycline by the transporters with antigen processing (TAP) protein (a mycobacterial multidrug efflux pump).

Many microorganisms are now resistant to multiple antibiotics. **Methicillin-resistant *Staphylococcus aureus* (MRSA)** incorporates several different mechanisms of resistance. MRSA produces a β-lactamase (penicillinase). Penicillinase-resistant antibiotics (e.g., methicillin) can be used as a substitute, but MRSA carrying the gene *mecA* is also methicillin resistant because of a lower affinity for β-lactams. Resistance to the glycopeptide antibiotic vancomycin is controlled by the gene *vanA,* which results in alterations in peptidoglycans and loss of the vancomycin-binding site.

Why have multiple antibiotic–resistant microorganisms appeared? Overuse of antibiotics can lead to the destruction

of the normal microbiome, allowing the selective overgrowth of antibiotic-resistant strains or pathogens that had previously been kept under control. For example, after treatment with the antibiotic clindamycin, the normal intestinal microbiome can become compromised, allowing the overgrowth of *Clostridium difficile* and the development of pseudomembranous colitis.[56] Also, lack of compliance concerning the necessity of completing the therapeutic regimen with antibiotics allows the selective resurgence of microorganisms that are more relatively resistant to the antibiotic.

With the development of multiple antibiotic–resistant strains, creativity in addressing this challenge must be rekindled. Antibiotics should no longer be used for minor infections, such as mild to moderate sinusitis.[57] New antibiotics may solve a portion of the problem or may exacerbate it further as pathogens develop resistance to new antibiotics as well. Available antibiotics that prove to be no longer effective must be replaced with alternative forms of therapy, including the increased development and use of vaccines and other therapies.

Active Immunization: Vaccines

Contracting and surviving an infectious disease is the most effective means of developing lifelong immunity against a particular pathogen. However, some infections cause a great deal of morbidity and mortality. The purpose of vaccination is to induce active immunologic protection before exposure to the risks of infection. For each vaccine an initial immunization protocol is developed to produce large numbers of memory cells and a sustained protective secondary immune response in the greatest number of individuals. In general, vaccine-induced protection does not persist as long as infection-induced immunity; thus, booster injections may be necessary to maintain protection throughout life. The Centers for Disease Control and Prevention maintain the most current immunization schedules for people of all ages. The schedules can be reviewed at www.cdc.gov/vaccines/recs/schedules/default.htm.

Mass vaccination programs have led to major changes in the health of the world's population. In the early 1950s an estimated 50 million cases of smallpox occurred each year, with about 15 million deaths. The World Health Organization (WHO) conducted a smallpox immunization campaign from 1967 to 1977 that resulted in the global eradication of smallpox by 1979. The 1988 immunization initiative against polio resulted in a 99% decrease in that disease. In 1960, 2525 cases of paralytic polio were reported in the United States, but no cases of naturally acquired polio have been reported since 1979. In 1994, polio was declared officially eradicated in all the Americas. The goal of the WHO is to eradicate polio worldwide by 2022.[58] Similar trends occurred for each disease against which an effective vaccine has been developed.

Development of a successful vaccine depends on many factors. These include characterizing the desired protective immune response (e.g., antibody, T cell), identifying the appropriate antigen to induce that response (i.e., immune responses against some antigens on an infectious agent are ineffective or even increase the risk for infection), determining the most effective route of administration (e.g., injected, oral, inhaled), optimizing the number and timing of vaccine doses to induce protective immunity in a large proportion of the at-risk population, and deciding the most effective, yet safe, form in which to administer the vaccine. For instance, most vaccines against viral infections (e.g., measles, mumps, rubella, varicella [chickenpox], rotavirus) contain live viruses that are weakened **(attenuated)** to continue expressing the appropriate antigens but are unable to establish more than a limited and easily controlled infection. The limited proliferative capacity of attenuated live viruses appears to afford better long-term protection than using purified viral antigen. Two exceptions are the vaccines against hepatitis B, which uses a recombinant viral protein, and hepatitis A, which is an inactivated (killed) virus.

Even attenuated viruses can, however, establish life-threatening infections in vaccine recipients whose immune system is congenitally deficient or suppressed (see Chapter 9). Two different vaccines were developed against polio. The Sabin vaccine is an attenuated virus that is administered orally (oral polio vaccine [OPV]). It provides systemic protection and induces a secretory immune response to prevent growth of the poliovirus in the intestinal tract. The live attenuated vaccine causes polio in some children who have unsuspected immune deficiencies (about 1 case in 2.4 million doses). The Salk vaccine is a completely inactivated virus administered by injection (inactivated polio vaccine [IPV]). It induces protective systemic immunity but does not provide adequate secretory immunity. Therefore, even if the individual is protected from systemic infection the "wild-type" poliovirus can transiently infect the intestinal mucosa, be shed, and spread to others.[59] When polio was epidemic, the live oral vaccine was preferred; however, about eight cases of paralytic polio per year in the United States resulted from the vaccine strain proliferating in individuals with inadequate immune systems. As a result, the CDC currently recommends vaccination with the killed virus.

Some common bacterial vaccines are killed microorganisms or extracts of bacterial antigens. The vaccine against pneumococcal pneumonia consists of a mixture of capsular polysaccharides from 10 strains of *S. pneumoniae.* Of the more than 90 known strains of this microorganism, only these 10 cause the most severe illnesses. However, the capsular vaccine is not very immunogenic in young children. A "conjugated" vaccine is available that contains capsular polysaccharides from seven strains that are conjugated to carrier proteins in order to increase immunogenicity. A similar vaccine is available for *Haemophilus influenzae* type B (Hib).

Some bacterial diseases are caused by potent toxins that act locally or systemically. These include diphtheria, cholera, and tetanus. Vaccination against the toxins is achieved using **toxoids**—purified toxins that have been chemically detoxified without loss of immunogenicity. Pertussis (whooping cough) vaccine was changed from a killed whole cell vaccine to an acellular vaccine that contained the pertussis toxin and additional bacterial antigens.

With so many available vaccines there has been an effort to mix vaccines in order to minimize the number of required injections. One of the first licensed vaccine mixtures was DPT, which now usually contains diphtheria (D) and tetanus (T) toxoids and

acellular pertussis vaccine (aP). More recent mixtures include DTaP with inactivated poliovirus, either with Hib conjugate to tetanus toxoid or with hepatitis B vaccine.

Common problems include access to vaccination programs in less developed countries or compliance of the susceptible population even when vaccination programs are available.[60] Depending on the microorganism, a certain percentage of the population (usually about 85%) should be immunized in order to achieve protection of the total population. This is referred to as *herd immunity*. If this level of immunization is not achieved, outbreaks of infection can occur. For instance, an effective measles (rubeola) vaccine was made available in 1963 and resulted in a dramatic decrease in the number of measles cases.[61] Many parents became complacent and did not obtain measles vaccination for their preschool children. As a result, a large increase in the number of cases and deaths in 1989 and 1990 occurred, which initiated a reemphasis on complete immunization before children could start school. More recently resistance to immunization with measles has increased, and in early 2008 the number of measles cases in the United States increased by about fourfold. In several European countries immunization programs have been disrupted by anti-vaccine groups. As a result the incidence of pertussis (whooping cough) increased by 10 to 100 times compared with neighboring countries that maintained a high incidence of immunization.

The refusal to vaccinate has generally been based on potential vaccine dangers. As with any medicine, complications can arise. In the case of vaccines, these include pain and redness at the injection site, fever, allergic reactions to vaccine ingredients, infection associated with attenuated viruses in immunodeficient individuals, and others. For instance, rotavirus is the most common cause of diarrheal disease in children globally, and more than 500,000 children die each year from severe acute diarrhea.[62] A rotavirus vaccine approved more than a decade ago was found to increase the risk for a life-threatening bowel obstruction resulting from twisting of the intestines, and the vaccine was recalled.[63] New rotavirus vaccines are available that are safe from adverse events.[63a] A commonly discussed fear is related to the presence of the preservative thimerosal in vaccines. Thimerosal is a mercury-containing compound that has been used as a preservative since the 1930s. Although no cases of mercury toxicity have been reported secondary to vaccination, thimerosal was removed from all vaccines in 2001, with the exception of inactivated influenza vaccines.[64] In 2003, groups in northern Nigeria claimed that the oral polio vaccine was unsafe, which led to suspension of polio immunization in two states and reduction of immunization in other states. The result was a 36% increase in cases of polio and thousands of cases of paralysis, including in previously polio-free areas.

Passive Immunotherapy

Passive immunotherapy is a form of countermeasure against pathogens in which preformed antibodies are given to the individual. This form of therapy has been used for decades. Horse serum–containing antibodies were given to treat diphtheria, pneumococcal pneumonia, tetanus, and other diseases in the early twentieth century. However, because of foreign proteins in the serum, many individuals developed an immune reaction against the horse proteins and an immune complex–mediated serum sickness. Passive immunotherapy with **human immunoglobulin** has been approved for several infections, including hepatitis B and hepatitis A. Treatment of potential rabies infection after a bite combines passive and active immunization. The rabies virus proliferates very slowly. Individuals who have been bitten receive a onetime injection with human rabies immunoglobulin, or more recently with monoclonal antibody, to further slow viral proliferation, followed by multiple injections with a killed viral vaccine to induce greater protective immunity.[65] For several other diseases more specific therapy with monoclonal antibodies is being evaluated, and a monoclonal antibody against respiratory syncytial virus has been approved for therapy.[66]

In the past, vaccines and therapeutic antibodies were developed for only the most deadly pathogens. With the increase in antibiotic-resistant microorganisms, the development and widespread use of new vaccines and antibodies against these microorganisms must be considered. For example, otitis media, a purulent ear infection, is caused primarily by *Streptococcus, Haemophilus,* and *Staphylococcus.* This infection routinely has been treated successfully with antibiotics; however, the increase in multiple antibiotic–resistant microorganisms may force a reevaluation of the use of childhood immunization as an alternative to preventing this disease. Other vaccines used now only to a limited degree may be used more widely in the future, and others may be developed soon, including vaccines against cholera, typhoid, malaria, West Nile virus, hantavirus, SARS, and several other diseases.

SUMMARY REVIEW

Emerging Infections

1. Deaths from infections are the eighth (influenza and pneumonia) and tenth (sepsis) leading causes of death in the United States and account for about one third of deaths worldwide.
2. Infectious disease is a significant cause of death and morbidity because of the reemergence of old infections thought to be controlled, the emergence of previously unknown infections, and the development of infections resistant to multiple antibiotics.
3. The current rate of emergence of previously unknown infections may be unprecedented. More than 40 unknown infections have arisen within 1 generation.
4. Although most infections are controlled, some uncontrolled infections have high mortality rates including SARS, Ebola virus, Marburg virus, “mad cow disease,” Nipah virus, and AIDS.
5. Many common and reemerging infections have become antibiotic and drug resistant. At least 25% of *S. pneumoniae* infections are penicillin resistant and some are resistant to multiple antibiotics.

SUMMARY REVIEW—cont'd

6. Resistant forms of *S. aureus,* a primary cause of infections of wounds, surgical incisions, and catheters, are endemic in some hospitals.
7. Antimicrobial resistance is routinely observed in tuberculosis, diarrheal diseases, hospital-acquired infections, malaria, meningitis, respiratory tract infections, STIs, and HIV.

Microorganisms and Humans: A Dynamic Relationship

1. The human body is a hospitable site for microorganisms to grow and flourish. These microorganisms make up the *normal microbiome* of the body.
2. The beneficial homeostasis between humans and microorganisms is maintained through the physical integrity of the gut and other mechanisms that sequester these microorganisms on the mucosal surface.

Microorganisms and Infections

1. The symbiotic relationship with the normal microbiome can be altered by injury, compromising protective barriers.
2. Cuts in the skin and compromised immunity can increase infections.
3. Damage to the intestinal tract releases intestinal bacteria into the bloodstream, potentially leading to sepsis, shock, and death.
4. When an individual's immune system is deficient, the person can become infected with opportunistic infections.
5. Unlike opportunistic infectious agents, true pathogens can circumvent an individual's defenses and directly cause infection. Successful infection with these agents usually requires adequate numbers of microorganisms rather than compromised immune defenses.
6. The process of infection includes colonization, invasion, multiplication, and spread.
7. Infectious microorganisms usually exist in reservoirs (e.g., contaminated soil, contaminated water, breast milk), animals, or another human.
8. As part of colonization, the microorganism stabilizes the adherence to tissue through surface receptors. Once colonization occurs, the infectious agent can invade surrounding tissue.
9. Because tissue is warm and nutrient rich, most microorganisms undergo *rapid* multiplication. Viral pathogens replicate within infected cells, and some bacteria are intracellular pathogens and replicate in macrophages and other cells.
10. Many pathogens produce only localized infections. Others are, however, highly invasive.
11. Successful spreading requires a variety of virulence factors, including adhesion molecules, toxins, and the ability to evade immunity.
12. Clinical infectious disease occurs in four distinct stages: (a) incubation period, (b) prodromal state, (c) invasion period, and (d) convalescence.
13. The hallmark of most infectious diseases is fever. Body temperature is regulated at a higher than normal level.
14. A large number of agents (pyrogens) can produce fever. Current classifications include endogenous (e.g., cytokines) and exogenous agents. However, the evidence for exogenous agents is limited and they indirectly affect the hypothalamus through endogenous pyrogens.
15. Several factors influence the capacity of a pathogen to cause disease, including communicability, immunogenicity, infectivity, mechanisms of action, pathogenicity, entry portal, toxigenicity, and virulence.
16. Infectious diseases also are classified by their prevalence and spread as endemic, epidemic, and pandemic.
17. Classes of infectious microorganisms include bacterial, fungal, parasitic, protozoal, and viral.
18. Bacteria are divided into several groups: "true bacteria," filamentous, spirochetes, mycoplasma, rickettsia, and chlamydia.
19. Stable colonization of bacteria requires adhesion. Many bacteria attach through pili, also called fimbriae.
20. Invasion by bacteria results in direct confrontation with an individual's defense mechanisms, including complement, antibodies, and phagocytes (neutrophils, macrophages). Evasion of these defenses can result in bacteremia and sepsis.
21. Efficient pathogens can produce a variety of toxic molecules that may kill the individual's cells, disrupt tissue, and protect themselves against inflammation. Exotoxins are released by bacteria during bacterial growth and can damage cell membranes, activate second messengers, and inhibit protein synthesis.
22. Endotoxins are contained in the cell walls of gram-negative bacteria and released during lysis of the bacteria. Bacteria that produce endotoxins are called *pyrogenic bacteria* because they activate inflammation and produce fever.
23. Bacteria can protect against phagocytosis by producing toxins and extracellular enzymes that destroy phagocytic cells.
24. Some bacteria can coat the Fc portion of an individual's antibody, preventing complement activation or phagocytosis.
25. Antigenic variation allows the pathogen to alter surface molecules that express antigens that are the targets of protective immune responses. The pathogen thus becomes resistant.
26. Other self-protective mechanisms for bacteria and other pathogens include degradation of immune molecules, neutralization of immune molecules, complement evasion, and immune suppression.
27. Tissue damage from bacterial infections is either directly by bacterial products or indirectly from infection.
28. *S. aureus* has become a major cause of hospital-acquired (nosocomial) infections. Antibiotic resistance also has become a major problem with *S. aureus.*
29. Fungal infection is called mycosis. Most pathologic fungi are from the environment and transmitted by inhalation or contamination of wounds.
30. In 2006, the opportunistic pathogen *P. carinii* was reclassified as a fungus and the specific variant that infects humans was renamed *P. jiroveci.*
31. *C. albicans* is the most common cause of fungal infections in humans. It resides in the skin, gastrointestinal tract, mouth, and vagina. Local defense mechanisms, including members of the bacterial microbiome, produce antifungal

SUMMARY REVIEW—cont'd

agents. The infection remains localized in individuals with an intact immune system.

32. Parasitic organisms establish a symbiosis with another species, whereby the parasite benefits. They range from unicellular protozoa to large worms. Although less common in the United States, parasites and protozoa are common causes of infection worldwide.
33. Parasitic and protozoal infections are rarely transmitted from human to human. Infection mainly spreads through vectors and includes malaria by mosquito bites, trypanosomes by the tsetse fly, and *Leishmania* spp. by sand fleas. Others are found in contaminated water or food (e.g., *G. lamblia*).
34. Malaria is one of the most common infections worldwide. It is transmitted through the bite of an infected *Anopheles* mosquito. The parasite enters the bloodstream, survives in the liver, and invades parenchymal cells. After several rounds of division, the liver cell ruptures and thousands of parasites enter the blood, infecting red blood cells.
35. Viruses are classified by the format of nucleic acid in the virion (RNA or DNA), either single stranded (ss) or double stranded (ds), and whether it uses the enzyme RT for replication.
36. Viral diseases are the most common affliction of humans and include the common cold, the "coldsore," hepatitis, HIV, and several types of cancer.
37. Viruses are intracellular parasites. The viral life cycle is completely intracellular and involves several stages: attachment, penetration, uncoating, replication, assembly, and release. New virions are released from the cell for transmission of the viral infection to neighboring, uninfected cells.
38. The primary defense mechanisms against viruses include antibody and cellular immunity. Nonspecific defenses include α- and β-interferons that block intracellular replication.
39. Successful viruses use a variety of mechanisms for bypassing immune rejection, including rapid division, intracellular survival, coating with self-proteins, antigenic variation, neutralization, complement evasion, and immune suppression.
40. Viruses inside the infected cell have several harmful effects, including inhibition of DNA, RNA, or protein synthesis; disruption of lysosomal membranes, resulting in lytic enzyme release; promotion of cell apoptosis; fusion of adjacent cells (i.e., giant cells); transformation into a neoplastic cell; and alteration of antigenic properties (i.e., decreasing immune effectiveness).

Acquired Immunodeficiency Syndrome (AIDS)

1. AIDS is a viral disease caused by HIV.
2. HIV infects and depletes a portion of the immune system (Th cells), making individuals susceptible to life-threatening infections and malignancies.
3. HIV/AIDS remains a major cause of death worldwide.
4. Aggressive antiretroviral therapy and public health campaigns have stabilized the number of new cases and deaths in the United States from HIV/AIDS, but the cases and deaths continue to increase rapidly worldwide.
5. In 2009, 50% of newly diagnosed cases of AIDS in the United States were attributed to male-to-male sexual contact, 30% to high-risk heterosexual contact, and 14% to injected drug abuse. About 25% of newly diagnosed cases were female, with about 74% contracted through high-risk heterosexual contact.
6. The epicenter of the AIDS pandemic is sub-Saharan Africa. Women have the highest risk of infection. Because of AIDS, the average life expectancy in South Africa has dropped from 64 years to 54 years.
7. HIV is a blood-borne pathogen present in body fluids (e.g., blood, vaginal fluid, semen, breast milk) with typical routes of transmission: blood or blood products, intravenous drug abuse, heterosexual and homosexual activity, and maternal-child transmission before or during birth.
8. At the end of 2009, an estimated 8640 children in the United States developed AIDS after contracting HIV infection from their mothers (e.g., across the placenta, through contact with infected blood during delivery, or through ingestion of infected breast milk).
9. Healthcare providers are at increased risk of contracting infections from another person's blood. However, as of May 2011, only 57 cases of confirmed HIV infection and 143 possible cases were contracted by occupational exposure.
10. HIV is a member of the *retrovirus* family, which carries genetic information in the form of two copies of RNA. An enzyme, reverse transcriptase (RT), converts RNA into a double-stranded DNA. Another enzyme, an *integrase,* inserts the new DNA into the infected cell's genetic material. On activation, translation of the viral information may be initiated, forming new virions, resulting in lysis and death of the infected cell, and shedding infectious HIV particles.
11. The primary surface receptor on HIV is the envelope glycoprotein gp120, which binds to the CD4 molecule found mostly on the surface of T-helper cells. Several other important co-receptors have been identified.
12. The major immunologic finding in AIDS is the striking decrease in the number of CD4 Th cells.
13. The presence of circulating antibody against HIV indicates infection by the virus, although many individuals are asymptomatic.
14. The current treatment for HIV infection is a combination of drugs called antiretroviral therapy (ART).

Countermeasures Against Pathogens

1. Effective means of countering infectious microorganisms are rigorous use of environmental infection control measures, including control of insect vector populations, establishment of modern sanitation facilities, and provision of clean water and uncontaminated food supplies. Prophylactic or interventive procedures include vaccines and antimicrobials.
2. With antibiotic-resistant pathogens, a greater emphasis is placed on the development of new vaccines.

CHAPTER OUTLINE

To observe the obvious, modern society is full of stress. As a culture, Westerners are champions of the work ethic, a Protestant philosophy originating in the sixteenth century that views idleness as taboo. Stressful experiences include daily hassles, major life events (e.g., loss of family member, loss of job), abuse, trauma, work-life balance, and many other events. For example, the pressure to remain in contact despite illness, travel, vacation, and other events that used to provide socially acceptable temporary absences is now customary in the American, and indeed global, culture. This prevalent assumption of constant availability is a newly identified stressor contributing to the more global and better studied stressors of work-related and relationship stressors. When added to other well-identified stressors such as financial problems, the result may be potential suffering from the so-called *stress-related disorders.*

When thinking about stress, one must consider the factors producing a perception of stress. Stress begins with a stimulus that the brain perceives as stressful, which in turn promotes adaptational and survival-related physiologic responses. These responses can become dysregulated and cause pathophysiologic conditions.[1] Another way to think about stress involves short- or long-term stressors and a discussion of the physiologic responses to these different types of events. Today most researchers feel that acute stress is considered to be immunoenhancing (protective) while chronic stress is now thought to be immunosuppressive (destructive).[1]

HISTORICAL BACKGROUND AND GENERAL CONCEPTS

Walter B. Cannon used the term *stress* to encompass both physiologic and psychologic ideas as early as 1914.[2] He applied the engineering concept of stress and strain in a physiologic context and believed that emotional stimuli also were capable of causing stress. In 1946, Hans Selye popularized these same findings, viewing stress as a biologic phenomenon.[3] Originally, Selye inadvertently discovered the biologic syndrome of stress while he was attempting to discover a new sex hormone by injecting crude ovarian extracts into rats.[3] He repeatedly found that three structural changes occurred: (1) enlargement of the cortex of the

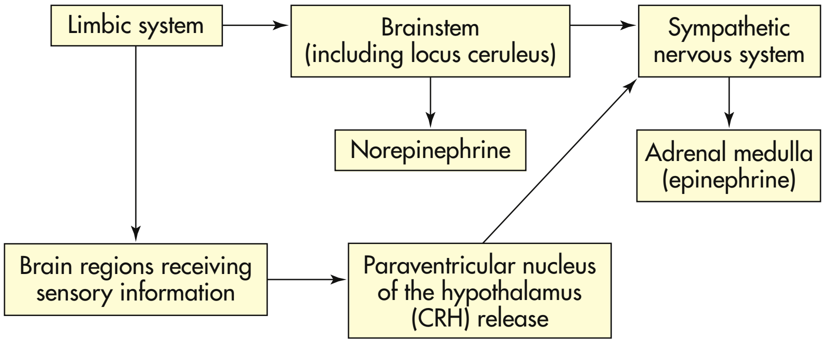

FIGURE 11-1 Neural Recognition and Response to Real or Predicted Stressors.

adrenal gland, (2) atrophy of the thymus gland and other lymphoid structures, and (3) development of bleeding ulcers in the stomach and duodenal lining. Selye soon discovered that these manifestations were not specific to injected ovarian extracts but also occurred after he exposed the rats to other noxious stimuli, such as cold, surgical injury, and restraint. He called these stimuli stressors. Selye concluded that this triad or syndrome of manifestations represented a nonspecific response to noxious stimuli, naming it the **general adaptation syndrome (GAS).** He identified three successive stages of the GAS: (1) the alarm stage or reaction, in which the central nervous system (CNS) is aroused and the body's defenses are mobilized (e.g., "fight or flight") (Figure 11-1); (2) the stage of resistance or adaptation, during which mobilization contributes to "fight or flight"; and (3) the stage of exhaustion, where continuous stress causes the progressive breakdown of compensatory mechanisms (acquired adaptations) and homeostasis. Exhaustion marks the onset of certain diseases (diseases of adaptation).

Initially one becomes alarmed by a stressor that activates the hypothalamus and sympathetic nervous system (see Figures 11-1 and 11-2). The resistance or adaptation phase begins with the actions of the hormones cortisol, norepinephrine, and epinephrine. Exhaustion (also known as allostatic overload; discussed later) occurs if stress continues and adaptation is not successful, ultimately causing impairment of the immune response, heart failure, and kidney failure, leading to death.

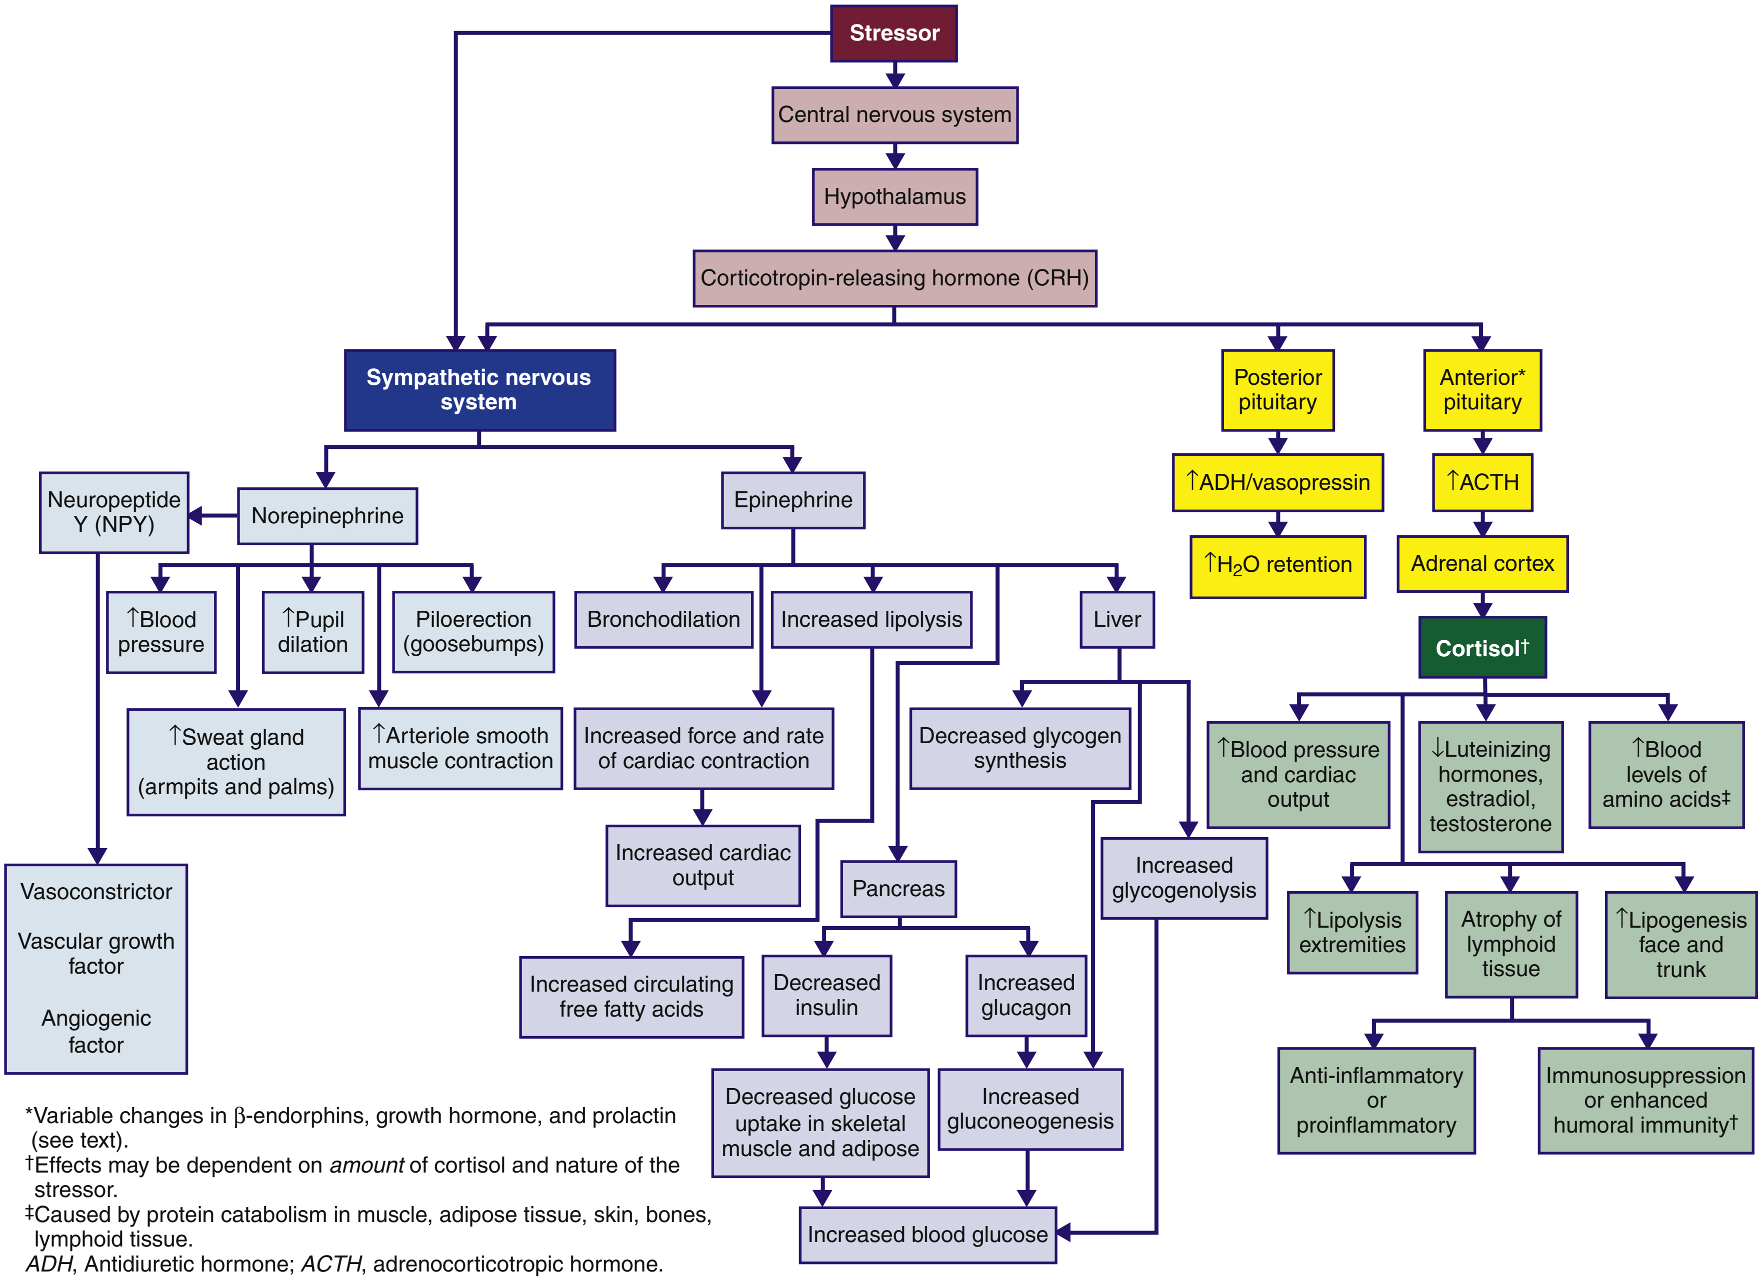
From a physiologic perspective, what is emerging across the disciplines involved—molecular biology, immunology, neurology, endocrinology, and behavioral science—is a more holistic and complex model that involves biochemical relationships of the CNS, autonomic nervous system (ANS), endocrine system, and immune system that cause the stress responses identified by Selye. More simply, these relationships are often cited together as the **hypothalamic-pituitary-adrenal (HPA) axis** (Figure 11-3). The reader may find it helpful to become familiar with the ANS function content in Chapter 15, p. 470.

In sequence, the hypothalamus secretes **corticotropin-releasing hormone (CRH),** which binds to specific receptors on pituitary cells that, in turn, produce **adrenocorticotropic hormone (ACTH).** ACTH is then transported through the blood to the adrenal glands located on the top of the kidneys. After binding to specific receptors on the adrenal glands, the glucocorticoid hormones (primarily cortisol; from the adrenal cortex) are released. Cortisol initiates a series of metabolic changes discussed in the section Glucocorticoids: Cortisol; however, overall, these hormones are thought to enhance immunity during acute stress and suppress immunity during chronic stress because of prolonged exposure and increased concentration.[1]

CONCEPTS OF STRESS

Selye believed that stressors cause a general or nonspecific response. However, research in the past 50 years has shown the remarkable sensitivity of the central nervous system and endocrine system to psychologic influences (emotion is included in psychologic and social stress and acts through psychologic mechanisms). Thus, although Selye's identification of the GAS is regarded as tremendously important and the cornerstone of stress research, the idea that stress is a purely physiologic response is vastly oversimplified. In the mid-1950s, studies showed that activation of the adrenal cortex occurred in humans in response to psychologic stressors,[4] in monkeys with conditioned emotional responses,[5] and in humans subjected to a stressful interview technique.[6] In the early 1960s, researchers found that plasma cortisol levels in groups of subjects increased while they watched war movies and decreased while they viewed Disney nature films.[7,8] Mason later demonstrated that the initiation of the GAS depended on psychologic factors surrounding the stressors.[9] He also showed that various factors, such as degrees of discomfort or unpleasantness or suddenness of the stress, could account for the presence or absence of physiologic stress responses.[9]

The term *stress* has been used persistently and widely across many disciplines despite numerous disagreements over its definition. Nevertheless, in recent years **stress** has been more usefully defined as a *transactional* or *interactional concept.* Transactionally, stress is viewed as the state of affairs arising when a person relates to (i.e., interacts or transacts with) situations in certain ways. People are not disturbed by situations per se but by the ways they appraise and react to situations. In general, a person experiences stress when a demand *exceeds* a person's coping abilities, resulting in reactions such as disturbances of cognition, emotion, and behavior that can adversely affect well-being. Moreover, psychologic stressors can elicit reactive or anticipatory stress responses. The **reactive response** is a physiologic response derived from psychologic stressors. For example, the stress of an examination may



*Variable changes in β-endorphins, growth hormone, and prolactin (see text).
†Effects may be dependent on *amount* of cortisol and nature of the stressor.
‡Caused by protein catabolism in muscle, adipose tissue, skin, bones, lymphoid tissue.
ADH, Antidiuretic hormone; *ACTH*, adrenocorticotropic hormone.

FIGURE 11-2 The Stress Response.

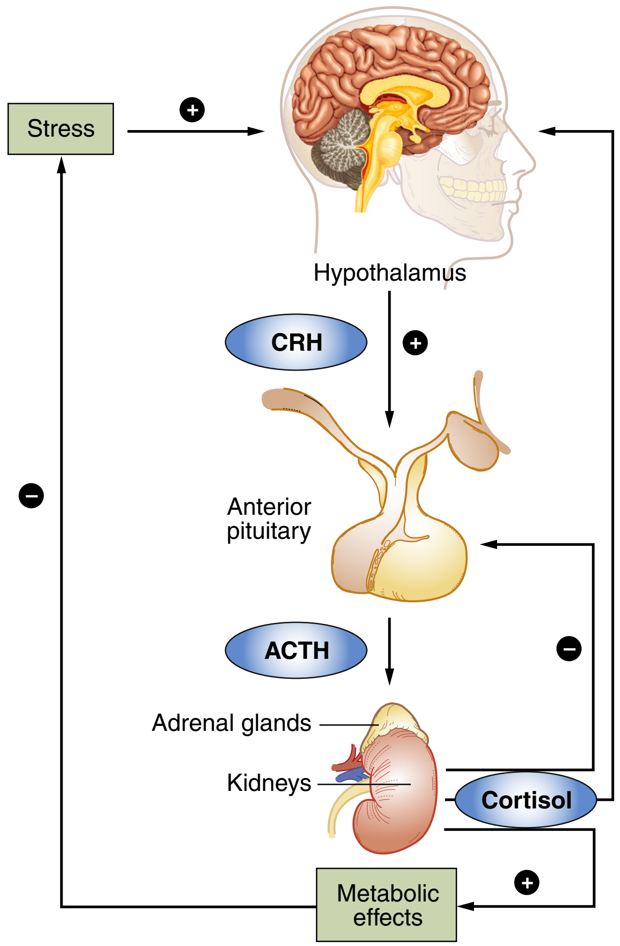


FIGURE 11-3 **Hypothalamic-Pituitary-Adrenal (HPA) Axis.** The response to stress begins in the brain. The hypothalamus is the control center in the brain for many hormones including corticotropin-releasing hormone (CRH). *ACTH, Adrenocorticotropic hormone.*

produce an increased heart rate and dry mouth in the unprepared student. The **anticipatory response** occurs when physiologic responses develop in anticipation of disruption of the optimal steady-state, also known as **homeostasis**. These anticipatory responses can be generated either by species-specific innate programs, such as reacting to the presence of predators and unfamiliar situations, or by experience-dependent memory programs created by conditioning.[10] Anticipatory responses are learned responses under fine control by regions located in the brain's limbic system. These regions are those most frequently associated with learning and memory and include the hippocampus, amygdala, and prefrontal cortex. In order for these regions to elicit a stress response, the paraventricular nucleus (PVN) of the hypothalamus must be stimulated. The limbic structures rarely interact directly with the PVN and are believed to influence the stress response through intermediary neurons, some of which are primarily used for the reactive response.

In a **conditional response** one learns that specific stimuli (i.e., objects or situational context) are associated with danger, and as such anticipation of subsequent encounters with the stimulus produces a physiologic stress response. For example, a child that is abused by a parent may experience a physiologic stress response in anticipation of further abuse when the parent enters the room. Under some circumstances these memory programs may become so strong that psychologic disorders, such as phobias, develop. In a similar fashion, some persons develop **posttraumatic stress disorder (PTSD)** in response to the memory, as opposed to the anticipation of traumatic events. PTSD is characterized by flashback memories, sleep disturbances, depression, and other symptoms. These symptoms have the potential to greatly interfere with normal activities such as employment and frequently disrupt personal relationships and quality of life.

Today there is evidence implicating stress as a precipitating factor for some diseases and conditions and as an exacerbating factor, worsening symptoms and outcomes, in others, such as atherosclerosis, irritable bowel syndrome, ulcers, asthma, autoimmune disorders, anxiety, delayed wound healing, chronic pain and fatigue syndromes, reproductive dysfunction, diabetes, and depression.[9-11] In addition, evidence published since 2000 generally supports a relationship between stress and human immunodeficiency virus (HIV) progression.[12]

Psychologic stress may cause or exacerbate (worsen) several disease states, including many of the diseases implicated as the leading causes of death in the United States (Table 11-1). For example, stress-induced chronic inflammation is suggested as being important in the functional decline that leads to frailty, disability, and untimely death; cardiovascular disease; and infectious diseases.[12-16] Additionally, important effects of acute emotional stress, such as the death of a loved one, on the heart muscle include three areas: (1) left ventricular contractile dysfunction, (2) myocardial ischemia, and (3) disturbances of heart rhythm (see What's New? Acute Emotional Stress and Adverse Heart Effects). Other examples include research linking stress to the recurrence of genital herpes virus in women with HIV.[13] As evidence has mounted concerning the important role that stress plays in certain disease processes, research has focused on the mechanisms responsible for these mind-body interactions. Along with a greater understanding of the relationship between the human stress response and disease, new strategies for treatment of stress-related disorders are emerging. It has recently been demonstrated that the interactions among social, psychologic, biologic, and behavioral factors are inherent in the causes and courses of many diseases. Molecular biologists, immunologists, neurologists, clinicians, and behavioral scientists are now exploring the role of the other half of the mind-body (dualistic) model—that is, the mind. What is emerging is a more holistic and complex model of health and disease states. This model involves the biochemical relationships of the central and autonomic nervous systems, the endocrine system, and the immune system and their relationships to stress-elicited coping behaviors, such as smoking and poor diet, that can also modify the integrity of the immune system. Discoveries of these complex links have led to the creation of the field of psychoneuroimmunology.

TABLE 11-1 EXAMPLES OF STRESS-RELATED DISEASES AND CONDITIONS

TARGET ORGAN OR SYSTEM	DISEASE OR CONDITION	TARGET ORGAN OR SYSTEM	DISEASE OR CONDITION
Cardiovascular system	Coronary artery disease Hypertension Stroke Disturbances of heart rhythm	Gastrointestinal system	Ulcer Irritable bowel syndrome Diarrhea Nausea and vomiting Ulcerative colitis
Muscle	Tension headaches Muscle contraction backache	Genitourinary system	Diuresis Impotence Frigidity
Connective tissues	Rheumatoid arthritis (autoimmune disease) Related inflammatory diseases of connective tissue	Skin	Eczema Neurodermatitis Acne
Pulmonary system	Asthma (hypersensitivity reaction) Hay fever (hypersensitivity reactions)	Endocrine system	Type 2 diabetes mellitus Amenorrhea
Immune system	Immunosuppression or deficiency Autoimmune diseases	Central nervous system	Fatigue and lethargy Type A behavior Overeating Depression Insomnia

WHAT'S NEW?

Acute Emotional Stress and Adverse Heart Effects

Myocardial Ischemia

- Individuals with coronary heart disease may develop myocardial ischemia during mental or acute emotional stress even though their exercise results are negative.
- Systemic vascular resistance increases during periods of mental or acute emotional stress with concomitant increased myocardial oxygen demand.

Left Ventricular Dysfunction

- This condition is more evident in older women.
- After acute emotional stress or trauma, there is an increase in sudden chest pain and shortness of breath.
- Left ventricular dysfunction is more common in the cardiac apex.
- Alterations occur possibly because of increases in the levels of catecholamines. Increased stress in daily life is associated with enhanced HPA axis response, a higher cortisol awakening response, and higher mean day and evening cortisol levels.

Ventricular Dysrhythmias

- Intense or unusual acute stress precipitates about 20% of serious ventricular dysrhythmias or sudden cardiac death.
- Altered brain activity may lead to changes in ventricular repolarization and electrical instability of the cardiac muscle.

Data from Critchley HD et al: *Brain* 128(Pt 1):75–85, 2005; Ramachandruni S et al: *J Am Coll Cardiol* 47(5):987–991, 2006; Soufer R: *Circulation* 110(13):1710–1713, 2004; Wittstein IS et al: *N Engl J Med* 352(6):539–548, 2005; Ziegelstein RC: *JAMA* 298(3):324–329, 2007. Kumari M et al: *Psychoneuroendocrinology*, 35(7):1091–1099, 2010.

Psychoneuroimmunologic Mediators of Stress

Psychoneuroimmunology (PNI) is the study of how the consciousness *(psycho)*, brain and spinal cord *(neuro)*, and the body's defenses against infection and abnormal cell division *(immunology)* interact. Psychoneuroimmunology assumes that all immune-mediated diseases result from interrelationships among psychosocial, emotional, genetic, and behavioral factors with the neurologic, endocrine, and immune systems.[11,17,18] The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states. Stressors can elicit the stress response or stress system through the action of the nervous and endocrine systems. Stressors include infection, noise, decreased oxygen supply, pain, malnutrition, heat, cold, trauma, prolonged exertion, radiation, responses to life events (including anxiety, depression, anger, fear, loss, and excitement), obesity, old age, drugs, disease, surgery, and medical treatment.

Although the field of PNI is relatively new, and a body of scientific literature is present, the subject of PNI has caused strenuous scientific debate, especially with respect to the causal role of personality in cancer mortality and morbidity.[19] For example, mouse models suggest a strong link between stress and breast cancer progression, yet this effect has not been consistently found in humans.[19,20] What is certain, however, is that hormones released by the stress response influence many metabolic systems and corresponding physiologic events, even if the mechanisms and subsequent physiologic events are yet to be fully understood. Further, sufficient data now exist to conclude that immune modulation by psychosocial stressors or interventions leads directly to health outcomes.[21-37] The strongest support to date for the link between psychosocial stressors and health outcomes remains in studies of infectious disease and wound healing.[38-43] However, a very recent meta-analysis of 10 studies conducted among persons living in England found that any level of psychologic distress is associated with increased mortality and increased risk of death from cardiovascular disease, external causes, and cancer (albeit only at higher levels of distress); 68,000 persons were used in this study and personal factors, such as age, smoking, and alcohol use, were adjusted accordingly.[44]

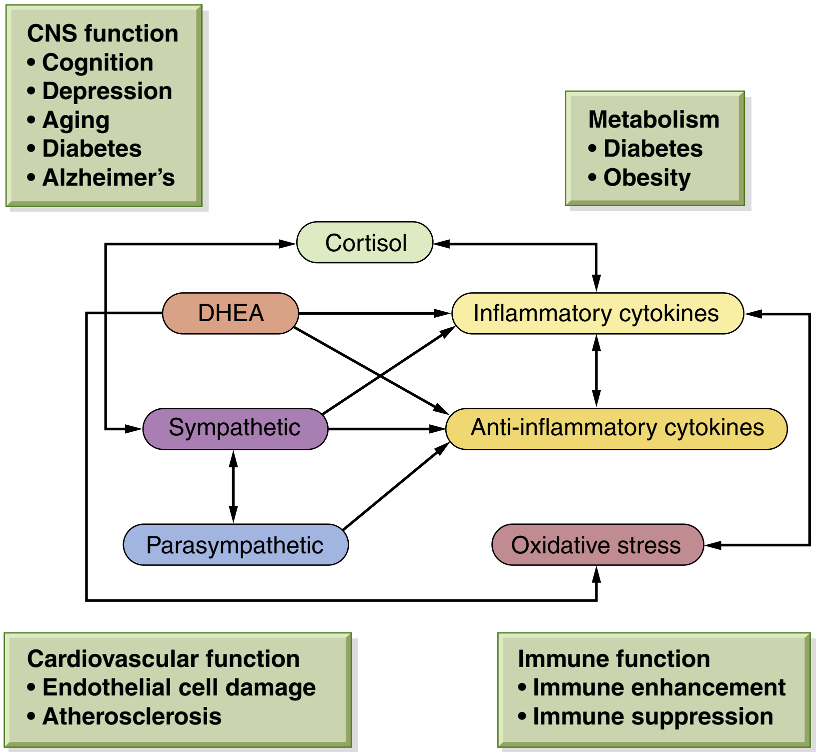

FIGURE 11-4 **Stress Interactions Are Nonlinear and Complex.** Nonlinearity means that when one mediator is increased or decreased, the subsequent compensatory changes in other mediators depend on time and level of change, causing multiple interacting variables. The inevitable consequences from adapting to daily life over time include changes in behavioral responses. For example, these changes include sleeping patterns, tobacco use, alcohol consumption, physical activity, and social interactions. These behavioral patterns are a part of the allostatic overload with chronic elevations in cortisol level, sympathetic activity, and proinflammatory cytokines, and a decrease in parasympathetic activity. (From McEwen BS: *Eur J Pharmacol* 583[2-3]:174–185, 2008.) *DHEA,* Dehydroepiandrosterone.

STRESS RESPONSE

The **stress response** is initiated by the central nervous system and endocrine system (see Figure 11-1). Specifically, **corticotropin-releasing hormone (CRH)** is released from the hypothalamus, and influences the sympathetic nervous system, the pituitary gland, and the adrenal gland (see Figure 11-2). CRH is also released peripherally at inflammatory sites called **peripheral**, or **immune, CRH.** The activation of these systems redirects adaptive energy to the CNS and stressed body sites.

Where the stress response begins depends on whether the stressor is perceived or real. Perceived stressors elicit an anticipatory response that usually begins in the limbic system of the brain, the area responsible for emotions and cognition. The limbic system indirectly elicits both an endocrine stress response by stimulating neural pathways responsible for receiving sensory information and a central stress response by directly stimulating the locus ceruleus (LC) to release norepinephrine (see Figure 11-1). Norepinephrine release promotes arousal, increased vigilance, increased anxiety, and other protective emotional responses. Real stressors elicit a reactive response that can begin either in the limbic system or in regions of the brain receiving specific sensory information (see Figure 11-1). This information is then relayed to the PVN. The PVN stimulates the LC and both central and endocrine stress responses.

Central Stress Response

Better understanding is emerging regarding the physiology involved in meeting the demands and challenges of daily life. Some refer to these challenges as "stressors," and the chronically stressed person may use the term "stressed out." The physiology is complex, involving both protection and damage. As previously mentioned, glucocorticoids from the adrenal cortex in response to ACTH from the pituitary gland (see Figure 11-3) comprise the major stress hormones along with the catecholamines epinephrine and norepinephrine. Other central hormones/mediators also play a role including the proinflammatory and anti-inflammatory cytokines that are regulated by glucocorticoids and catecholamines (Figure 11-4).[21]

Catecholamines can increase proinflammatory cytokine production, causing, for example, increased heart rate and blood pressure. Glucocorticoids are known to inhibit this proinflammatory production; however, inhibition depends on dose and cell or tissue type.[30] More simply, glucocorticoids can also promote inflammation depending on dose and cell type.[31] The increased understanding of these effects suggests the possibility that chronic and dysfunctional HPA axis stimulation (as may

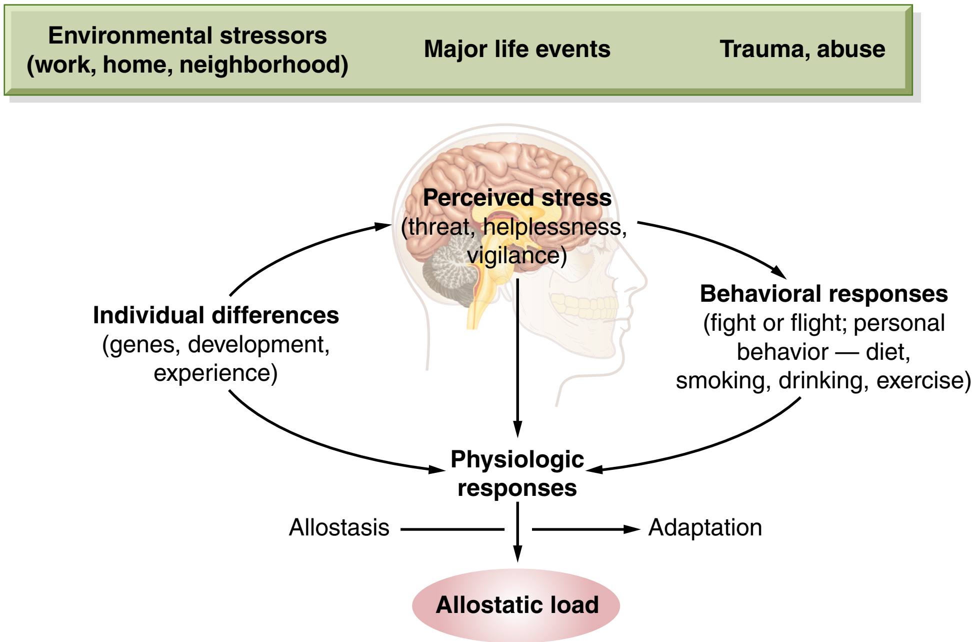

FIGURE 11-5 **Physiologic and Behavioral Stress Responses.** Stress processes arise from bidirectional communication patterns between the brain and other physiologic systems (autonomic, immune, neural, and endocrine). Importantly, these bidirectional mechanisms are protective, promoting short-term adaptation (allostasis). Chronic stress mechanisms, however, can lead to long-term dysregulation and promote behavioral responses and physiologic responses that lead to stress-induced disorders/diseases (allostatic load) that compromise health. (From McEwen BS: *Eur J Pharmacol* 583[2-3]:174–185, 2008.)

occur during chronic inflammation) increases inflammation in the brain and other tissue, possibly contributing to other diseases including osteoporosis, metabolic disease (diabetes, obesity), and cardiovascular disease.[32] Additionally, these interactions are nonlinear and are very complex.

Parasympathetic System

The parasympathetic system balances the sympathetic nervous system and, thus, also influences adaptation or maladaptation to stressful events. The parasympathetic system also has anti-inflammatory effects. The parasympathetic system opposes the sympathetic (catecholamine) responses, for example, by slowing the heart rate.[31] Researchers evaluate the relative balance of the parasympathetic and sympathetic nervous systems using a technique known as heart rate variability (the measurement of R wave variability from heartbeat to heartbeat).

Allostasis is considered an adaptive physiologic response to stressful events (e.g., fight or flight).[21] Chronic or dysregulated **allostasis** (long-term or chronic exaggerated responses to stress) can lead to disease. **Allostatic load** (Figure 11-5) is the individualized cumulative amounts of stressors that exist in our lives and that influence our physiologic responses. Allostatic load includes our genetic makeup, our lifestyle (including damaging health behaviors), daily events, and dramatic events (such as disasters).[21,45] Over time this load exacts a toll on our bodies (i.e., "wear and tear"). Because the brain is a key player in deciding what is stressful, it is influential in determining when we have reached allostatic overload. Moreover, these responses are individualized in that what would be considered normal for one person is considered extremely stressful for another.[45]

Under conditions of allostatic overload, the parasympathetic system may decrease its restraint of the sympathetic system, resulting in increased or prolonged inflammatory responses.[21,31] Physiologically, in response to acute and chronic stress some regions of the brain (the hippocampus, amygdala, and prefrontal cortex) may respond by undergoing structural remodeling, which can alter behavioral and physiologic responses (such as cognitive impairment or depression).[21] Key mediators involved in **allostatic overload** (exaggerated pathophysiologic responses to stress) include the glucocorticoid cortisol, catecholamines (released from sympathetic nervous system activation), and proinflammatory cytokines; in addition, there is a decline in parasympathetic activity. A prevalent example is sleep deprivation resulting from excessive stress. Sleep deprivation has significant damaging effects including elevated evening cortisol level; elevated insulin and blood glucose levels; increased blood pressure; reduced parasympathetic activity; increased levels of proinflammatory cytokines; and increased concentrations of the gut hormone ghrelin, which increases appetite. Altogether, these alterations can lead to increased caloric intake, depressed mood, cognitive problems, and a host of other responses from insomnia.[34]

Neuroendocrine Regulation

The sympathetic nervous system (SNS) is aroused during the stress response and causes the medulla of the adrenal gland to release catecholamines (80% epinephrine and 20% norepinephrine) into the bloodstream. The adrenal medulla is actually an extension of the SNS because preganglionic fibers from the splanchnic nerve terminate in the medulla, where they innervate

TABLE 11-2 PHYSIOLOGIC EFFECTS OF CATECHOLAMINES*

ORGAN/TISSUE	PROCESS OR RESULT
Brain	Increased blood flow; increased glucose metabolism
Cardiovascular system	Increased rate and force of contraction
	Peripheral vasoconstriction
Pulmonary system	Bronchodilation
Skeletal muscle	Increased glycogenolysis
	Increased contraction
	Increased dilation of muscle vasculature
	Decreased glucose uptake and utilization (decreases insulin release)
Liver	Increased glucose production
	Increased glycogenolysis
Adipose tissue	Increased lipolysis
	Decreased glucose uptake
Skin	Decreased blood flow
Gastrointestinal and genitourinary tracts	Decreased protein synthesis
	Decreased smooth muscle contraction
	Increased renin release
	Increased gastrointestinal sphincter tone
Lymphoid tissue	Acute and chronic stress inhibits several components of innate immunity, particularly decreasing number of natural killer cells
Macrophages	Inhibit and stimulate macrophage activity
	Depend on availability of type 1/proinflammatory cytokines, presence or absence of antigenic stressors, and peripheral corticotropin-releasing hormone (CRH)

Data from Elenkov IJ, Chrousos GP: *Ann N Y Acad Sci* 966:290–303, 2002; Granner DK: Hormones of the adrenal medulla. In Murray RK et al, editors: *Harper's biochemistry,* ed 25, New York, 2000.
*Some of these responses require glucocorticoids (e.g., cortisol) for maximal activity (see text for explanation).

the chromaffin cells that produce the catecholamine hormones. Simultaneously, hypothalamic CRH stimulates the pituitary gland to release a variety of hormones, including antidiuretic hormone and oxytocin from the posterior pituitary gland, and prolactin, endorphins, growth hormone (GH), and adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. ACTH stimulates the cortex of the adrenal gland to release cortisol (see Figure 11-2).

Catecholamines

Circulating catecholamines essentially mimic direct sympathetic stimulation. Catecholamines cannot cross the blood-brain barrier and are synthesized locally in the brain. In response to stress, the chromaffin cells of the adrenal medulla produce large quantities of epinephrine and small amounts of norepinephrine. Once released, catecholamines circulate bound to the plasma protein albumin. The physiologic effects of the catecholamines on organs and tissues are summarized in Table 11-2. Norepinephrine regulates blood pressure by constricting smooth muscle in all blood vessels. During stress, norepinephrine raises blood pressure by constricting peripheral vessels; it dilates the

TABLE 11-3 PHYSIOLOGIC ACTIONS OF α- AND β-ADRENERGIC RECEPTORS

RECEPTOR	PHYSIOLOGIC ACTIONS
α_1	Increased glycogenolysis; smooth muscle contraction (blood vessels, genitourinary tract)
α_2	Smooth muscle relaxation (gastrointestinal tract); smooth muscle contraction (some vascular beds); inhibition of lipolysis, renin release, platelet aggregation, and insulin secretion
β_1	Stimulation of lipolysis; myocardial contraction (increased rate, increased force of contraction)
β_2	Increased hepatic gluconeogenesis; increased hepatic glycogenolysis; increased muscle glycogenolysis; increased release of insulin, glucagon, and renin; smooth muscle relaxation (bronchi, blood vessels, genitourinary tract, gastrointestinal tract)

pupils of the eye, causes piloerection, and increases sweat gland action in the armpits and palms (see Figure 11-2).

Epinephrine is rapidly transported to and acts on several organs, but it is metabolized quickly, making it short-acting. Metabolically, epinephrine causes transient hyperglycemia (high blood glucose level), decreases glucose uptake in the muscles and other organs, and decreases insulin release from the pancreas. This is accomplished by activating enzymes whose actions promote glucose formation (gluconeogenesis) and glycogen breakdown (glycogenolysis) in the liver, while inhibiting glycogen formation. This prevents glucose from being taken up by peripheral tissue and preserves it for the CNS. Further, very little adrenal norepinephrine reaches distal tissue; thus, the effects caused by norepinephrine during the stress response are primarily elicited from the SNS.[46,47]

Epinephrine has a greater influence on cardiac action and is the principal catecholamine involved in metabolic regulation. Epinephrine enhances myocardial contractility (inotropic effect), increases the heart rate (chronotropic effect), and increases venous return to the heart, all of which increase cardiac output and blood pressure. Epinephrine dilates blood vessels of skeletal muscle, allowing for greater oxygenation. Epinephrine in the liver and skeletal muscles is rapidly metabolized and dilates blood vessels supplying skeletal muscles, allowing for more oxygenation. Epinephrine also mobilizes free fatty acids and cholesterol by stimulating lipolysis, freeing triglycerides and fatty acids from fat stores, and by inhibiting the degradation of circulating cholesterol to bile acids. The metabolic actions of epinephrine aid the metabolic actions of cortisol, which are similar.

Table 11-2 summarizes other well-known effects of adrenal catecholamines. All of these effects prepare the body to take physical action: to fight or flee. Stressors commonly associated with catecholamine release by the adrenal medulla include exercise, thermal changes, and acute emotional states.

The catecholamines stimulate two major classes of receptors: α-adrenergic receptors and β-adrenergic receptors. These two classes are divided further into two subclasses: (1) α_1 and α_2 and (2) β_1 and β_2. Table 11-3 summarizes the actions of the two subclasses of adrenergic receptors. Epinephrine binds to and

TABLE 11-4 PHYSIOLOGIC EFFECTS OF CORTISOL

FUNCTIONS AFFECTED	PHYSIOLOGIC EFFECTS
Carbohydrate and lipid metabolism	Diminishes peripheral uptake and utilization of glucose; promotes gluconeogenesis in liver metabolism cells; enhances gluconeogenic response to other hormones; promotes lipolysis in adipose tissue
Protein metabolism	Increases protein synthesis in liver and decreases protein synthesis (including immunoglobulin synthesis) in muscle, lymphoid tissue, adipose tissue, skin, and bone; increases plasma level of amino acids; stimulates deamination in liver
Anti-inflammatory effects (systemic effects)	High levels of cortisol used in drug therapy suppress inflammatory response; inhibit proinflammatory activity of many growth factors and cytokines; however, over time some individuals may develop tolerance to glucocorticoids, causing an increased susceptibility to both inflammatory and autoimmune disease
Proinflammatory effects (possible local effects)	Cortisol levels released during stress response may increase proinflammatory effects
Lipid metabolism	Lipolysis in extremities and lipogenesis in face and trunk
Immune effects	*Treatment* levels of glucocorticoids are immunosuppressive; thus, they are valuable agents used in numerous diseases; the T-cell or innate immunity system is particularly affected by these larger doses of glucocorticoids with suppression of Th1 function or innate immunity; *stress* can cause a different pattern of immune response; these nontherapeutic levels can suppress innate (Th1) and increase adaptive (Th2) immunity—the so-called Th1 to Th2 shift; several factors influence this complex physiology and include long-term adaptations, reproductive hormones (i.e., overall, androgens suppress and estrogens stimulate immune responses), defects of hypothalamic-pituitary-adrenal axis, histamine-generated responses, and acute vs. chronic stress; thus stress seems to cause a Th2 shift *systemically* whereas *locally,* under certain conditions, it can induce proinflammatory activities and by these mechanisms may influence onset or course of infections and autoimmune/inflammatory, allergic, and neoplastic diseases
Digestive function	Promotes gastric secretion
Urinary function	Enhances excretion of calcium
Connective tissue function	Decreases proliferation of fibroblasts in connective tissue (thus delaying healing)
Muscle function	Maintains normal contractility and maximal work output for skeletal and cardiac muscle
Bone function	Decreases bone formation
Vascular system/myocardial function	Maintains normal blood pressure; permits increased responsiveness of arterioles to constrictive action of adrenergic stimulation; optimizes myocardial performance
Central nervous system function	Somehow modulates perceptual and emotional functioning; essential for normal arousal and initiation of daytime activity
Possible synergism with estrogen in pregnancy?	Suppresses maternal immune system to prevent rejection of fetus?

activates both α- and β-adrenergic receptors. Norepinephrine at physiologic concentrations binds primarily to α-adrenergic receptors.[48]

Catecholamines can modify the numbers of cells of the immune system circulating in the blood.[49] Injection of epinephrine into healthy human subjects is associated with a transient increase of the number of lymphocytes (e.g., T cells and natural killer [NK] cells) in the peripheral blood. Specifically, the levels of T cytotoxic and NK cells increase, whereas little change occurs in B lymphocytes. The main change involves the NK cells.[49] Qualitatively, lymphocyte responsiveness of T and B lymphocytes is reduced. Similar quantitative and qualitative changes are found 5 to 6 minutes after exposure to a psychologic or physical stressor.[50] However, the effects of acute elevation of catecholamine levels on the alteration of lymphocyte function are short-lived, lasting only about 2 hours.[51]

Glucocorticoids: Cortisol

The adrenal cortex is activated during stress by ACTH (see Figure 11-2), which increases adrenocortical secretion of glucocorticoid hormones, primarily cortisol (*hydrocortisone is* a synthetically produced but chemically identical version of cortisol). These steroid molecules reach *all* tissues, including the brain, easily penetrate cell membranes, and react with numerous intracellular glucocorticoid receptors. Because they spare almost no tissue or organ and influence a large proportion of the human genome, they exert significant diverse biologic actions.[22] The feedback mechanisms of the HPA axis sense and determine the circulating glucocorticoid levels, whereas other tissues passively accept the actions of circulating glucocorticoids.[22] Chronic dysregulation of the HPA axis, especially elevated cortisol level, has been linked to a wide variety of disorders including obesity, sleep deprivation, lipid abnormalities, hypertension, diabetes, atherosclerosis, loss of bone density, hippocampal atrophy, and cognitive impairment.[45]

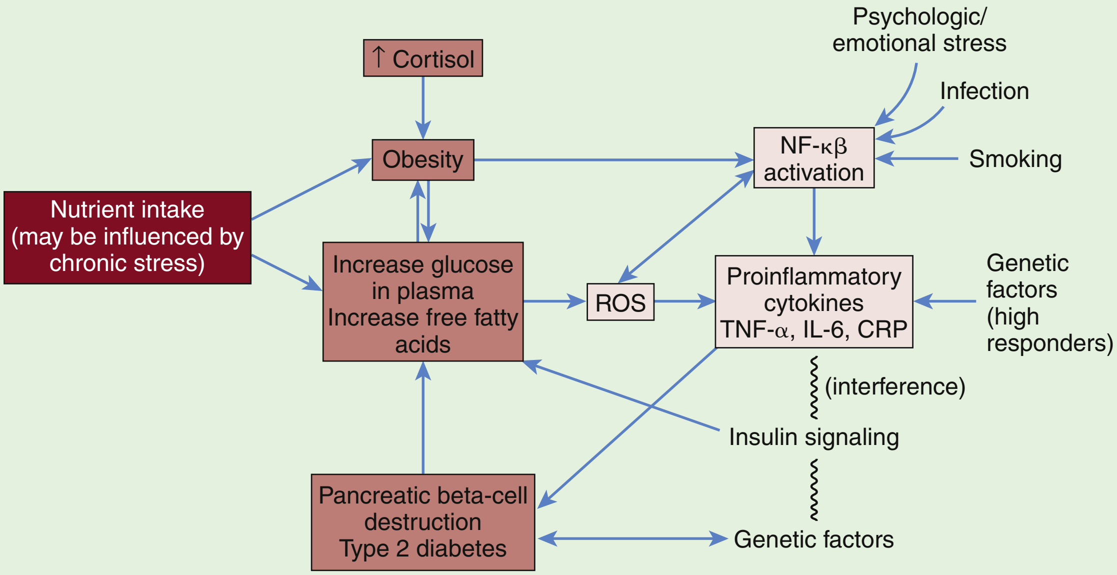
Cortisol circulates in the plasma, both protein bound and free. The main plasma-binding protein is called **transcortin** or **corticosteroid-binding globulin.** The unbound, or free, fraction is approximately 8% of the total plasma cortisol and is biologically active.[48] Cortisol mobilizes substances needed for cellular metabolism. One of the primary effects of cortisol is the stimulation of gluconeogenesis, or the formation of glucose from noncarbohydrate sources, such as amino acids or free fatty acids in the liver. In addition, cortisol enhances the elevation of blood glucose level promoted by other hormones, such as epinephrine, glucagon, and growth hormone. This action by cortisol is said to be *permissive* for the actions of other hormones. Cortisol also inhibits the uptake and oxidation of glucose by many body cells. The overall action of cortisol increases blood glucose concentration, thereby enabling the body to combat the stressor. The physiologic effects of cortisol are summarized in Table 11-4.

Cortisol also affects protein metabolism. It has an anabolic effect; that is, it increases the rate of synthesis of proteins and ribonucleic acid (RNA) in the liver. The anabolic effect of cortisol, however, is countered by its catabolic effect on protein

BOX 11-1 GLUCOCORTICOIDS, INSULIN, INFLAMMATION, AND OBESITY

The signs and symptoms of Cushing syndrome (e.g., excess glucocorticoids [GCs]) include truncal obesity, relatively thin extremities, a "moon face," and a "buffalo [neck] hump." In such individuals the possibility of associated hypertension is high as well as increased risk of infection and metabolic syndrome or frank type 2 diabetes. In addition, the likelihood of an elevated ratio of intra-abdominal subcutaneous fat mass to nonabdominal fat mass is high because the glucocorticoids mediate the redistribution of stored calories into the abdominal region. The specific increase in abdominal fat stores is a consequence of elevated levels of glucocorticoids combined with increased insulin action. However, the increased levels of glucocorticoids need not be present in the circulation, but can be generated locally in fat by conversion of inactive cortisone to active cortisol through the action of the isoenzyme 11-β-hydroxysteroid dehydrogenase (11-β-HSD) type-1. This conversion is referred to as "pre-receptor" metabolism of cortisol. The active steroid is secreted directly to the liver through the portal vein. In vitro insulin synthesis and secretion from the pancreas are inhibited by the glucocorticoids. However, increasing levels of glucocorticoids in vivo are associated with increasing insulin secretion possibly because of an anti-insulin effect on the liver, which appears to be vulnerable to the negative effects of glucocorticoids on insulin action. Hepatic insulin resistance is strongly associated with abdominal obesity.

Recent data reveal that the plasma concentration of inflammatory mediators, such as tumor necrosis factor-alpha (TNF-α) and interleukin-6 (IL-6), is increased in the insulin-resistant states of obesity and type 2 diabetes. Two mechanisms might be involved in the pathogenesis of inflammation: (1) glucose and macronutrient intake (i.e., which can be mediated through chronic stress) causes oxidative stress; and (2) the increased concentrations of TNF-α and IL-6 associated with obesity and type 2 diabetes might interfere with insulin signal transduction. This interference might promote inflammation. Chronic overnutrition (obesity) might thus be a proinflammatory state with oxidative stress.



Stress, Inflammation, Obesity, and Type 2 Diabetes. The induction of reactive oxygen species (ROS) generation and inflammation through the proinflammatory transcription factor, NF-kβ, activates most proinflammatory genes. Macronutrient intake, obesity, free fatty acids, infection, smoking, psychologic stress, and genetic factors increase the production of ROS. Interference with insulin signaling (insulin resistance) leads to hyperglycemia and proinflammatory changes. Proinflammatory changes increase the levels of TNF-α and IL-6, and also lead to the inhibition of insulin signaling and insulin resistance. Inflammation in pancreatic beta cells leads to beta-cell dysfunction, which in combination with insulin resistance leads to type 2 diabetes. *CRP,* C-reactive protein.

Data from Dallman MF et al: *Endocrinology* 145(6):2633–2638, 2004; Dandona P, Aljada A, Brandyopadhyay A: *Trends Immunol* 25(1):4–7, 2004; Kim SP et al: *Diabetes* 52:2453–2460, 2003; Masuzaki H et al: *Science* 94:2166–2170, 2001; Padgett DA, Glaser R: *Trends Immunol* 24(8):444–448, 2003; Spencer SJ, Tilbrook A: *Stress* 14(3), 2011.

stores in other tissues. Protein catabolism acts to increase levels of circulating amino acids, and chronic exposure to excess cortisol can severely deplete protein stores in muscle, bone, connective tissue, and skin. Further, cortisol acts to reduce protein synthesis in nonhepatic tissues, a loss for which dietary protein cannot compensate. Some evidence suggests that cortisol depresses transport of amino acids into muscle cells while enhancing their uptake into the liver. Finally, cortisol promotes gastric secretion in the stomach and intestines, potentially causing gastric ulcers. This could account for the gastrointestinal ulceration observed by Selye. This is in opposition to norepinephrine, which reduces gastric secretion.

Cortisol also has a powerful effect that reverses the insulin-induced suppression of hepatic gluconeogenesis, as well as basal levels of cortisol that stimulate the activity of hepatic enzymes responsible for glycogen and glucose production. The increased amino acid uptake into liver and the increased levels of glucose-producing enzymes favor the production of glucose. Although diseases of excess cortisol secretion, such as Cushing disease, produce characteristics of type 2 (non–insulin-dependent) diabetes mellitus, recent studies found that chronic stress also may facilitate the development of type 2 diabetes.[52,53] Glucocorticoids contribute to the development of metabolic syndrome and the pathogenesis of obesity (Box 11-1). The mechanism

for this action is under investigation, but it is believed that the development of diabetes is secondary to cortisol-induced obesity. Cortisol promotes lipogenesis in certain regions of the body and to a lesser extent promotes lipolysis in other regions by increasing the actions of lipolytic hormones, such as catecholamines and growth hormone. Chronic cortisol excess induces lipogenesis in the abdomen, trunk, and face, resulting in central obesity. Finally, glucocorticoids may affect fetal programming of the HPA axis by causing an adverse intrauterine environment because of alterations in cortisol secretion during pregnancy.[54]

Cortisol and the Immune System

Cortisol secretion during stress exerts beneficial effects by inhibiting initial inflammatory effects, for example, vasodilation and increased capillary permeability.[32] Cortisol also promotes resolution and repair. These actions are mainly accomplished by facilitating the effects of glucocorticoid receptor (GR), namely, the transcription of genetic material (through DNA binding) within leukocytes.[32] Because GR is so widely expressed, glucocorticoids influence virtually all immune cells. However, whether cortisol-induced effects are adaptive or destructive may depend on the intensity, type, and duration of the stressor; the tissue involved; and the subsequent concentration and length of cortisol exposure. Finally, glucocorticoids have been shown to induce T-cell apoptosis.[32]

Cortisol acts to suppress the activity of Th1 cells, which leads to a decrease in innate immunity and to the proinflammatory response. Cortisol also stimulates the activity of Th2 cells, which leads to an increase in adaptive immunity and the anti-inflammatory response. Epinephrine and norepinephrine have a similar effect: a decrease in Th1 activity and an increase in Th2 activity.

Initially, immune responses are regulated by cells of *innate immunity* called antigen-presenting cells (APCs), such as monocytes/macrophages, dendritic cells, and other phagocytic cells, and by Th1 and Th2 lymphocytes (cells involved in *adaptive immunity*). These cells secrete chemical messengers, called *cytokines,* that regulate innate and adaptive immune responses. Cytokines are a group of chemicals such as interferons, interleukins, and tumor necrosis factors that can stimulate or inhibit various components of the immune system. Antigen-presenting cells also release cytokines that induce T cells to differentiate into Th1 cells. Th1 cells and APC cytokines work together to stimulate the activity of cytotoxic T cells, natural killer cells, and activated macrophages—the major components of innate immunity. These cytokines also stimulate the synthesis of nitric oxide and other inflammatory mediators that increase chronic delayed-type inflammatory responses. Because of this effect, these cytokines are sometimes referred to as proinflammatory cytokines.

The cytokines secreted by the Th2 cells act to inhibit Th1 cells and can promote adaptive immunity by stimulating the growth and activation of mast cells and eosinophils, as well as the differentiation of B-cell immunoglobulins. Thus, these cytokines are sometimes referred to as anti-inflammatory cytokines[55] (Figure 11-6). Moreover, cytokines can act synergistically, antagonistically, or reciprocally. However, the roles of cytokines are highly complex and much remains unknown. Regardless, the decrease in Th1 activity and increase in Th2 activity is sometimes called a **Th1 to Th2 shift.** Individuals experiencing a Th1 to Th2 shift are more likely to experience allergic responses, infections, and temporary worsening of autoimmune conditions such as arthritis.

The preceding description of the effect of stress hormones on the Th1-Th2 balance may not be accurate for certain local responses.[55,56] It has been documented that the release of catecholamines (epinephrine and norepinephrine) can cause certain epithelial cells of the lung to release cytokines that promote recruitment of leukocytes, potentially enhancing inflammation and worsening lung function. This paradoxical stress-induced potentiation of inflammation in the lungs may explain why "acute respiratory distress syndrome" often develops in individuals with major infections associated with profound activity of the stress response.[57]

Stress hormones, especially glucocorticoids (cortisol), have been used therapeutically as powerful anti-inflammatory/immunosuppressive agents for years. The synthetic forms of glucocorticoid hormones (exogenous types of anti-inflammatory glucocorticoids administered for a pharmaceutical reaction) are poorly metabolized when compared to endogenous glucocorticoids, leading to a longer half-life and no circadian rhythm for these compounds. Moreover, these synthetic compounds bind to different targets, so each has a unique effect.[31] Therapeutic levels of glucocorticoids inhibit the accumulation of leukocytes at the site of inflammation and inhibit the release of substances involved in the inflammatory response (i.e., kinins, plasminogen-activating factor, prostaglandins, and histamine) from the leukocytes. Glucocorticoids inhibit fibroblast proliferation and function at the site of an inflammatory response. This inhibition accounts for the poor wound healing, increased susceptibility to infection, and decreased inflammatory response that often are noted in individuals with chronic glucocorticoid excess.

Paradoxically, elevated levels of glucocorticoids and catecholamines (epinephrine and norepinephrine)—both endogenous and exogenously administered—may decrease innate immunity and increase autoimmune responses. These effects can accentuate inflammation in general and potentially increase neuronal death (e.g., in stroke victims).[31] This may help explain the seemingly contradictory stress response of immunosuppression and increased risk of infection (decreased innate immunity) with a heightened antibody response and autoimmune disease (increased adaptive immunity).

Corticotropin-releasing hormone (CRH) influences the immune system indirectly by the activation of cortisol (glucocorticoids) and catecholamines. CRH is secreted by the hypothalamus and also peripherally at inflammatory sites (called peripheral or immune CRH).[25,55] Peripheral (immune) CRH is proinflammatory, causing an increase in vasodilation and vascular permeability.[58] Therefore, it appears that mast cells are the target of peripheral CRH. Mast cells release histamine, which is a well-known mediator of acute inflammation and allergic reactions (see Figure 11-6). Recent evidence has indicated that immune cells may have histamine receptors and that

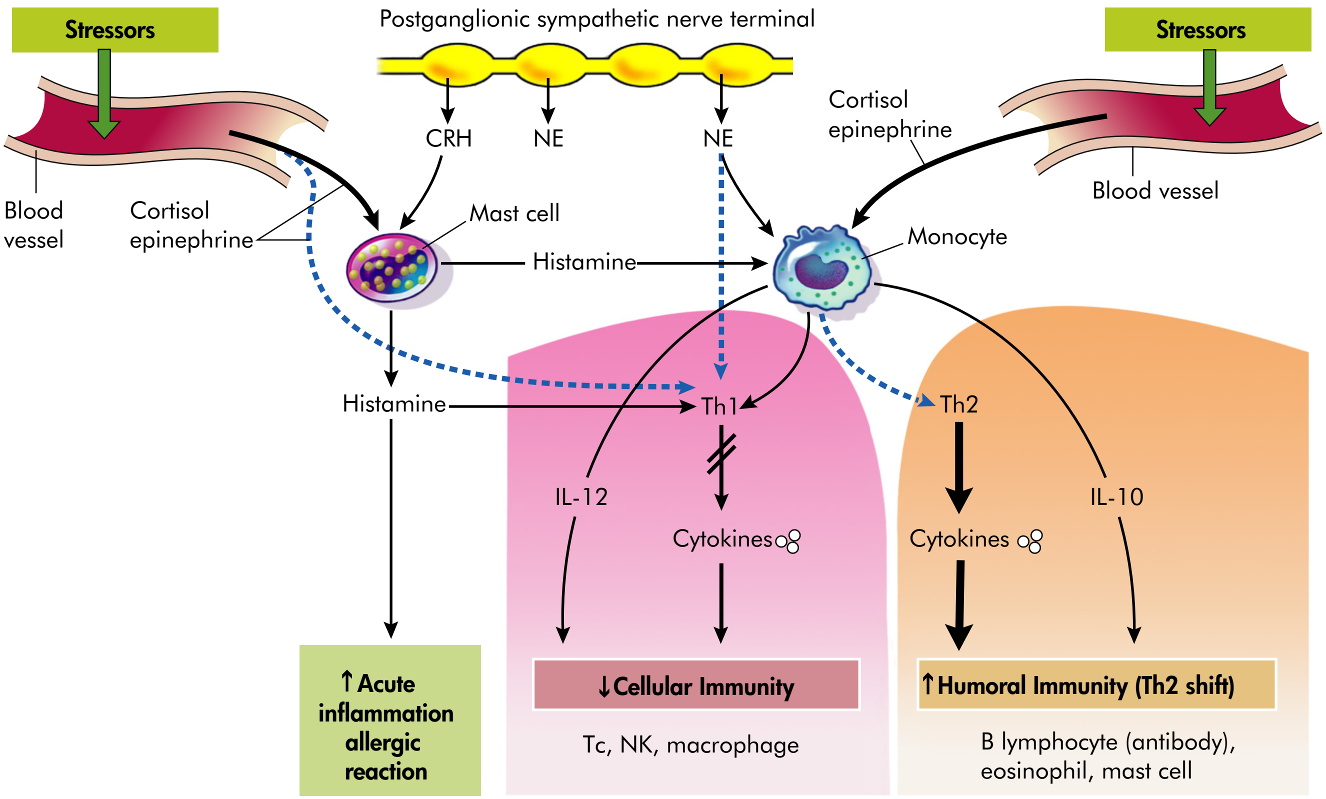


FIGURE 11-6 **Effect of Corticotropin-Releasing Hormone (CRH)—Mast Cell—Histamine Axis, Cortisol, and Catecholamines on the Th1/Th2 Balance—Innate and Adaptive Immunity.** Adaptive immunity provides protection against multicellular parasites, extracellular bacteria, some viruses, soluble toxins, and allergens. Innate immunity provides protection against intracellular bacteria, fungi, protozoa, and several viruses. Type 1 cytokines or proinflammatory cytokines include IL-12, interferon-gamma (IFN-γ), and tumor necrosis factor-alpha (TNF-α). Type 2 cytokines or anti-inflammatory cytokines include IL-10 and IL-4. Solid lines *(black)* represent stimulation, whereas dashed lines *(blue)* represent inhibition (i.e., Th1 and Th2 are mutually inhibitory, IL-12 and IFN-γ inhibit Th2, and vice versa; IL-4 and IL-10 inhibit Th1 responses). Stress and CRH modulate inflammatory/immune and allergic responses by stimulating cortisol (glucocorticoid), catecholamines, and peripheral (immune) CRH secretion and by changing the production of regulatory cytokines and histamines. *CRH* (peripheral, immune), Corticotropin-releasing hormone; *IL,* interleukin; *NE,* norepinephrine; *NK,* natural killer cell; *Tc,* cytotoxic T cell; *Th,* helper T cell; *dashed lines,* decreased (inhibited); *solid lines,* increased (stimulation). histamine may have an effect similar to catecholamines. This finding suggests that histamine induces acute inflammation and allergic reactions while suppressing Th1 activity (decreasing innate immunity) and promoting Th2 activity (increasing adaptive immunity).[57-59] A number of stress factors initiate CRH production, including high levels of interleukin-1 (IL-1) and IL-6. Increased CRH secretion results in an increase in cortisol secretion. Cortisol in turn inhibits further cytokine release by macrophages and monocytes. The observation that IL-1 can elicit changes in the nervous and endocrine systems by stimulating CRH production in the hypothalamus is part of a growing body of evidence demonstrating immune-induced regulation of the CNS. The release of the immune inflammatory mediators IL-6, tumor necrosis factor-alpha (TNF-α), and interferon is triggered by bacterial or viral infections, cancer, and tissue injury that in turn initiate a stress response through the HPA pathway. Enhanced systemic production of these cytokines also induces other CNS and behavior changes seen frequently during the acute phase of an infectious episode, acting either directly in a distant, systemic "endocrine" way or indirectly through the mediation of neuropeptides. These effects include pyrogenesis (fever), induction of slow-wave sleep, and anorexia, all of which are adaptive responses to infection and possibly cancer. Slow-wave sleep is associated with enhanced release of growth hormone (GH) and a reduction in levels of cortisol, which is beneficial for tissue repair and enhanced immune response.

In summary, stress can activate an excessive immune response and, through cortisol and catecholamines, suppress the Th1 response, causing a Th1 to Th2 shift. Locally, stress can exert proinflammatory or anti-inflammatory effects depending on the chemicals that are released in the local environment and the way that the cells of the local environment respond to those chemicals. Moreover, different types of stressors may have variable effects on the immune response. Thus *systemic responses to stress* may cause a decrease in innate immunity and enhance adaptive immunity, whereas *local responses to stress,* under certain conditions, can induce proinflammatory activities that

may influence the onset and cause of infectious, autoimmune/inflammatory, allergic, and neoplastic diseases.

Other Hormones

The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states. For example, **neuropeptide Y (NPY),** a sympathetic neurotransmitter, has been shown to be a stress mediator. Because NPY is a growth factor for many cells, it is implicated in atherosclerosis and tissue remodeling.[49] Other hormones that influence the stress response are listed in Table 11-5. Neuropeptides and hormones have a significant effect on the immune response. Whether this effect on immune function is suppressive or potentiating depends on the type of factor secreted, with some factors enhancing activity, some suppressing activity, and some doing both, depending on the concentration and length of exposure, the target cell, and the specific immune function studied.

Hormones of the Female Reproductive System. Cortisol exerts inhibiting effects by suppressing levels of luteinizing hormone (LH), estradiol, progesterone, and possibly testosterone.[60,61] The HPA axis exerts powerful, multilevel effects on the female reproductive system. Stress generally inhibits the female reproductive system (Figure 11-7), primarily through the HPA axis by (1) suppression of hypothalamic gonadotropin-releasing hormone (GnRH) secretion by CRH and CRH stimulation of β-endorphin release; (2) inhibition of GnRH, pituitary LH, and ovarian estradiol (E_2) secretion by cortisol; and (3) cortisol-induced target tissue resistance by estradiol.[62,63] The locus ceruleus–norepinephrine (LC/NE) system provides positive input to the reproductive system, which is frequently altered by the stress-activated HPA axis. Sexual stimulation and GnRH neuron activation, however, may cause the gonadal axis to be resistant to suppression by the HPA axis. Through estradiol, the reproductive system provides positive input to both components of the stress system by stimulating CRH secretion and inhibiting reuptake and catabolism of catecholamines. Table 11-6 presents potential pathologic effects of central and peripheral CRH in women.

Estrogen stimulates the HPA axis. In addition, HPA axis responsiveness is greater in women than that in men.[63] Estrogen directly stimulates the CRH gene promoter and the central noradrenergic (norepinephrine) system, which may help explain adult women's slight hypercortisolism, increases in affective anxiety and eating disorders, mood cycles, and vulnerability to autoimmune and inflammatory disease, all of which follow estradiol concentration fluctuations. Estradiol downregulates glucocorticoid receptor binding in the anterior pituitary, hypothalamus, and hippocampus—this tends to *increase* HPA activity by interfering with glucocorticoid-negative feedback, whereas progesterone opposes these effects.[64] Thus alterations in estradiol levels during normal menses, perimenopause (including increases as well as decreases), and menopause alter the regulatory feedback loop, and adaptations over time develop as a new equilibrium is established in the relationship (see Figure 11-7). Over time, these changes increase the incidence of mood alterations, eating disorders, anxiety, depression, weight alterations, and inflammatory and immune disorders.

The adipocyte-derived peptide hormone leptin interacts directly and indirectly with the adrenal and gonadal axes; leptin levels are higher in women than in men. Leptin regulates appetite (satiety) and energy balance. It also inhibits the HPA axis at both hypothalamic and adrenocortical levels. In addition, leptin positively influences the female reproductive axis by inhibition of the HPA axis and arcuate proopiomelanocortin (POMC) neuronal system and through activation of the LC/NE system. By promoting satiety and sympathetic system outflow, leptin is thought to provide the peripheral signal to a central mechanism regulating the size of body fat stores.[65] Thus leptin may be significant in control of the onset of puberty because of its relationship to the amount of fat mass, in the adaptive activation of the HPA axis, and in inhibition of gonadal function that takes place in cases of starvation and anorexia nervosa.[66-68]

Endorphins and Enkephalins. Endorphins and enkephalins (endogenous opiates) are released into the blood as part of the response to stressful stimuli. They are proteins found in the brain that have pain-relieving capabilities. Stressful stimuli include traumatic injury and an acute, intense stress situation, such as first-time parachute jumping. In inflamed tissue, immune cell–derived endorphins activate endorphin receptors on peripheral sensory nerves, leading to pain relief or analgesia.[69] Hemorrhage increases β-endorphin levels, which appear to inhibit blood pressure increase or delay compensatory changes that would increase blood pressure.[70] Thus endogenous opiates modulate blood pressure instability and neuroendocrine and cytokine responses to blood losses.[71,72]

In a number of conditions or activities in which endogenous opiate activity is increased, subjects not only experience insensitivity to pain but also report increased feelings of excitement, positive well-being, or euphoria. In addition, cells of the immune system synthesize and release opioids when the lymphoid cells are activated.[73] T and B lymphocytes and mononuclear phagocytic cells have receptors for opioids. Endorphins may play a role in the excitement and exhilaration produced by dancing, contact sports, and combat. There is little direct evidence, however, documenting the endorphin system in most of these activities.

Growth Hormone (Somatotropin). Growth hormone (GH) is released from the anterior pituitary gland and is produced by lymphocytes and mononuclear phagocytic cells.[74] GH affects protein, lipid, and carbohydrate metabolism and counters the effects of insulin. It is involved in tissue repair and may participate in the growth and function of the immune system. Receptors for GH are present on lymphoid cells.[75] This finding suggests a role for GH in regulating phagocytic function and possibly antigen presentation. GH levels increase in the blood after a variety of acutely stressful stimuli, such as cardiac catheterization, electroshock therapy, gastroscopy, surgery, fever, and physical exercise. Psychologic stimuli associated with increased levels of GH include taking examinations, viewing violent or sexually arousing films, anticipating exhausting exercise, and performing certain psychologic tests. However, prolonged activation of the stress response (chronic stress) leads to suppression of GH and other growth factor effects on target tissues.[76] (This is not to be confused with a congenital

TABLE 11-5 OTHER HORMONES THAT INFLUENCE THE STRESS RESPONSE

HORMONE	SOURCE	ACTION
β-Endorphins (endogenous opiates)	Pituitary and hypothalamus	Activates endorphin (opiate) receptors on peripheral sensory nerves, leading to pain relief or analgesia Hemorrhage increases levels to inhibit blood pressure or delay compensatory changes that would increase blood pressure[1]
Growth hormone (GH, somatotropin)	Anterior pituitary gland	Affects protein, lipid, and carbohydrate metabolism Counters effects of insulin Involved in tissue repair May participate in growth and function of immune system[2] Levels increase after a variety of stressful stimuli (cardiac catheterization, electroshock therapy, gastroscopy, surgery, fever, physical exercise) Increased levels associated with psychologic stimuli (taking examinations, viewing violent or sexually arousing films, certain psychologic performance tests) Prolonged stress (chronic stress) suppresses growth hormone
Prolactin	Anterior pituitary gland; numerous extrapituitary tissue sites	Increases in response to many stressful stimuli (including procedures such as gastroscopy, proctoscopy, pelvic examination, and surgery)[3] Requires more intense stimuli than those leading to increases in catecholamine or cortisol levels Levels show little change after exercise
Oxytocin	Hypothalamus	Promotes bonding and social attachment In animals associated with reduced hypothalamic-pituitary-adrenal (HPA) activation levels and reduced anxiety[4]
Testosterone	Leydig cells in testes	Regulates male secondary sex characteristics and libido Levels decrease after stressful stimuli (anesthesia, surgery, marathon running, mountain climbing)[5] Decreased by psychologic stimuli; however, some data indicate that psychologic stress associated with competition (e.g., pistol shooting) increases both testosterone and cortisol levels, especially in athletes older than 45 years[6] Markedly reduced in individuals with respiratory failure, burns, and congestive heart failure[7] Decreased levels occur during aging and are associated with a lower cortisol responsiveness to stress-induced inflammation[8]
Estrogen	Ovaries	Works in concert with oxytocin, exerting a calming effect during stressful situations[9]
Melatonin	Produced by pineal gland	Increases during stress response; release is suppressed by light and increased in the dark; receptors have been identified on lymphoid cells, possibly higher density of receptors on T cells than B cells; suppression of lymphocyte function by trauma was reversed by melatonin[10]
Somatostatin (SOM)	Produced by sensory nerve terminals found in and released from lymphoid cells and hypothalamus	Natural killer (NK) function and immunoglobulin synthesis are decreased by SOM; growth hormone secretion decreased by SOM
Vasoactive intestinal peptide (VIP)	Found in neurons of central nervous system (CNS) and in peripheral nerves	VIP increases during stress; VIP-containing nerves are located in both primary and secondary lymphoid tissues, around blood vessels, and in gastrointestinal tract; VIP receptors are on both T and B cells; VIP may influence lymphocyte maturation; cytokine production by T cells is modified by VIP; B cells and antibody production are influenced by VIP
Calcitonin gene–related peptide (CGRP)	Found in spinal cord motor neurons and in sensory neurons near dendritic cells of skin and in primary and secondary lymphoid tissues	CGRP receptors are present on T and B lymphocytes; thus it is likely that CGRP can modulate immune function; CGRP may enhance acute inflammatory response because it is a vasodilator; maturation of immune B lymphocytes is inhibited by CGRP; IL-1 is inhibited by CGRP, which is important for activation of T cells; it has been shown to interfere with lymphocyte activation
Neuropeptide Y (NPY)	Present in neurons of CNS and in neurons throughout body; co-localized in nerve terminals in lymphatic tissues with norepinephrine	Lymphocytes have receptors for NPY and thus may modulate their function;[11] several lines of evidence suggest that NPY is a neurotransmitter and neurohormone involved in stress response; increased levels of NPY occur in plasma in response to severe or prolonged stress; it may be responsible for stress-induced regional vasoconstriction (splanchnic, coronary, and cerebral); it may also increase platelet aggregation[2]
Substance P (SP)	Produced by a neuropeptide classified as tachykinin (increases heart rate subsequent to lowering blood pressure) found in brain, as well as nerves innervating secondary lymphoid tissues	SP increases in response to stress; receptors for SP are found on membranes of both T and B cells, mononuclear phagocytic cells, and mast cells; proinflammatory activity induces release of histamine from mast cells during stress response; causes smooth muscle contraction, causes macrophages and T cells to release cytokines, and increases antibody production

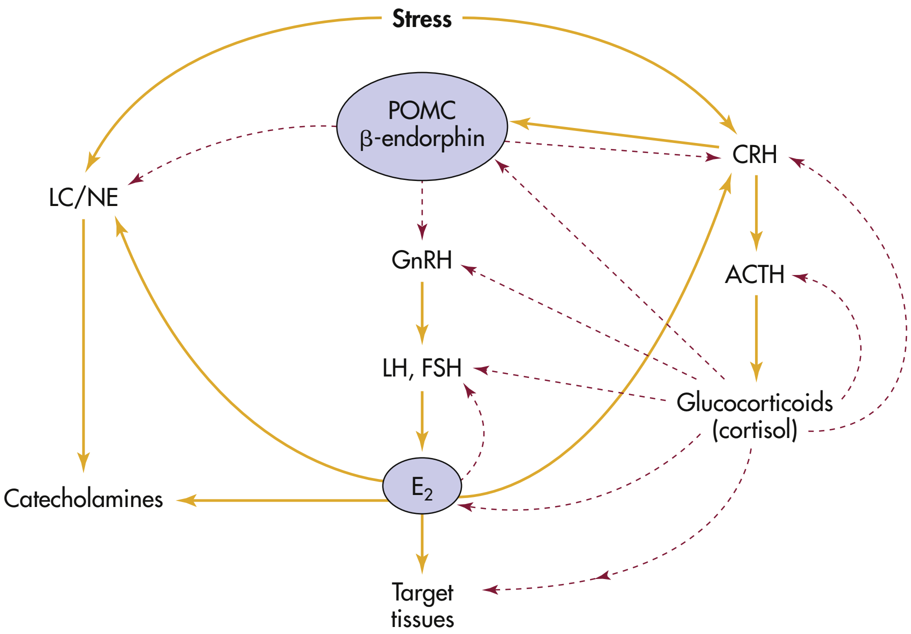

FIGURE 11-7 **Stress and the Female Reproductive System.** Interactions of the reproductive system with the hypothalamic-pituitary-adrenal (HPA) axis and locus ceruleus–norepinephrine system (LC/NE). Corticotropic cells of the pituitary gland express proopiomelanocortin (POMC) peptides. Stress generally inhibits the female reproductive system primarily through the HPA by (1) suppressing hypothalamic gonadotropin-releasing hormone (GnRH) secretion by corticotropin-releasing hormone (CRH) and CRH-induced β-endorphins; (2) inhibiting GnRH, pituitary luteinizing hormone (LH), and ovarian estradiol (E_2) secretion by cortisol; and (3) enhancing cortisol-induced target tissue resistance to estradiol. The LC/NE system provides positive input to the reproductive system, which can be overridden by the stress-activated HPA. Estradiol can cause the reproductive system to stimulate the stress system by stimulating CRH secretion and inhibiting reuptake and catabolism of catecholamines. *ACTH,* Adrenocorticotropic hormone; *FSH,* follicle-stimulating hormone. Dashed lines refer to inhibitory pathways. Solid lines refer to direct stimulatory pathways. (Adapted from Chrousos GP et al: *Ann Intern Med* 129[3]:229–240, 1998.)

GH deficiency, which leads to short stature, decreased muscular strength, and bone density pathology.) When under stress, chronic glucocorticoid stimulation decreases the release of GH from the pituitary gland, resulting in potentially decreased skeletal muscle, increased bone catabolism, reduced oxygen uptake, increased fat production, worsening sleep patterns, decreased force of cardiac contractions, decreased thyroid function, and poorer mood state. In other words, glucocorticoids antagonize the beneficial actions of GH.[77]

Prolactin. Prolactin is released from the anterior pituitary gland as well as numerous extrapituitary tissue sites. It is necessary for lactation and breast development. Prolactin receptors are present in many different tissues, including the liver, kidney, intestine, and adrenals. Prolactin is also produced by lymphoid cells.[78] Prolactin levels in plasma increase as a result of a variety of stressful stimuli, including gastroscopy, proctoscopy, pelvic examination, and surgery. The level of prolactin also rises during parachute jumping, during motion sickness, after taking examinations, and after receiving various sexual stimuli, for example, stimulation of the nipple or areola in women. Unlike GH, prolactin levels show little change after exercise. Like GH, however, a prolactin level increase appears to require more intense stimuli than those leading to increases in catecholamine or cortisol levels. Immune cells also are influenced by prolactin. Prolactin acts as a second messenger for IL-2 and is known to have a positive influence on B-cell activation and differentiation. Several classes of lymphocytes have receptors for prolactin, suggesting a direct effect of prolactin on immune function.

Oxytocin. Oxytocin is well known as a hormone produced in high levels by the hypothalamus during childbirth and lactation. It is also produced during orgasm in both sexes and has been shown to promote bonding and social attachment. Oxytocin also has antistress properties, as has been shown in animal experiments in which elevations in endogenous oxytocin level were associated with reduced HPA activation levels and reduced anxiety.[79] Oxytocin in some tissues works in concert with estrogen; these two hormones have a calming effect during stressful situations.[80] In contrast, another hormone closely resembling oxytocin, vasopressin, acts in concert with testosterone to increase blood pressure and heart rate, thus enhancing the "fight or flight" stress response. Thus different effects of stress on males and females may be explained, in part, by gender-related hormonal profiles that dictate to some extent the characteristics, quality, and outcomes of the stress response.

Testosterone. Testosterone, a hormone secreted by Leydig cells, regulates male secondary sex characteristics and libido. Testosterone levels decrease after stressful stimuli. This decrease in testosterone level occurs after stimuli such as ether or anesthetic administration, surgery, marathon running,

TABLE 11-6 POTENTIAL PATHOLOGIC EFFECTS OF CENTRAL AND PERIPHERAL CORTICOTROPIN-RELEASING HORMONE (CRH) IN WOMEN

CHANGES	ALTERATIONS
Central CRH	
Increased secretion	Hypercortisolism
	Melancholic depression
	Eating disorders
	Chronic active alcoholism
	Chronic active exercise
	Consequences: osteoporosis, visceral obesity, infertility
	Tau protein misfolding-Alzheimer disease?*
Decreased secretion	Atypical depression
	Seasonal affective disorder
	Chronic fatigue and fibromyalgia syndromes
	Rheumatoid arthritis
	Postpartum blues, depression, and autoimmunity
	Premenstrual tension syndrome
	Menopausal depression
Peripheral CRH	
Increased secretion of immune CRH	Inflammatory disorders
Increased secretion of placental CRH	Premature labor
Decreased secretion of placental CRH	Delayed labor
Decreased secretion of ovarian CRH	Ovarian dysfunction
	Anovulation
	Defective corpus luteum function
Increased secretion of ovarian CRH	Early menopause
Decreased secretion of endometrial CRH	Infertility
	Early spontaneous abortion

and mountain climbing. The mechanism causing decreased levels of testosterone is thought to be exerted by cortisol and β-endorphin.

Psychologic stimuli also lead to a decrease in testosterone levels. Men engaged in rigorous combat training and those engaged in the first several weeks of officer candidate school experience significant drops in testosterone levels.[81,82] However, other data have shown that the psychologic stress associated with some types of competition (e.g., pistol shooting) *increases* both testosterone and cortisol levels, especially in athletes older than 45 years.[83] Moreover, individuals with acute illness, such as respiratory failure, burns, and congestive heart failure, show a marked reduction in plasma testosterone level.[84]

The direct immunologic effects of sex hormones contribute to the sexual dimorphism seen in the incidence of autoimmune disease[85] and the greater susceptibility to sepsis and mortality in males following injury.[86] Estrogens generally are associated with a depression of T-cell–dependent immune function and an enhancement of B-cell functions, and androgens suppress both T- and B-cell responses.[84] In injury, however, males produce greater amounts of proinflammatory cytokines, a profile that is associated with poor outcome.[87] Additionally, androgens appear to induce a greater degree of immune cell apoptosis following injury, a mechanism that may elicit a greater immunosuppression in injured males vs. females.[88] (A list of other hormones, including melatonin, substance P, neuropeptide Y, calcitonin gene–related peptide, somatostatin, and vasoactive intestinal peptide, is contained in Table 11-5.)

Stress and the Immune System

Many immune-related conditions and diseases are associated with stress. Several conditions with variable pathophysiologic characteristics appear to have a common origin[89,90] relating to chronic inflammatory processes. These conditions include cardiovascular disease, osteoporosis, arthritis, type 2 diabetes mellitus, chronic obstructive pulmonary disease (COPD), other diseases associated with aging, and some cancers; all are characterized by the prolonged presence of proinflammatory cytokines.[89,91] It is important to remember that inflammation is associated with impairment of normal tissue function. Athough inflammation is a normal response and considered beneficial, an excessive inflammatory response can damage tissue. Stress and negative emotions are associated directly with the production of increased levels of proinflammatory cytokines, providing a possible link between stress, immune function, and disease.[92,93] Stress and negative emotions are associated directly with the production of increased levels of proinflammatory cytokines, providing a possible link between stress, immune function, and disease (see What's New? Psychosocial Stress and Progression to Coronary Heart Disease). Research is now focused on the regulatory interactions between the immune system and the nervous and endocrine systems, which may represent mechanistic pathways for stress-associated immune-mediated diseases. The immune, nervous, and endocrine systems communicate through similar pathways using hormones, neurotransmitters, neuropeptides, and immune cell products.[32] The complexity of this system can be daunting. Various components of immune system responses can be affected by neuroendocrine-produced factors involved in the stress reaction. Conversely, immune cell–derived cytokines and other products affect neurocrine and endocrine cells.[94]

The immune, nervous, and endocrine systems communicate through similar pathways involving hormones, neurotransmitters, neuropeptides, and immune cell products. Immune system responses are potentially affected by all known neuroendocrine-produced factors involved in the stress reaction. Conversely, immune cell–derived cytokines and other products have effects on neurocrine and endocrine cells. Several pathways regulate communication among these systems with both direct and indirect patterned effects (Figure 11-8).

The stress response directly influences the immune system through hypothalamic and pituitary peptides and through products of the sympathetic branch of the ANS. These factors include CRH, ACTH, endorphins, substance P, epinephrine, norepinephrine, dopamine, serotonin, histamine, GH,

WHAT'S NEW?

Psychosocial Stress and Progression to Coronary Heart Disease

The link between stress and coronary heart disease was proposed as early as the 1970s; however, it was only recently that evidence and proposed mechanisms for development of the disease were identified. Much work continues to focus on elucidating the interaction between stress and cardiovascular disease.

Studies show that persons with highly reactive personality types and who experience high levels of anxiety with stress are much more likely to progress from prehypertension to hypertension and then to develop cardiac disease, specifically coronary heart disease, than those who have better coping abilities. Further long-term psychologic stress, such as that experienced in a strained marriage or an unhappy work environment, not only was shown to speed the progression of hypertension and coronary heart disease but also is correlated with higher mortality rates from coronary heart disease.

Trait anger, defined as a stable personality trait characterized by frequency, intensity, and duration of anger, also was shown to be a factor in the development of coronary heart disease at higher rates than in the general population. Individuals with trait anger also experienced more strokes. Hostile individuals with advanced cardiovascular disease may be particularly susceptible to stress-induced increases in sympathetic activity and inflammation.

One popular mechanism for the interaction between psychosocial stress and cardiovascular disease suggests that stress triggers an inflammatory response that, over time, increases the chances of developing coronary heart disease. The primary mechanisms proposed are chronically elevated cortisol levels and dysregulation of the circadian rhythm for cortisol release. Further, chronic stress alters hypothalamic-pituitary-adrenal (HPA) function, resulting in an abnormal stress response pattern. This alteration in HPA activity was found in persons with coronary heart disease along with increased levels of inflammatory markers. The elevation in levels of inflammatory markers seen with chronic stress is important because these markers were shown to interact with lipids, specifically low-density lipoprotein (LDL), to increase the production of atherosclerotic plaques.

Because coronary heart disease is one of the major causes of death in industrialized countries, development of successful interventional programs is of high priority. Programs in which dietary changes, exercise, stress management, and positive support systems are implemented continue to show positive results for slowing the progression of heart disease and decreasing the risk factors for disease development. Further, individuals in these programs experience improvement in depression, stress, and overall mental health.

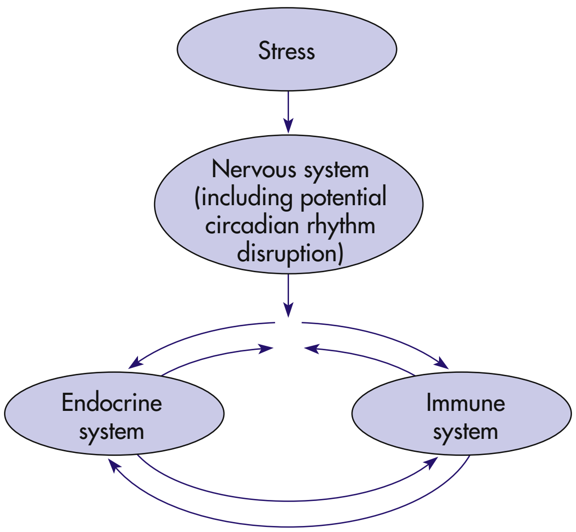

FIGURE 11-8 Nervous System–Endocrine System–Immune System Interactions. Interconnections of pathways of communication among the immune, nervous, and endocrine systems.

vasoactive intestinal polypeptide (VIP), β-endorphin, methionine-enkephalin, leucine-enkephalin, and somatostatin. Direct suppressive effects of CRH have also been reported on two immune cell types possessing CRH receptors—the monocyte/macrophage and CD4 (T helper) lymphocyte.[95] Release of endogenous opiates occurs during stress, and these peptides are known to have concentration-dependent, enhancing or suppressive effects on various immune cells.[96] Immune cells have been shown to have surface receptors for epinephrine, serotonin, ACTH, CRH, endorphins, GH, and prolactin, as well as intracellular steroid receptors.

Products of the sympathetic branch of the ANS also influence immune cell behavior. There is direct innervation of the thymus, spleen, lymph nodes, and bone marrow,[97] and histochemical studies have verified the presence of cholinergic and adrenergic nerve terminals in the lymphoid organs and tissues. There is evidence for the interaction of norepinephrine released from nerve endings with lymphocytes and macrophages in the spleen. This finding implicates the presence of a route of communication between the ANS and immune system through direct delivery of chemical mediators that alter immune cell behavior in a paracrine (cell to adjacent cell) fashion in the microenvironment of the lymphoid organ.

The pineal gland regulates the immune response and mediates the apparent effects of the circadian rhythm on immunity. Blockage of production of melatonin (by continuous light or by pharmacologic means) results in suppression of the immune response, whereas administration of melatonin reverses these effects. This immunomodulation pathway may affect immune changes found with dysregulation of circadian rhythm, a common occurrence among older adults, acutely ill persons, and stressed individuals.[98] Melatonin also modulates seasonal changes in immune function and affects tumor development.[99]

In summary, stress-induced immune changes affect many immune cell functions, including decreased natural killer cell and T-cell cytotoxicity and impaired B-cell function.[11] These impairments in immune function may have health consequences for stressed individuals, including increased risk of infection and some types of cancer.[100,101] The complex and bidirectional communication among systems involves common use of signal molecules and their receptors, which in turn regulates the behavior of cells in each system. Thus the most recent findings are that (1) there are direct effects of CNS neuropeptides on

immune cells; (2) stress-induced endocrine products influence immune cell and neurologic cell function; and (3) immune cell products (cytokines) affect nervous and endocrine cell function through direct and indirect pathways.

STRESS, PERSONALITY, COPING, AND ILLNESS

It is not entirely clear why cortisol secretion during stress is beneficial. It has been suggested that gluconeogenesis prompted by cortisol ensures an adequate source of glucose (energy) for body tissues, and nerve cells in particular. The pooling of amino acids from catabolized proteins may ensure amino acid availability for protein synthesis in certain cells. The redistribution of protein to sites where replacement is critical, such as muscle or cells of damaged tissue, would be beneficial. Short-term, cortisol-induced alterations in immune cell distribution (e.g., traffic) patterns may be adaptive, with a decrease in peripheral blood cell numbers as effector cells locate to sites of injury or inflammation. In addition, decreased immune cell activity by cortisol may be beneficial in some situations because it prevents immune-mediated tissue damage by prolonged cell exposure to high levels of certain cytokines. Whether cortisol-induced effects are adaptive or destructive may depend on the intensity, type, and duration of the stressor, and the subsequent concentration and length of cortisol exposure that target cells of the individual experience.

Extreme physiologic stressors, such as severe burn injury, represent a predictable stimulus for the stress responses described previously. A less severe and defined event or situation, however, can be a stressor for one person and not for another. Many stressors, such as fasting or temperature changes, do not necessarily cause a physiologic stress response if psychologic factors are minimized. Stress itself is not an independent entity but a system of interdependent processes that are moderated by the nature, intensity, and duration of the stressor and the perception, appraisal, and coping efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress. Further, adjustment to repetitive stressors is known to be individualized, based on a person's appraisal of a situation.[102] Illustrating the influence of an individualized stress appraisal on physiologic processes, a meta-analysis of the relationships between stressors and immunity found that a higher *perception* of stress was associated with reduced T-cytotoxic (Tc) cell cytotoxicity although not with levels of circulating Th or Tc lymphocytes.[103]

Psychosocial distress may be predictive of psychologic and physical health outcomes. In **psychologic distress** the individual feels a general state of unpleasant arousal after life events that manifests as physiologic, emotional, cognitive, and behavioral changes. Periods of depression and emotional upheaval often are associated with adverse life events and place the affected individual at risk for immunologic deficits, increasing the risk of ill health.[104] An older meta-analysis of studies demonstrates the longstanding relationship between depression and reduction in lymphocyte proliferation and NK cell activity.[105] Multiple moderating factors may be important in immune modulation in depressed individuals, including comorbidities such as alcoholism. Examples of triggering mechanisms include bereavement, academic and job-related pressures, life events (positive and negative changes), and aging. Adverse life events having the most negative effect on immunity are characterized as uncontrollable, undesirable, and overtaxing the individual's ability to cope.

Studies have strengthened the association of stress with potential for illness in humans (see What's New? Telomeres, Disease, and Childhood Stress). One study examined medical students who were immunized with hepatitis B vaccine on the third day of a stressful examination period; the time to seroconversion and level of antibody titer to the vaccine were measured later. The students with the most rapid seroconversion and the highest titers also reported being less stressed and had a good social support system (which may reduce stress).[106] Even more convincing is a study in which the psychologic stress status was determined in healthy individuals after experimentally controlled exposure to a respiratory tract virus by nasal inoculation. Individuals reporting more stress had an increased incidence of clinical cold and respiratory symptoms compared with subjects reporting less stress, and other infections, including HIV, were shown to be potentially influenced by psychosocial factors.[107-110]

Animal studies have found that stress contributes to the initiation, growth, and metastasis of certain tumors.[111] Studies of mechanisms in humans reveal stress affects important processes in cancer including antiviral responses, deoxyribonucleic acid

WHAT'S NEW?

Telomeres, Disease, and Childhood Stress

Shortening of the tips of chromosomes, or telomeres, is a potential physiologic mechanism linked to stress, cellular aging, and disease mortality. In experimental animal studies, telomere-deficient mice have been used to study telomere loss and shortening and associated tissue atrophy, stem cell depletion, organ system failure, and impaired tissue injury responses. Accumulating evidence reveals telomere damage as a stimulus for age-associated organ damage and disease risk. In humans, an emerging field is the discovery of mechanisms that mediate the effects of childhood stress on late-life disease, morbidity, and mortality. For example, recent evidence from the Environmental-Risk Longitudinal Twin Study found that children who experienced two or more kinds of violence exposure (i.e., maternal domestic violence, frequent bullying victimization, physical maltreatment by an adult) showed significantly more telomere erosion between age 5 at baseline and age 10 at follow-up measurements. This was observed even after adjusting for gender, socioeconomic status, and body mass index. In addition, investigators in 2004 compared telomere lengths in white blood cells of mothers of chronically ill children compared to those from mothers of healthy children. The longer the mother was a care provider for her child, the shorter were her telomeres. For mothers with the most self-reported stress, telomere shortening was equivalent to at least a decade of aging. In addition, a study of 4441 women aged 41 to 80 provided support for an association between adverse experiences during childhood and shorter telomere length in adulthood.

Data from Armanios M, Blackburn EH: *Nat Rev Genet* 13(10):693–704, 2012; Blackburn EH, Epel ES: *Nature* 490(7419):169–171, 2012; Epel ES et al: *Proc Natl Acad Sci U S A* 101(49):17312–17315, 2004; Jaskelioff M et al: *Nature* 469(7328):102–106, 2011; Shalev I et al: *Mol Psychiatry* 2012 Apr 24 [Epub ahead of print]; Surtees PG et al: *J Gerontol A Biol Sci Med Sci* 66(11):1152–1162, 2011.

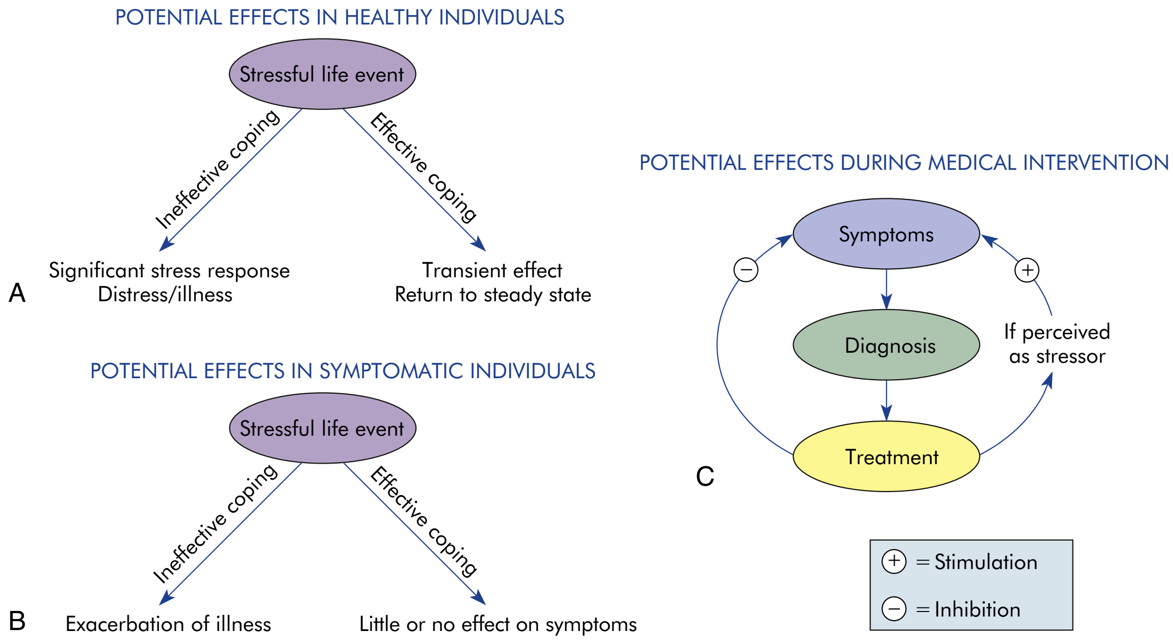

FIGURE 11-9 Health Outcome Determination in Stressful Life Situations Is Moderated by Numerous Factors. Whether an individual experiences distress or illness depends on the subject's appraisal of the event and the coping strategies used during the stressful period. Models **A** and **B** reflect possible outcomes in stressed healthy and symptomatic individuals. Model **C** illustrates the dynamic clinical setting in which the diagnosis of a serious illness and subsequent medical interventions may be perceived as stressful challenges and have potentially detrimental influences on physical outcome.

(DNA) repair, and aspects of cellular aging.[111] The role of epigenetics and stress is a new and developing field with strong implications for the intersection between stress and disease. A very recent study suggests that breast cancer bone metastases may be influenced by chronic stress by increasing the levels of Receptor Activator of Nuclear Factor κB Ligand (RANKL) that are expressed by osteoblasts, a known chemoattractant for RANK-expressing breast cancer cells.[112] However, the overall evidence is mixed from prospective studies linking stress with cancer incidence and progression. Stress may be more likely to influence progression and recurrence of cancer; however, the critical prospective studies have been mostly unsupportive.[12] Studies examining impairments in antiviral immunity and chronic activation of hormonal responses (e.g., HIV-related tumors, hepatocellular carcinoma, and cervical cancer) may be more successful designs for defining the stress-related mechanisms.[111]

Previous and current evidence is showing a relationship between immune stimulation and heart disease.[113] The relationship between stress and cardiovascular health may be mediated by stress-induced changes in immune function, which may potentiate proinflammatory processes and permit alterations that lead to heart disease[114] (see What's New? Acute Emotional Stress and Adverse Heart Effects [p. 342] and What's New? Psychosocial Stress and Progression to Coronary Heart Disease [p. 354]). A new study of heart disease and inflammation demonstrates that monocytes and splenic macrophages invade atherosclerotic plaques after an initial myocardial infarction (heart attack), rendering them unstable and as such contribute to secondary heart attacks.[115]

In the past decade a significant amount of evidence has accumulated linking severe psychosocial stress resulting from negative life events to a chronic syndrome with mental and physical consequences. Posttraumatic stress disorder (PTSD) has been described in many populations.[116-118] A cascade model has been proposed to describe the pathogenesis and clinical course illustrating the clinical, epidemiologic, neurobiologic, and psychosocial components of PTSD.[119] The study of PTSD has contributed to the knowledge concerning mechanisms involved in the chronic stress and disease relationship. Recently an appreciation of the association of chronic stress with high levels of cortisol production and paradoxical biounavailability (i.e., bound to plasma protein and therefore not bioavailable) of cortisol has been gained.[120]

The interaction with healthcare providers in a clinical setting, the diagnosis of a major illness, and the execution of various clinical procedures (e.g., blood draws, injections, examinations, surgical procedures) also may represent significant negative life events to many individuals (Figure 11-9) (for example, mammography and the activation of the HPA axis).

The influence of repetitive but episodic stress on cancer survivors demonstrates a connection between events such as mammography and activation of the HPA axis. Early research with breast cancer survivors by Cordova and colleagues[121] demonstrated a link between sympathetic activity and HPA axis activation, noting that some women reported symptoms of PTSD (heart palpitations, panic, shakiness, nausea) during thoughts of recurrence triggered by events such as finding themselves near the hospital where they received initial treatment.[121] HPA axis activation also influences organs and tissues that enable bidirectional communication processes (feedback

loops) between neuroendocrine and immune processes.[94] For example, among breast cancer survivors 3 to 5 years post diagnosis, elevated baseline cortisol levels and blunted cortisol reactivity were reported in response to the anticipation of a real, regularly scheduled mammogram, and alterations in cortisol level and heart rate variability were reported in women simulating the threat of cancer with a controlled laboratory stressor.[122,123] Further, Ma and colleagues[122] reported that the threat of cancer recurrence (using a simulated mammography event as a stressor to elicit thoughts of cancer recurrence) elicited greater alterations in heart rate variability when compared with another simulated controlled stressor. These studies suggest activation of the autonomic nervous system to events, such as mammography, that occur repeatedly throughout breast cancer survivorship, although the timing of onset of these autonomic activation responses to a stressor is unclear. Similar ANS activation may occur in association with events particular to the management of many other types of chronic illnesses as well as interactions with the healthcare system.

These additional stresses may affect the course of illness as well as interfere with the efficacy of the medical intervention. Identifying and reducing stress in the clinical setting have particular applicability in both disease prevention and illness management. In addition to medical procedures, patient-provider communication also provides an important area for future research. Recent studies of cancer communication and patient-provider interaction have demonstrated a link between communication events and emotional outcomes, such as uncertainty and mood state in breast cancer survivors.[124,125] Although a logical extension, it remains to be seen if these emotional outcomes affect physiologically based health outcomes caused by activation of the HPA axis and subsequent immune processes.

Coping

Personality characteristics are associated with individual differences in appraisal and response to stressors.[126] The coping response of individuals may exaggerate or moderate physical consequences of the stress response. **Coping** is defined as the process of managing stressful demands and challenges that are appraised as taxing or exceeding the resources of the person.[127] One response may be a negative change in behavior resulting in potentially adverse health effects (e.g., increased smoking, change in eating habits). Serious disturbances of the sleep-wake cycle are observed in many people under stress and in many clinical settings. Further, sleep disturbances may exacerbate the pathophysiologic status of certain patient populations.[128-130] Investigators have reported that sleep deprivation and circadian disruption, even in young, otherwise healthy individuals, have detrimental influences on respiratory and immune system function. Even partial sleep deprivation was associated with reduced NK cell activity in healthy subjects, and only recently have seriously ill patients been assessed for adequacy and structure of sleep during recovery.[128]

Coping can be considered as adaptive or maladaptive. Adaptive coping strategies, especially those that are problem focused and those that encourage seeking social support, are beneficial during stressful experiences. The extent to which an individual responds to distress, using effective positive coping strategies, determines the degree of successful moderation of the stress challenge. Conversely, ineffective negative coping attempts may exacerbate the effects of distress on health, thus augmenting the potential for illness. Mediating factors that may influence stress susceptibility or resilience include age, socioeconomic status, gender, social support status, personality and lifestyle, self-esteem, genetics, life events, past experiences, and current health status.[131] Evidence suggests that effective intervention may result in greater stress resilience and improved psychologic and physiologic outcomes. In a study of nursing home residents randomly assigned to control or social support intervention groups, improved psychologic measures and immune function (NK cell activity) were observed in the experimental group at 6 weeks.[132] In another study, women with recurrent metastatic breast cancer were given either routine follow-up (routine care) or weekly support group sessions. Survival in the support treatment group was an average of 19 months longer than in the routine care group, suggesting a mediating influence of additional support for these women.[25,133]

The importance of social support for seriously ill individuals has focused attention on the health and well-being of family members who function as caregivers (see What's New? Partner's Survival and Spouse's Hospitalizations and/or Death). Significant stress manifested as depression, anxiety, and fatigue has been noted in family caregivers of those with cancer, Alzheimer disease, and burn trauma.[134] Individuals and caretakers exhibited suppression of various measures of immune function, with improved function associated with better perceived social support.[135-137] Gender-based coping differences may be attributed, in part, to the hormonal milieu of the individual, with females more likely to offer social support, a behavior with an oxytocin/estrogen association.[73]

WHAT'S NEW?

Partner's Survival and Spouse's Hospitalizations and/or Death

A Harvard study shows that a spouse's chances of dying increase not only when the partner dies but also when that partner becomes seriously ill. The 9-year follow-up study consisted of 518,240 elderly couples. Mortality after the partner's hospitalization varied according to the spouse's diagnosis. For elderly people whose spouse had been hospitalized, the short-term risk of dying approaches that of an elderly person after his or her spouse's death. A wife's hospitalization increased her husband's chances of dying within 1 month by 35%; a husband's hospitalization increased his wife's chances of dying by 44%. Likewise, a wife's death increased her partner's 1-month mortality risk by 53%, and a husband's death raised his partner's risk by 61%. The researchers commented that a spouse's illness or death can increase a partner's mortality by causing severe stress and removing a primary source of emotional, psychologic, practical, and financial support.

From a recent review, longitudinal studies put the long-term excess risk of death associated with widowhood compared to marriage at about 15%, and estimates of short-term effects during the first few months immediately post-bereavement range from 50% to 90%. However, there is substantial heterogeneity in the magnitude of effects reported in different studies.

Data from Christakis NA, Allison PD: *N Engl J Med* 354(7):719–730, 2006; Moon JR et al: *PLoS One* 6(8):e23465, 2011.

Interventions to prevent or manage stress-related psychologic or physical problems include both short- and long-term coping strategies. Stress management consists of educational components specific to the individual's problems and relaxation techniques, which may include meditation, imagery, massage, and biofeedback. These approaches may be used on an individual or a support group basis. Incorporation of these approaches into clinical training facilitates their use in the clinical arena. Research should focus on the efficacy of such approaches with various populations.

AGING AND STRESS: STRESS-AGE SYNDROME

A set of neurohormonal and immune alterations, as well as tissue and cellular changes, sometimes develops with aging. These changes, which recently have been defined as stress-age syndrome, include the following:[131,138]

- Alterations in the excitability of structures of the limbic system and hypothalamus
- Increase of the blood concentrations of catecholamines, antidiuretic hormone (ADH), ACTH, and cortisol
- Decrease of the concentrations of testosterone, thyroxine, and others
- Alterations of opioid peptide concentration
- Immunodepression and pattern of chronic inflammation
- Alterations in lipoproteins
- Hypercoagulation of the blood
- Free radical damage of cells

Some of the alterations are adaptational, whereas others are potentially damaging. These stress-related alterations of aging can influence the course of developing stress reactions and lower adaptive reserve and coping.[139]

Interventions to potentially prevent or manage stress-related psychologic or physical problems include both short- and long-term coping strategies. Educational components are specific to the individual's problems. Relaxation techniques may include meditation, mindfulness, imagery, massage, yoga, and biofeedback. These approaches may be used on an individual or group basis. Incorporation of these approaches into clinical training facilitates their use in the clinical arena. Future research should focus on the efficacy of such approaches with various populations.

In summary, it is clear that the mind and body are connected through a multitude of complex physical and emotional interactions. Understanding the complexity of these interactions is a challenge for many researchers. Areas of promise include investigating relationships between the potential for illness with respect to stressors, as well as developing effective stress management techniques and approaches that can be easily and cost-effectively employed.

SUMMARY REVIEW

Historical Background and General Concepts

1. Modern society is full of stress.
2. In general, a person experiences stress when a demand exceeds a person's coping abilities.
3. Hans Selye identified three structural changes in rats subjected repeatedly to noxious stimuli (stressors): enlargement of the cortex of the adrenal gland, atrophy of the thymus gland and other lymphoid tissues, and ulceration of the gastrointestinal tract.
4. Selye believed that the three changes were caused by a nonspecific physiologic response to any long-term stressor. He called this response the general adaptation syndrome (GAS).
5. The GAS occurs in three stages: the alarm stage, the stage of resistance or adaptation, and the stage of exhaustion. Diseases of adaptation develop if the stage of resistance or adaptation does not restore homeostasis.
6. Selye identified three components of physiologic stress: the stressor, the physiologic or chemical disturbance produced by the stressor, and the body's adaptational response to the stressor.
7. We now know that, while important, the physiologic view of stress as outlined in the GAS is an oversimplified model of stress responses. We currently view the stress response as the product of the interaction of the mind and body.

Concepts of Stress

1. Psychologic stress may cause or exacerbate (worsen) several disease states. Stress is related to the severity of symptoms and the outcomes of diseases and conditions. Research is focused on the mechanisms responsible for these mind-body interactions.
2. Stress has been defined as the state of affairs arising when a person relates to (i.e., interacts or transacts with) situations in a certain way. The way a person appraises and reacts to situations has a profound impact on stress.
3. The nonspecific physiologic response consists of interaction among the sympathetic branch of the autonomic nervous system (ANS) and other neural signals that activate the endocrine system, known as the HPA axis.
4. The nonspecific physiologic response is a common residual response and can be elicited with diverse agents such as cold, heat, x-rays, adrenaline, insulin, tubercle bacilli, and muscular exercise. Although the reactions of these stages are nonspecific, evidence supports the coexistence of highly specific, adaptive reactions to any of these agents.
5. As with a physically mediated stress response, psychologic stressors can elicit a reactive stress response; that is, a physiologic response can be derived from psychologic stressors.
6. Another type of psychologic-mediated stress response is the anticipatory response.
7. In a conditioned response, the organism learns that specific stimuli are associated with danger and anticipation of subsequent encounters with that particular stimulus produces a physiologic stress response (e.g., PTSD).
8. Psychoneuroimmunology (PNI) is the study of the interaction of consciousness *(psycho)*, the brain and spinal cord *(neuro)*, and the body's defense against external infection and abnormal cell division *(immunology)*.

SUMMARY REVIEW—cont'd

9. Psychoneuroimmunology assumes that all immune-related disease is multifactorial. The immune system is integrated with other physiologic processes and is sensitive to changes in CNS and endocrine functioning, such as those that accompany psychologic states.
10. CRH is released centrally from the brain and peripherally at inflammatory sites.

Stress Response

1. The stress response is initiated by the CNS and endocrine system. Where the stress response begins depends on whether the stressor is perceived or real.
2. Perceived stressors elicit an anticipatory response that usually begins in the limbic system of the brain. The limbic system elicits an endocrine stress response indirectly by stimulating neural pathways responsible for receiving sensory information and elicits a central response directly by stimulating the LC to release LC/NE.
3. Real stressors elicit a reactive response that can begin either in the limbic system or in the brain in response to specific sensory information. This information is then relayed to the PVN. The PVN stimulates the LC and both central and endocrine stress responses.
4. The neuroendocrine response to stress consists of sympathetic stimulation of the adrenal medulla to secrete catecholamines (norepinephrine and epinephrine) and stressor-induced stimulation of the hypothalamus to secrete CRH, which in turn stimulates the pituitary to secrete ACTH, which then stimulates the adrenal cortex to secrete steroid hormones, particularly cortisol.
5. In general, the catecholamines prepare the body to act, and cortisol mobilizes energy stores (e.g., glucose) and other substances needed to fuel the action.
6. Epinephrine exerts its chief effects on the cardiovascular system. Epinephrine increases cardiac output and increases blood flow to the heart, brain, and skeletal muscles by dilating vessels that supply these organs. It also dilates the airways, thereby increasing delivery of oxygen to the bloodstream.
7. Norepinephrine's chief effects complement those of epinephrine. Norepinephrine constricts blood vessels of the viscera and skin; this has the effect of shifting blood flow to the vessels dilated by epinephrine. Norepinephrine also increases mental alertness.
8. CRH influences the immune system indirectly by the activation of glucocorticoids (cortisol) and catecholamines. Peripheral CRH is proinflammatory, causing vasodilation and vascular permeability. It appears that the mast cells are the target of peripheral CRH.
9. Cortisol's chief effects involve metabolic processes. By inhibiting the use of metabolic substances while promoting their formation, cortisol mobilizes glucose, amino acids, lipids, and fatty acids and delivers them to the bloodstream. Cortisol's effect on the immune system is concentration and location dependent and may include either stimulation or inhibition of the immune system.
10. The nervous, endocrine, and immune systems communicate through the common use of signal molecules and their receptors, which in turn regulate the behavior of cells in each system during stress challenge.
11. There are direct and indirect pathways of influence among the nervous, endocrine, and immune systems. Neuropeptides have direct effects on immune cells, as well as indirect influences through neuromediated endocrine modulation of immune function. Endocrine products (cortisol) also influence nerve cell behavior. Immune cell products affect both nerve and endocrine cell function, reflecting an adaptive role for the immune system as a "signal" organ to alert other systems of threatening stimuli.
12. Other hormones are affected by the stress response and include increased circulating levels of β-endorphins, growth hormone, and prolactin and a decrease in antidiuretic hormone level with extreme stress. Concentrations of luteinizing hormone, estradiol, progesterone, and possibly testosterone decrease during the stress response.

Stress, Personality, Coping, and Illness

1. Stress is a system of interdependent processes that are moderated by the nature, intensity, and duration of the stressor and the coping efficacy of the affected individual, all of which in turn mediate the psychologic and physiologic response to stress.
2. Many studies have linked psychologic distress with altered immune function, and evidence strengthens the association of stress with potential for illness in humans.
3. Adaptive coping strategies, especially those that are problem focused and those that encourage seeking social support, are beneficial during stressful experiences.

Aging and Stress: Stress-Age Syndrome

1. With aging, sometimes a set of neurohormonal and immune alterations develop; these changes have been defined recently as stress-age syndrome.
2. These stress-related alterations of aging can influence the course of developing stress reactions and lower adaptive reserve and coping.

CHAPTER OUTLINE

Cancer is a leading disease, cause of death, and source of morbidity of adults in the Western world. The incidence of cancer increases markedly with advancing age and is strongly affected by gender, lifestyle, ethnicity, infection, and genetics. Over the past 35 years intensive research has led to a significantly enhanced understanding of this complex and frightening disease. We now understand that cancer is a collection of more than 100 different diseases, caused by an accumulation of genetic and epigenetic alterations. Environment, heredity, and behavior interact to modify the risk of developing cancer and the response to treatment. Improvements in treatment strategies and supportive care, coupled with new, often individualized therapies based on advances in our fundamental understanding of the basic pathophysiology of malignancy, have contributed to an increasing number of effective options for these diverse, often lethal, disorders collectively called *cancer*.

CANCER CHARACTERISTICS AND TERMINOLOGY

Any discussion of cancer must start with a definition of what it is and what it is not. Although most readers may have an intuitive understanding of this disorder, composing an exact definition that encompasses this broad category is more challenging. In general, a **tumor** is an abnormal growth resulting from uncontrolled proliferation and serves no physiologic function.

*Dr. Virshup contributed to the previous edition.

TABLE 12-1 CHARACTERISTICS OF BENIGN VS. MALIGNANT TUMORS

BENIGN TUMORS	MALIGNANT TUMORS
Grow slowly	Grow rapidly
Have a well-defined capsule	Are not encapsulated
Are not invasive	Invade local structures and tissues
Are well differentiated; look like the tissue from which they arose	Are poorly differentiated; may not be able to determine tissue of origin
Have a low mitotic index; dividing cells are rare	High mitotic index; many dividing cells
Do not metastasize	Can spread distantly, often through blood vessels and lymphatics

The term *cancer* derives from the Greek word for crab, *karkinoma,* which the physician Hippocrates used to describe the appendage-like projections extending from tumors. The word tumor originally referred to any swelling that was caused by inflammation, but is now generally reserved for describing a new growth, or **neoplasm.** Not all tumors or neoplasms, however, are cancer. The term **cancer** refers to a *malignant* tumor and is not used to refer to *benign* growths, such as lipomas or hypertrophy of an organ. Yet it is important to recognize that benign neoplasms also can be life threatening if they enlarge in critical locations. For example, a benign meningioma at the base of the skull may cause symptoms by compressing adjacent normal brain tissue. The definitions of benign vs. malignant are presented in the following text and in Table 12-1.

Tumor Classification and Nomenclature

Proper identification of a cancer is important for many reasons. Different lesions will have different causes, different rates and patterns of progression, and different responses to treatment. Cancer classification starts with knowing the site of origin and microscopic appearance of the lesion, but can extend to a detailed description of critical genetic changes in the cancer.

Benign tumors, which are not referred to as cancers, are usually encapsulated and well differentiated. They retain some normal tissue structure and do not invade the capsules surrounding them or spread to regional lymph nodes or distant locations. Benign tumors are generally named according to the tissues from which they arise, and include the suffix "-oma." For example, a benign tumor of the smooth muscle of the uterus is a *leiomyoma,* and a benign tumor of fat cells is a *lipoma.*

Some tumors initially described as benign can progress to cancer and then are referred to as **malignant tumors.** These tumors are distinguished from benign tumors by their more rapid growth rates and specific microscopic alterations, including loss of differentiation and absence of normal tissue organization. One of the hallmarks of cancer cells, as seen under the microscope, is **anaplasia,** the loss of cellular differentiation, irregularities of the size and shape of the nucleus, and the loss of normal tissue structure. Malignant tumors may present with different degrees of encapsulation; some lack a capsule, and even if a capsule is apparent, its integrity has been compromised so that tumor cells can grow to invade nearby blood vessels, lymphatics, and surrounding structures. The most important and most deadly characteristic of malignant tumors is their ability to spread far beyond the tissue of origin, a process known as *metastasis* (Figures 12-1 and 12-2; see Table 12-1).

In general, cancers are named according to the cell type from which they originate. Cancers arising in epithelial tissue are called **carcinomas,** and if they arise from or form ductal or glandular structures are named **adenocarcinomas.** Hence, a malignant tumor arising from breast glandular tissue is a mammary adenocarcinoma. Cancers arising from connective tissue usually have the suffix **sarcoma.** For example, malignant cancers of skeletal muscle are known as rhabdomyosarcomas. Cancers of lymphatic tissue are called **lymphomas,** whereas cancers of blood-forming cells are called **leukemias.** However, many cancers, such as Hodgkin disease and Ewing sarcoma, are named for historical reasons that do not follow this naming convention. Table 12-2 presents the nomenclature and classification of selected tumors.

Classification of Tumors—Classical Histology and Modern Genetics

Carcinoma in situ (often abbreviated **CIS**) refers to preinvasive epithelial malignant tumors of glandular or squamous cell origin. Cancers develop incrementally, as they accumulate specific genetic lesions. Careful surveillance for cancer often detects abnormal growths in epithelial tissues that have atypical cells and an increased proliferation rate compared with normal surrounding tissues. These early stage cancers are localized to the epithelium and have not penetrated the local basement membrane or invaded the surrounding stroma (see Figure 12-1). Based on these characteristics, they are not malignant but are often called **carcinoma in situ (CIS).** CIS is recognized in a number of sites, including the cervix, skin, oral cavity, esophagus, and bronchus. In glandular epithelium, in situ lesions occur in the stomach, endometrium, breast, and large bowel. In the breast, ductal carcinoma in situ (DCIS) fills the mammary ducts but has not progressed to local tissue invasion. DCIS lesions are readily treatable, although the optimal therapeutic approach is controversial. CIS lesions can have one of the following three fates: they can remain stable for a long time, they can progress to invasive and metastatic cancers, or they can regress and disappear. CIS can vary from low-grade to high-grade dysplasia, with the high-grade lesions having the highest likelihood of becoming invasive cancers. The time that such preinvasive lesions remain in situ before becoming invasive is unknown.[1] Some carcinomas of the cervix appear as preinvasive lesions in situ for several years before they progress to invasive carcinoma and metastatic tumors (see Figure 12-1). Knowing how to best treat low-grade CIS lesions is challenging because the proportion that progress to cancer vs. the proportion that will never cause clinical problems is usually not known. Although most persons prefer removal of any CIS as opposed to "watchful waiting," this topic continues to be a source of great debate.

Because our knowledge about the molecular alterations in cancer can influence the choices of therapy, it becomes increasingly important for clinicians to accurately molecularly classify each cancer. The classification, and hence the treatment

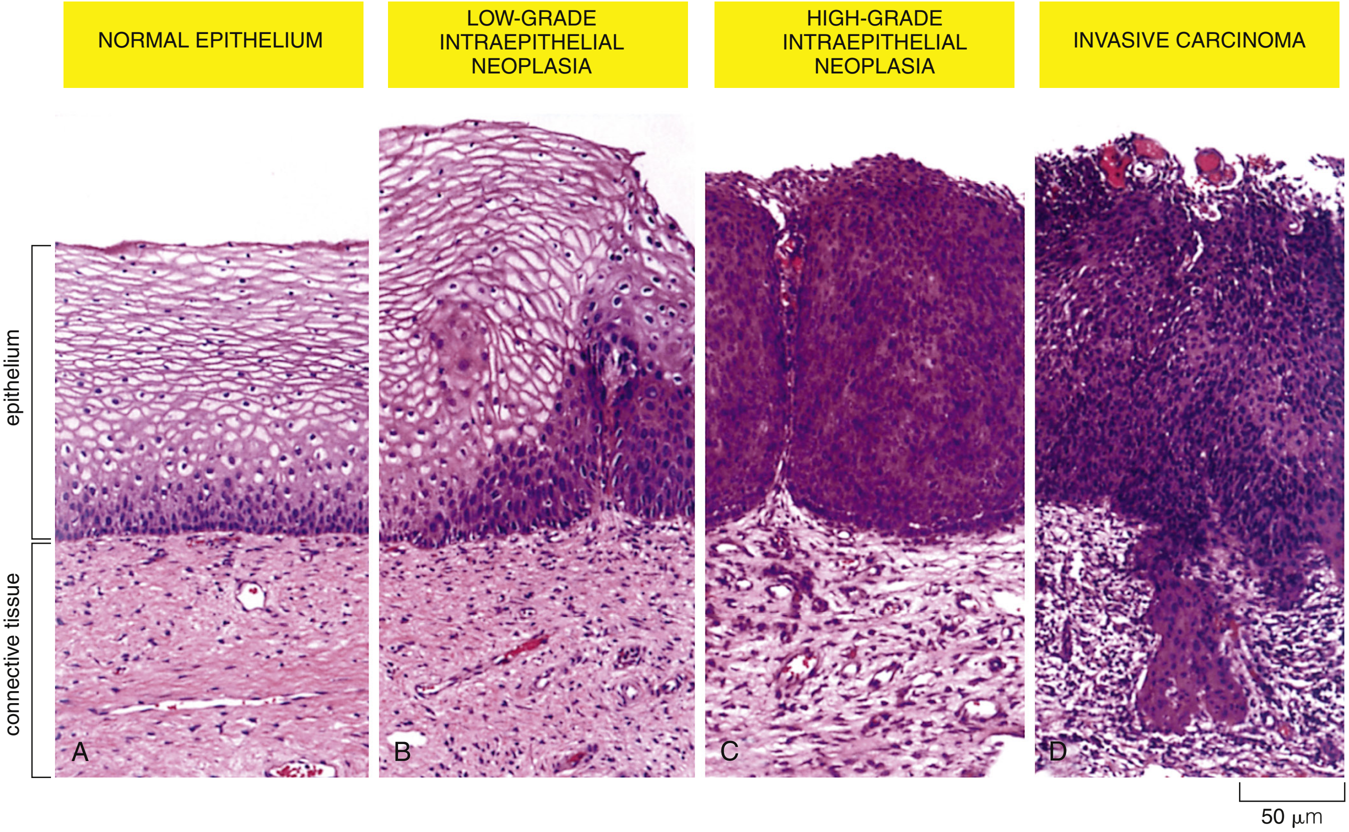

FIGURE 12-1 **Progression from Normal to Neoplasm in the Uterine Cervix.** A sequence of cellular and tissue changes progressing from low-grade to high-grade intraepithelial neoplasms (also called carcinoma in situ) and then to invasive cancer is seen often in the development of cancer. In this example of the early stages of cervical neoplastic changes, the presence of anaplastic cells and the loss of normal tissue architecture signify the development of cancer. The high rate of cell division and the presence of local mutagens and inflammatory mediators all contribute to the accumulation of genetic abnormalities that lead to cancer. (From Alberts B et al: *Molecular biology of the cell,* ed 5, New York, 2002, Garland.)

decisions, of cancers was originally based on gross and light microscopic appearance and is now commonly accompanied by immunohistochemical analysis of protein expression. Increasingly, this is supplemented by a more extensive molecular analysis of the tumors. Sometimes a single gene is examined (for example, to determine if there is a characteristic chromosomal translocation diagnostic of chronic myelogenous leukemia [CML]), and sometimes a panel of genes and proteins are examined (e.g., in breast cancer) to determine if the tumor expresses estrogen receptor, progesterone receptor, and the epidermal growth factor (EGF) receptor HER2, or if there are mutations in specific genes that include response to therapy. In a research setting, and increasingly in clinical settings, expression and mutation analysis of a large number of genes can be measured using polymerase chain reaction (PCR), microarray, or advanced DNA sequencing technology. These analyses can be used to classify tumors more precisely and may predict the most effective therapy. This detailed analysis of each tumor is a form of **personalized medicine** that offers therapy based on a very detailed knowledge of each individual's characteristics and their specific cancer.[2] This enhanced molecular characterization subdivides cancers into therapeutically and prognostically relevant smaller groups. As an example, breast cancers can now be subclassified into more than four types (luminal A, luminal B, basal-like, and others) based on their expression of specific markers, such as estrogen receptor, HER2/Neu, and other specific genes and proteins. Each subtype has a different response to therapy and a different prognosis (Figure 12-3).

Tumor Markers

During surveillance or diagnosis of cancer as well as following therapy, specific biochemical markers of tumors have proven to be helpful. These **tumor markers** are substances produced by both benign and malignant cells that either are present in or on tumor cells or are found in blood, spinal fluid, or urine (Table 12-3). Some tumor markers have been known for many decades. For diseases associated with a tumor marker, there is indeed a "blood test for cancer." Tumor markers include hormones, enzymes, genes, antigens, and antibodies. Liver and germ cell tumors secrete a protein known as *alpha fetoprotein (AFP)* into the blood, and prostate tumors secrete *prostate specific antigen (PSA)* into the blood. If the tumor marker itself has biologic activity, then it can cause symptoms, a phenomenon known as a **paraneoplastic syndrome.** For example, the adrenal medulla normally secretes the catecholamine epinephrine (adrenaline). Benign tumors of the adrenal medulla (pheochromocytoma) can produce catecholamines (e.g., adrenaline) in vast excess, leading to rapid pulse rate, high blood

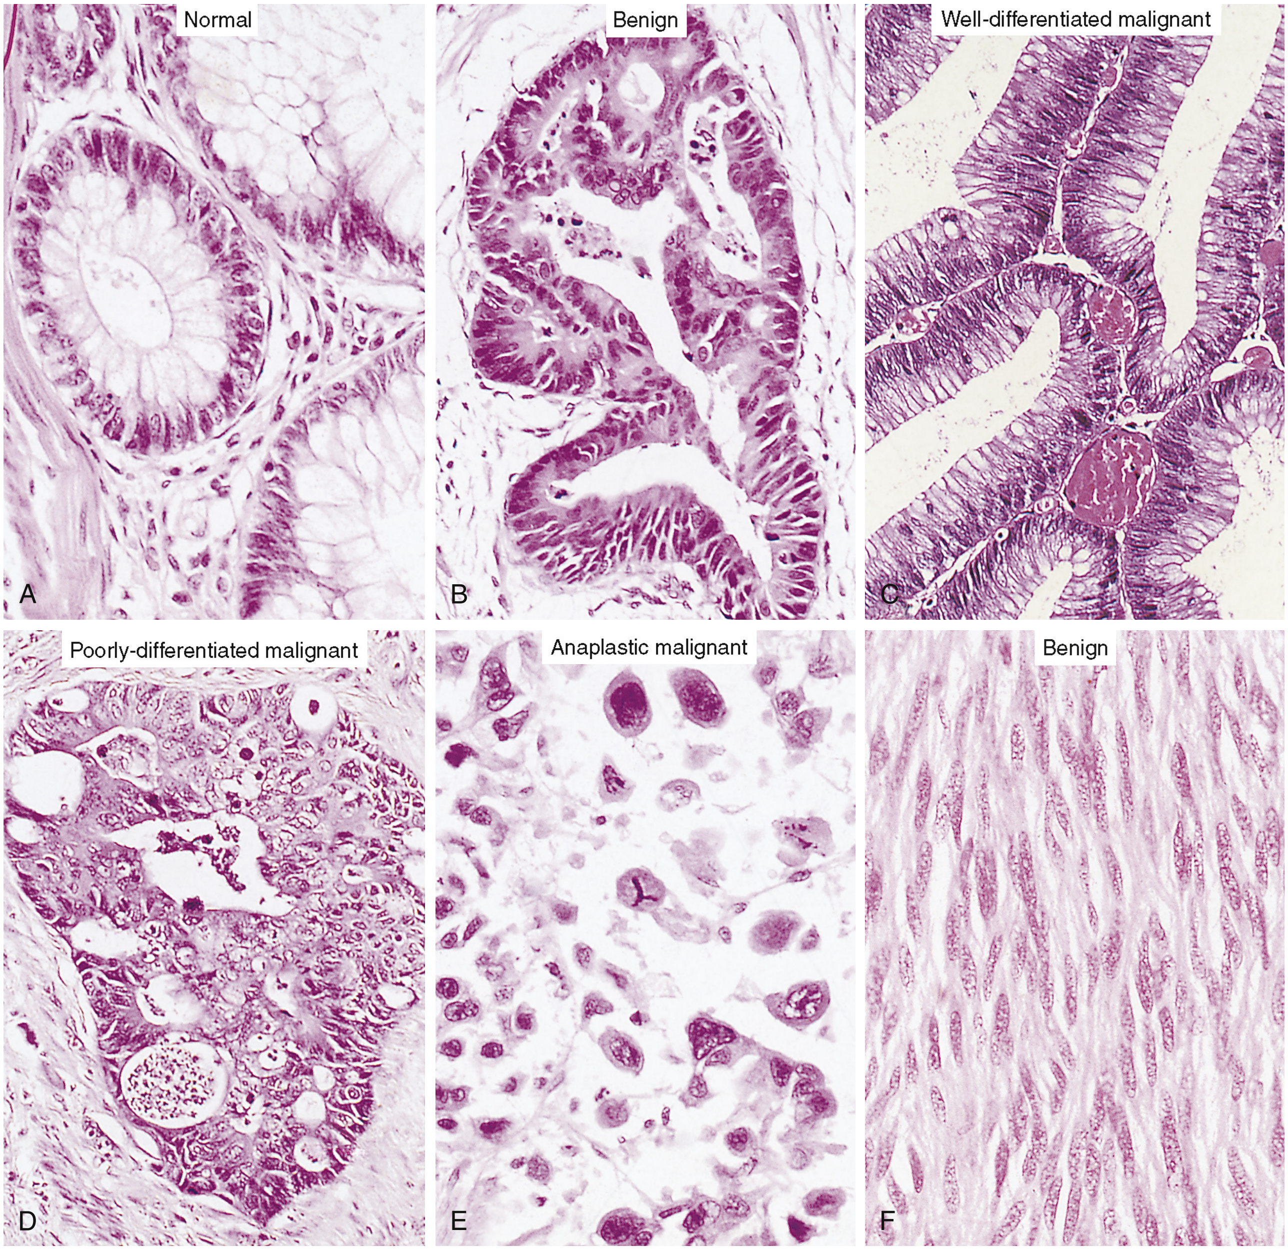

FIGURE 12-2 **Loss of Cellular and Tissue Differentiation During the Development of Cancer.** The cells of a benign neoplasm **(B)** resemble those of the normal colonic epithelium **(A),** in that they are columnar and have an orderly arrangement. Loss of some degree of differentiation is evident in that the neoplastic cells do not show much mucin vacuolization. Cells of the well-differentiated malignant neoplasm **(C)** of the colon have a haphazard arrangement and although gland lumina are formed, they are architecturally abnormal and irregular. Nuclei vary in shape and size, especially when compared with those in **A.** Cells in the poorly differentiated malignant neoplasm **(D)** have an even more haphazard arrangement, with very poor formation of gland lumina. Nuclei show greater variation in shape and size compared with the well-differentiated malignant neoplasm in **C.** Cells in anaplastic malignant neoplasms **(E)** bear no relation to the normal epithelium, with no recognizable gland formation. Tremendous variation is found in the size of cells and their nuclei, with very intense staining (hyperchromatic nuclei). Not knowing the site of origin would make it impossible to classify this tumor by microscopic appearance alone. Well-differentiated tumors often resemble their cell of origin, as shown in the example of a benign tumor of smooth muscles **(F).** (From Stevens A, Lowe J: *Pathology,* ed 2, London, 2000, Mosby.)

pressure, diaphoresis (i.e., sweating), and tremors. Detection of elevated blood or urine levels of catecholamines helps to confirm the diagnosis, and treatment of the disease relieves the symptoms. Tumor markers can be used in three ways: (1) to screen and identify individuals at high risk for cancer; (2) to help diagnose the specific type of tumor in individuals with clinical manifestations relating to their tumor, as in adrenal tumors or enlarged liver or prostate; and (3) to follow the clinical course of a tumor. For example, a falling PSA level after radiation or surgical therapy for prostate cancer indicates successful treatment, and a later rise in the PSA level may indicate a recurrence.

TABLE 12-2 **NOMENCLATURE AND CLASSIFICATION OF BENIGN AND MALIGNANT TUMORS***

CELL OR TISSUE OF ORIGIN	BENIGN TUMOR	MALIGNANT TUMOR
Tumors of Epithelial Origin		
Squamous cells	Squamous cell papilloma	Squamous cell carcinoma
Basal cells	—	Basal cell carcinoma
Glandular or ductal epithelium	Adenoma	Adenocarcinoma
	Cystadenoma	Cystadenocarcinoma
Transitional cells	Transitional cell papilloma	Transitional cell carcinoma
Bile duct	Bile duct adenoma	Bile duct carcinoma (cholangiocarcinoma)
Liver cells	Hepatocellular adenoma	Hepatocellular carcinoma
Melanocytes	Nevus	Malignant melanoma
Renal epithelium	Renal tubular adenoma	Renal cell carcinoma
Skin adnexal glands		
Sweat glands	Sweat gland adenoma	Sweat gland carcinoma
Sebaceous glands	Sebaceous gland adenoma	Sebaceous gland carcinoma
Germ cells (testis and ovary)	—	Seminoma (dysgerminoma)
		Embryonal carcinoma, yolk sac carcinoma
Tumors of Mesenchymal Origin		
Hematopoietic/lymphoid tissue		
Leukocytes		Leukemias
Granular leukocytes and precursors		Granulocytic leukemia
		Myelocytic leukemias
		Myelogenous leukemias
Plasma cells		Multiple myeloma
Lymphoid		
Nongranular leukocytes and prelymphocytes		Lymphomas
Proliferating lymphocytes and monocytes		Lymphocytic leukemia
Proliferating immature precursor monocytes		Lymphoblastic leukemia
Solid tumors of lymph tissue (thymus, spleen, lymph nodes)		Lymphoma or lymphosarcoma
Neural and retinal tissue		
Nerve sheath	Neurilemoma, neurofibroma	Malignant peripheral nerve sheath tumor
Nerve cells	Ganglioneuroma	Neuroblastoma
Retinal cells (cones)	—	Retinoblastoma
Connective tissue		
Fibrous tissue	Fibromatosis (desmoid)	Fibrosarcoma
Fat	Lipoma	Liposarcoma
Bone	Osteoma	Osteogenic sarcoma
Cartilage	Chondroma	Chrondrosarcoma
Muscle		
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Endothelial and related tissues		
Blood vessels	Hemangioma	Angiosarcoma
		Kaposi sarcoma
Lymph vessels	Lymphangioma	Lymphangiosarcoma
Synovium	—	Synovial sarcoma
Mesothelium	—	Malignant mesothelioma
Meninges	Meningioma	Malignant meningioma
Tumors of Uncertain Origin	—	Ewing tumor

Modified from Murphy GP et al: *American Cancer Society's textbook of clinical oncology,* ed 2, New York, 1995, American Cancer Society.

***Note:** This list is intended to provide only an introduction to tumor nomenclature.

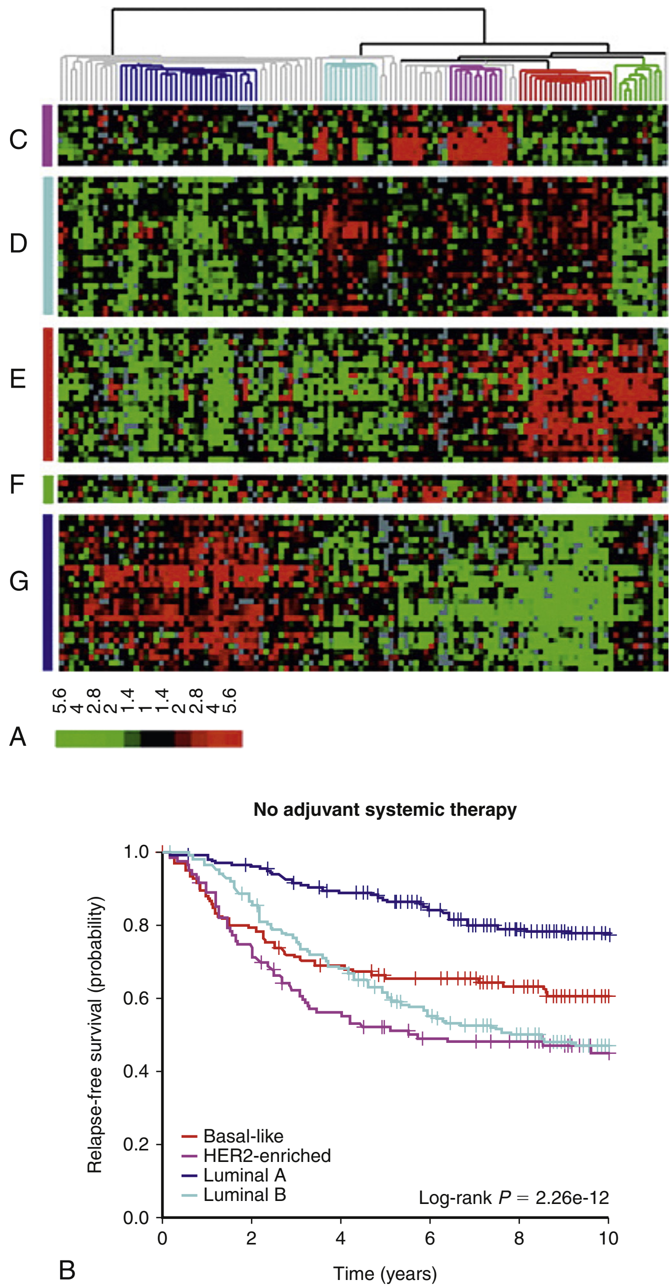

FIGURE 12-3 Molecular Markers Aid in Cancer Classification and Treatment Choices. **A,** Cancers can be classified based on gene expression patterns. In this breast cancer study, gene expression was measured in tumors from 115 patients. Each row is a different gene, and each column is a different patient sample. Red denotes high gene expression; green signifies low gene expression. Using this molecular subtyping method, breast cancer can be subdivided into at least four molecular subtypes—luminal A, luminal B, HER2, and basal. The group on the far right is normal breast tissue. **B,** Molecular classification predicts overall survival. In this group of women, breast cancer molecular subtypes were determined by gene expression profiles in a group of women with similar stage tumors, as in **(A)**. The molecular subtype is a good predictor of response to chemotherapy and survival. This molecular subtyping method can help select the best therapy for women. (**A** from Sorlie T et al: *Proc Natl Acad Sci U S A* 100[14]:8418–8423, 2003; **B** from Parker JS et al: *J Clin Oncol* 27[8]:1160–1167, 2009.)

There are several significant problems in using tumor marker assays to screen populations of healthy individuals for cancer. Testing large populations will always detect a few normal individuals with test results at the high end of the normal distribution (the "false positives"), which can lead to expensive and invasive additional tests, and unnecessary concern. Similarly, some individuals with disease will have test results in the normal range ("false negatives"). Furthermore, some nonmalignant conditions also can produce tumor markers. The presence of an elevated tumor marker therefore may suggest a specific diagnosis, but it is not used alone as a definitive diagnostic test. Identification of ideal sensitive and specific tumor markers that are elevated early in the course of common cancers remains a high priority because the early detection of cancer often improves the treatment outcome.

The Biology of Cancer Cells

Transformation and Differentiation

Cancer cells behave differently than normal cells in several important ways. **Transformation** refers to the process by which a normal cell becomes a cancer cell. **Autonomy** refers to the cancer cell's independence from normal cellular controls and is part of the transformational process. These differences are most readily seen in specialized laboratory assays, especially those examining the growth patterns of normal and cancerous cells in laboratory incubators. Transformed cells lack many of the normal "social controls" seen in nontransformed cells. They often have markedly decreased requirements for external growth factors. Normal cells cease to divide when they fill a petri (or tissue culture) dish. Transformed cells, unlike normal cells, lack **contact inhibition** and continue to crowd, eventually piling up on each other (Figure 12-4). Normal cells usually will not grow unless they are attached to a firm surface (like a petri dish). However, cancer cells are often **anchorage independent;** that is, they continue to divide even when suspended in a soft agar gel. Normal cells have a limited life span in the laboratory; they may divide in a petri dish 10 or 50 times, but then they cease growing. Cancer cells usually are **immortal** in that they seem to have an unlimited life span and will continue to divide for years under appropriate laboratory conditions. One of the most commonly used laboratory cell lines, HeLa cells, was derived from a cervical cancer specimen obtained in 1951 that continues to grow and divide in laboratories around the world.[3] Cancerous cells can be assayed in mice as well; when normal human cells are injected into a special type of mouse (genetically engineered to lack an immune system to prevent rejection of human cells) they will not grow. However, cancerous cells from humans can continue to grow and even metastasize in these mice.

Cancer cells often show defects in the normal process of differentiation; that is, the process of acquiring a specialized function and organization, such as evolving into a muscle cell (see Chapter 43) or a nerve cell (see Chapter 15). **Anaplasia** is the absence of differentiation (see Figure 12-2) and means literally "without form." In clinical specimens, *anaplasia* is recognized by a loss of organization and a marked increase in nuclear size with evidence of ongoing proliferation. In

TABLE 12-3 **EXAMPLES OF TUMOR MARKERS**

MARKER NAME	NATURE	TYPE OF CANCER
Alpha fetoprotein (AFP)	70-kDa protein	Hepatic, germ cell
Carcinoembryonic antigen (CEA)	200-kDa glycoprotein	GI, pancreas, lung, breast, etc.
β-Human chorionic gonadotropin (β-hCG)	Glycopeptide hormone β-chain	Germ cell
Prostate-specific antigen (PSA)	33-kDa glycoprotein	Prostate
Catecholamines	Epinephrine and precursors	Pheochromocytoma (adrenal medulla)
Homovanillic acid/vanillylmandelic acid (HVA/VMA)	Catecholamine metabolites	Neuroblastoma
Urinary Bence Jones protein	Ig light chain	Multiple myeloma
Adrenocorticotropic hormone (ACTH)	Peptide hormone	Pituitary adenomas

GI, Gastrointestinal; *Ig,* immunoglobulin; *kDa,* kilodalton.

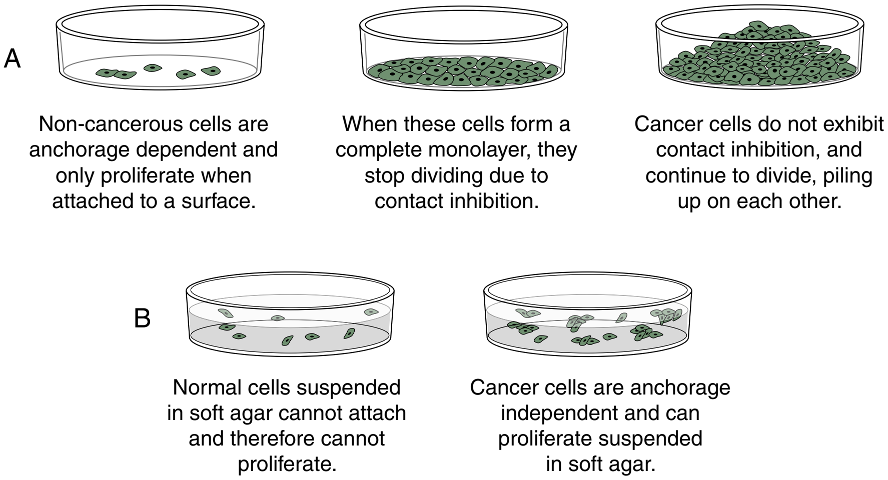

FIGURE 12-4 **Cancerous Cells Show Abnormal Growth in the Laboratory.** Cancer cells, unlike most normal cells **(A),** usually continue to grow and pile on top of one another after they have formed a confluent monolayer in culture (loss of contact inhibition) and **(B)** can grow without being attached to a surface, called anchorage independence.

contrast to normal cells, which are uniform in size and shape, *anaplastic* cells are of variable size and shape, or **pleomorphic.** For example, a benign muscle tumor (benign myoma) will retain the ability to make muscle, whereas in a malignant muscle tumor (rhabdomyosarcoma), new muscle formation is seen only rarely, and even then appears highly disorganized. Thus the muscle cancer cells appear undifferentiated. The most malignant tumors tend to have the most *anaplasia* and be the least differentiated.

Cancer Metabolism

Cancer cells live in a distinct milieu from normal cells and have different nutritional requirements from nonproliferating cells. The successful cancer cell divides rapidly, with the consequent requirement for the building blocks of new cells. Cancers often must grow in a hypoxic and acidic environment. Cancers also are parasites, able to selectively extract nutrients from the bloodstream without any evolutionary pressure for balanced metabolism. Nonmalignant cells in the presence of adequate oxygen normally generate adenosine triphosphate (ATP) by mitochondrial oxidative phosphorylation (OXPHOS), generating 36 ATP molecules from each glucose molecule that is broken down to water and carbon dioxide. Only in the absence of sufficient oxygen do normal cells perform anaerobic glycolysis, generating only two ATP molecules per molecule of glucose, with lactic acid as a byproduct. However, even in the presence of oxygen, cancer cells perform glycolysis, not OXPHOS[4] (Figure 12-5). Although this aerobic glycolysis was originally postulated as some form of cancer-specific mitochondrial dysfunction, it is now apparent that this is instead a highly regulated and beneficial adaptation for cancer cells. This shift from OXPHOS to glycolysis allows lactate and its metabolites to be used for the more efficient production of lipids and other molecular building blocks needed for rapid cell growth. Furthermore, many cancer genes promote this switch to aerobic glycolysis. Alterations in a number of cancer genes, including receptor tyrosine kinases, *AKT*, *PTEN*, *TP53*, and *MYC*, inhibit OXPHOS and promote the activity of glycolytic and related metabolic pathways that support the rapid growth of cancers.[4,5]

Clinically the high glucose utilization of a cancer can be exploited for its detection. ^{18}F-Fluorodeoxyglucose (FDG) is incorporated into cells in the same way as glucose, with two key differences. Because it is missing a key hydroxyl group it cannot be broken down by glycolysis and, thus, FDG accumulates in cells. Because it is tagged with ^{18}F, it can be imaged by positron emission tomography (a PET scan). Small metastatic tumor masses that are consuming huge amounts of glucose can readily be detected with this imaging method (Figure 12-6).

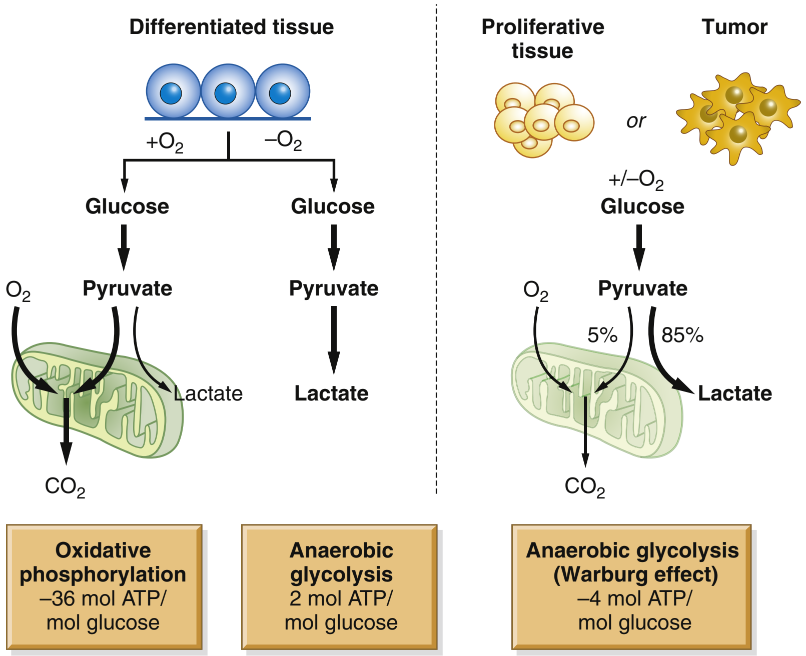

FIGURE 12-5 Cancers Have Altered Metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to turn glucose into CO_2 and energy (in the form of ATP). Cancers take a different approach; even in the presence of oxygen, they do not use OXPHOS. Instead, they consume large quantities of glucose to make cellular building blocks, supporting rapid proliferation. *ATP,* Adenosine triphosphate. (From Van der Heiden MG, Cantley LC, Thompson CB: *Science* 324:1029–1033, 2009.)

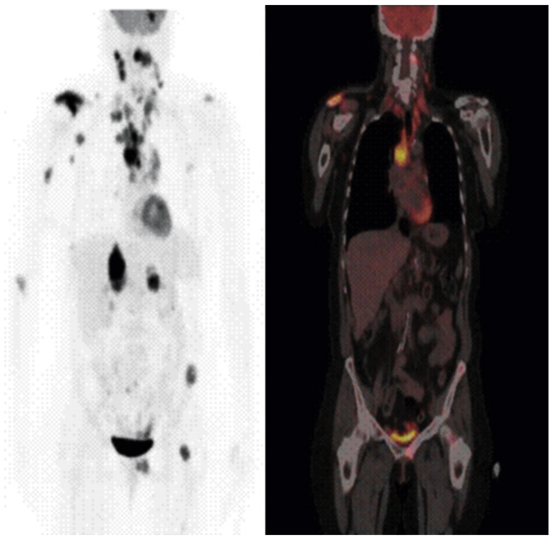

FIGURE 12-6 Intense Glucose Requirement Aids in Diagnosis of Metastatic Non–Small Cell Lung Cancer. This 54-year-old woman had a non–small cell lung cancer (NSCLC) resected from the left upper lobe. Five years later, these studies were obtained. The positron emission tomography (PET) scan using 18-fluorodeoxyglucose (FDG) shows metastatic lesions in the brain, right shoulder, and mediastinal and cervical lymph nodes, as well as in the liver, left pelvis, and proximal femur. *PET whole-body image (left):* Representative coronal image from the whole-body FDG-PET/CT–fused image of the same patient *(right).* The fused image consists of the computed tomography (CT) image with the metabolic information superimposed in color. The pattern of spread is most likely from the primary tumor to the large mediastinal lymph nodes, followed by lymphatic spread to cervical nodes. Blood-borne dissemination produced the bone, brain, and liver metastases. Normally, only the heart, brain, and bladder show a strong signal in PET scans. (Images courtesy John Hoffman, MD, Huntsman Cancer Institute, Salt Lake City, UT.)

Cancer Stem Cells

Many tissues, most notably the skin, intestines, and blood-forming cells, continuously renew themselves. The human gut sheds and replaces hundreds of grams of cells each day. This ongoing proliferation of these tissues with a high turnover rate depends on their regeneration from a small fraction of cells known as **adult stem cells.** Adult stem cells have two essential characteristics: first, they self-renew (that is, some fraction of the cell divisions creates new stem cells); and second, they are **multipotent,** or have the ability to differentiate into multiple different cell types. In the bone marrow, it is estimated that only 0.05% (1 in 20,000) of the blood-forming cells are stem cells, yet this small pool of stem cells can be stimulated to divide and to repopulate all the mature bone marrow–derived cells in approximately 2 weeks after bone marrow transplantation. As few as 10 stem cells are sufficient to entirely repopulate the entire bone marrow of a mouse in bone marrow transplantation experiments. Similarly, the absorptive and goblet cells lining the intestine have a life span of less than 1 week, after which they undergo cell death, or apoptosis, and slough into the intestinal lumen. They too must be replenished by ongoing proliferation of intestinal stem cells. A key feature of stem cells is that they can divide asymmetrically (i.e., during division, the cytoplasmic contents are unevenly distributed between the daughter cells); they can give rise to another stem cell and one daughter cell that ultimately terminally differentiates into diverse cell types, depending on the needs of the tissue (Figure 12-7). Multipotent bone marrow stem cells can self-renew and differentiate into all types of bone marrow–derived cells, such as red cells, lymphocytes, and neutrophils. Certain adult stem cells have a broader range of potential fates. For example, mesenchymal stem cells

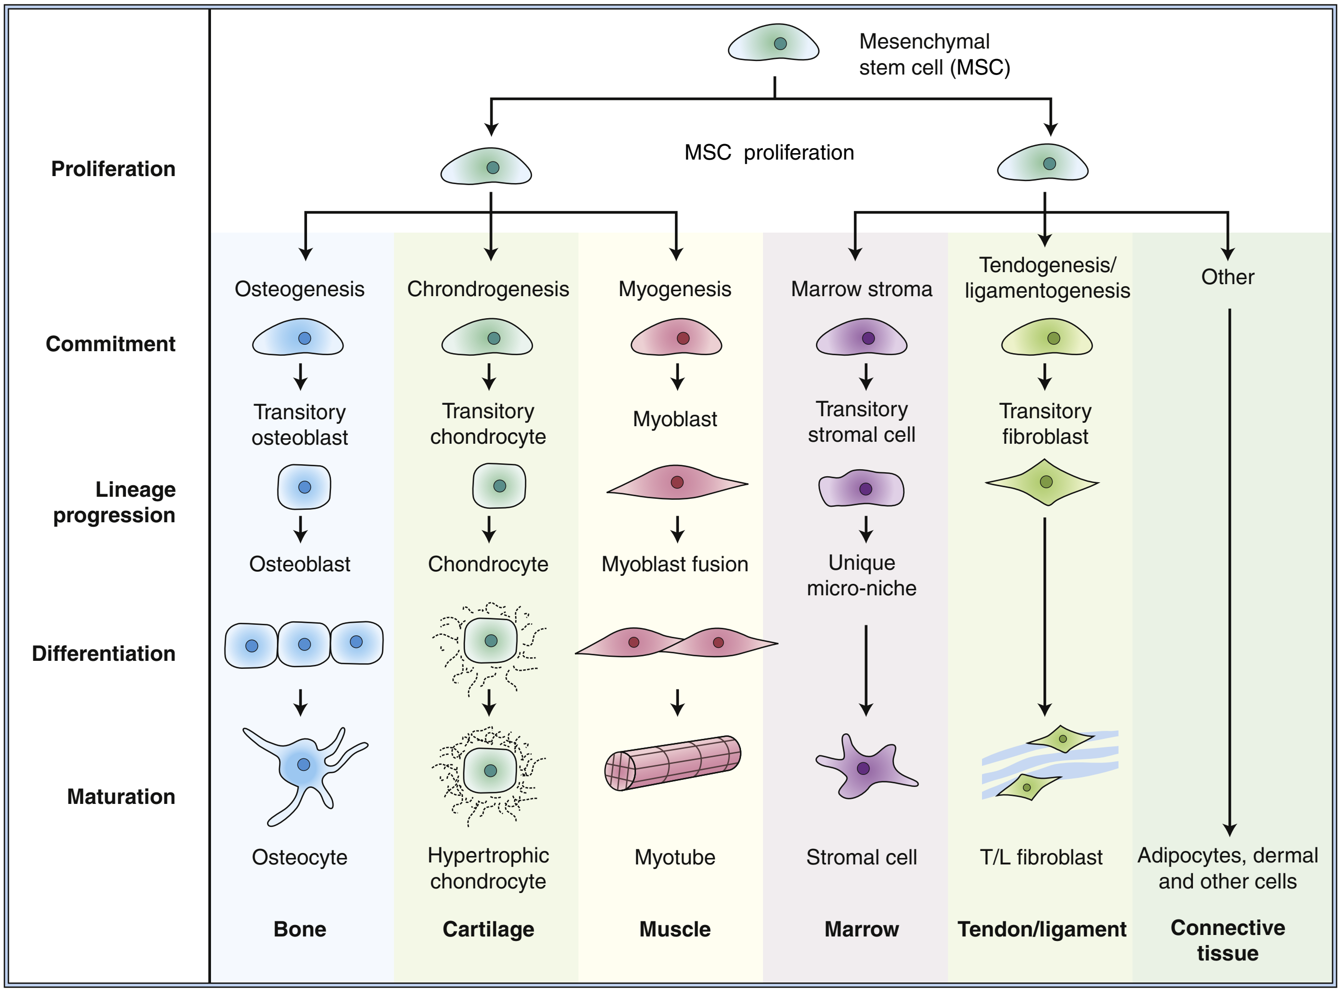

FIGURE 12-7 Postulated Multiple Lineage–Specific Differentiation of Mesenchymal Stem Cells. Differentiation occurs progressively as the offspring of stem cells commit to various lineages. Mesenchymal stem cells can renew themselves and give rise to multiple tissue types. (Modified from Caplan A, Bruder S: *Trends Mol Med* 7[6]:259–264, 2001.)

are able to differentiate into multiple types of cells, such as blood vessels, neurons, and muscle cells. Theoretically, such a stem cell might be able to give rise to all cell types in the body, and as such, could be useful in regeneration of diseased tissues.

Many cancers, like normal tissues, are heterogeneous, with differences in cell shape, size, behavior, and protein expression. There are two models to explain this heterogeneity within tumors. In the clonal evolution model, all the cancer cells divide regularly, and heterogeneity arises from proliferation, mutation, epigenetic changes, differences in local environment, and natural differentiation of cells. In this model, most of these cells are still robust cancer cells, capable of forming complex tumors in experimental animals. In contrast, in the cancer stem cell model, heterogeneity arises because there is a rare cancer stem cell whose offspring do not have stem cell properties, but undergo a limited number of divisions while generating heterogeneity through epigenetic and environmental alterations. However, similar to the adult tissue stem cells, only the cancer stem cell, if transplanted, is postulated to be capable of forming complex and heterogeneous tumors. The typical cancer stem cell experiment separates cancer cells into different pools depending on some measurable characteristic such as cell surface proteins, and then assays how many cells must be injected into an experimental mouse to form a cancer. In some cases, these tumor-initiating cells are very rare, with only 1 in 10,000 human colon cancer cells able to re-form a complex and heterogeneous colon cancer in mice (Figure 12-8).[6] However, these tumor-initiating cells are not always rare; in human melanomas, one in four cells can initiate a complex tumor in the appropriate mouse model.[7] This is an experimentally difficult area of research, because human cancers are examined in mice where there are multiple barriers to transplantation, including immune responses, as well as species differences in the various growth factors, cytokines, and microenvironment that can all influence the results. Therefore most progress is likely to be made by studying cancer stem cells arising in mouse tumors rather than human tumors.

Enthusiasm for the cancer stem cell model arises, in part, from its therapeutic potential. Most of the drugs now used in treating cancer can kill a large fraction of cancer cells but may not touch the cancer stem cell. If less than 1 in 100,000 cells in a cancer is responsible for perpetuating a cancer, then perhaps we

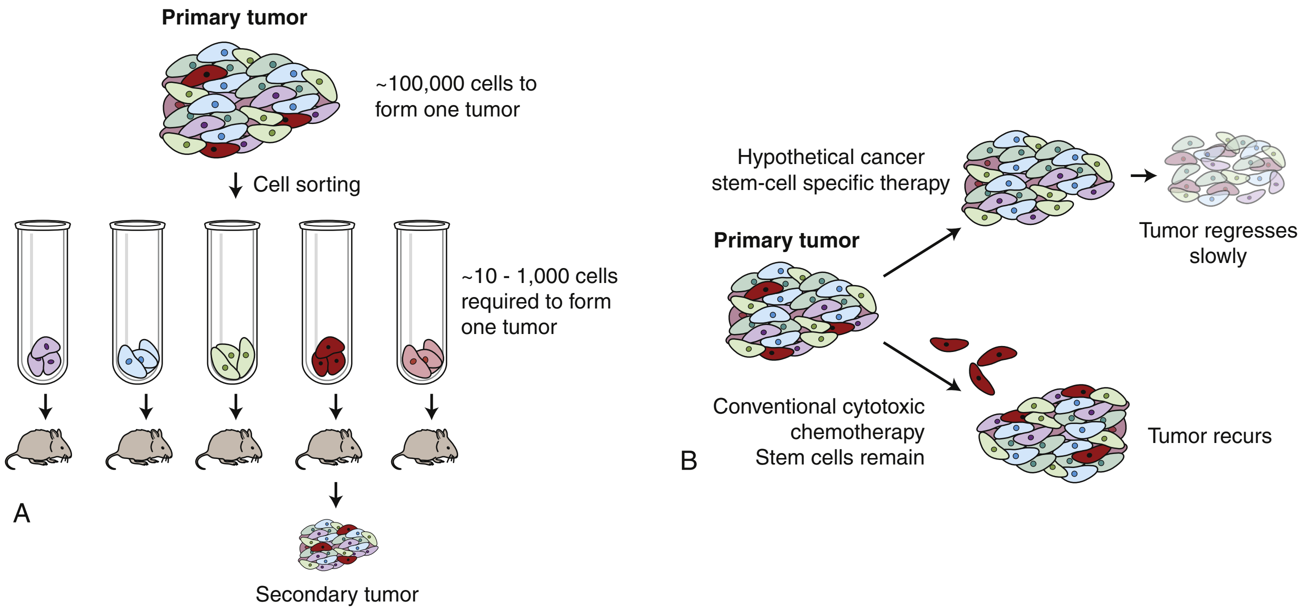

FIGURE 12-8 **Concept of Cancer Stem Cells. A,** Only rare cells within a cancer can initiate cancer regrowth. In laboratory experiments it takes as many as 100,000 breast cancer cells injected into a mouse mammary fat pad to form a new cancer. If the breast cancer cells are sorted, one rare subtype *(shown here in red)* is much more proficient at forming new cancers. **B,** Conventional chemotherapy can destroy the bulk of a cancer. However, if the cancer stem cells *(red cells)* are not destroyed, the cancer may regrow. If therapies can be devised that kill the cancer stem cells, then durable long-term responses may be achieved.

should be looking for drugs that target those rare cells instead of using more toxic drugs that initially shrink tumors but do not kill the cancer stem cells.

THE GENETIC BASIS OF CANCER

Cancer-Causing Mutations in Genes

Before the advent of modern molecular biology, many different causes of cancer were postulated, based on epidemiologic studies as well as investigations of specific carcinogens and viruses. We now understand that changes in the genes of the cancer cell cause the cell to become cancerous. As our knowledge of cancer biology continues to increase so too does our understanding of the many ways that heritable changes in cells can contribute to cancer. These changes include deoxyribonucleic acid (DNA) mutations, but also include changes in DNA and histone chemical modification (epigenetic changes), and, most recently recognized, changes in non–coding microribonucleic acid (miRNA) expression (also see Chapters 4, 6, and 13). Although the word *mutation* is used extensively here, it can also refer to heritable changes in gene and non–coding RNA expression (**epigenetics**) that do not involve changes in DNA sequence.

Cancer is predominantly a disease of aging. Perhaps the most revealing epidemiologic data are presented in Figure 12-9. The incidence of most cancer, that is, the fraction of individuals in each age group who develop cancer, increases dramatically with age. The best explanation for these epidemiologic data is that each individual acquires a number of genetic “hits” or mutations over time. When sufficient mutations have occurred, cancer develops. These epidemiologic data are consistent with the

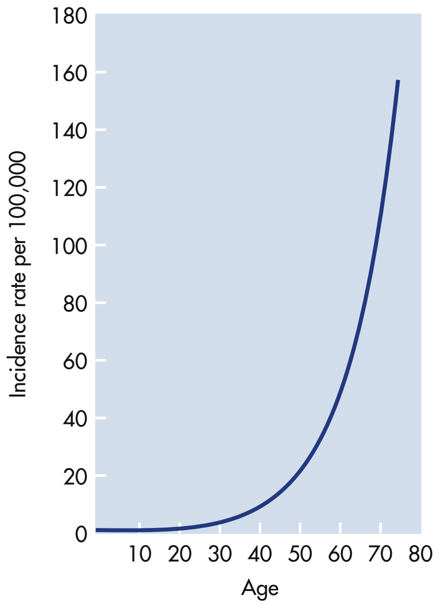

FIGURE 12-9 **Marked Increases in Cancer with Age.** The graph depicts the number of cases of colon cancer diagnosed per 100,000 women in England and Wales in 1 year. The incidence of cancer increases dramatically with advancing age. These data suggest that accumulation of genetic and epigenetic alterations over time increases the risk of developing cancer. The slope of the curve suggests that five to seven mutations must occur before full-blown cancer develops. (Modified from Alberts B et al: *Molecular biology of the cell,* ed 4, New York, 2002, Garland.)

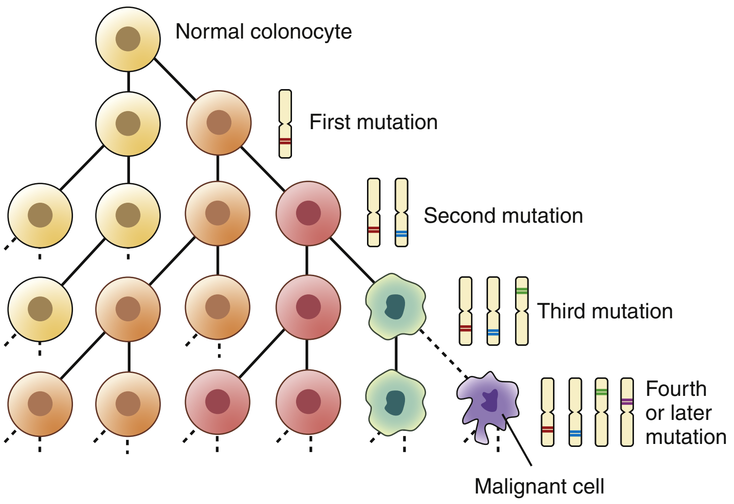

Genetic Event	Cell Behavior
Inactivation of *APC*	Cell seems normal but is predisposed to proliferate excessively
Mutational activation of K-*ras*	Cell begins to proliferate too much but is otherwise normal
Loss of DCC, over-expression of COX-2	Cell proliferates more rapidly; it also undergoes structural changes
Loss of *TP53*, activation of telomerase	Cell grows uncontrollably and looks obviously abnormal

FIGURE 12-10 Clonal Proliferation Model of Neoplastic Progression. During clonal proliferation, progressively altered populations of cells arise over time. As genetic and epigenetic changes occur, different subclones (indicated by different color cells) coexist for a time. Clones that grow the fastest out-compete other clones, producing increasingly more malignant, and abnormal-appearing, growths. The sequential accumulation of mutations has been well studied in the progression from a normal colon cell to a benign intestinal polyp to a malignant colon cancer. One of the earliest mutations in colon cancer is loss of the tumor-suppressor gene *APC.* Additional mutations, often in the oncogene *ras,* activation of COX-2, and loss of the tumor suppressors DCC and *TP53* occur as the lesion progresses from a benign polyp to an invasive carcinoma. *APC,* Adenomatous polyposis coli; *COX-2,* cyclooxygenase-2; *DCC,* deleted in colon cancer. (Modified from Mendelsohn I et al: *The molecular basis of cancer,* ed 2, Philadelphia, 2001, Saunders; Kumar V, Cotran RS, Robbins SL: *Basic pathology,* ed 6, Philadelphia, 1997, Saunders.)

observation of mutations in early and advanced cancers and with data obtained from the study of experimental cancers created in the laboratory—the accumulation of four to seven specific hits over time is required to cause a full-blown cancer.[8]

Clonal Selection

As a cell accumulates specific mutations, it can acquire, step-by-step, the characteristics of a cancer cell, for example, anchorage-independent growth, lack of contact inhibition, and immortality. That mutant cell may then have a selective advantage over its neighbors; its progeny can accumulate faster than its nonmutant neighbors. This is referred to as **clonal proliferation** or **clonal expansion** (Figure 12-10). As a clone with a mutation proliferates, it may become an early stage tumor, for example, a carcinoma in situ or a benign colonic polyp. Additional heritable changes can occur in these early lesions that permit progression to more advanced tumors. The process of tumor development is a form of darwinian evolution; cells with a genetic change that confers a survival advantage out-compete their neighbors. The progressive accumulation of distinct advantageous (from the point of view of the cancer cell, not the individual!) mutations leads from normal cells to fully malignant cancers.

One organ in which this correlation of genetic and clinical progression has been especially well studied is the colon.[9] The colon is accessible to inspection with a colonoscope, and so neoplastic lesions of varying size can readily be detected and removed. Intestinal polyps are benign neoplasms and the first stage in development of colon cancer. Small polyps tend to have only a few detectable mutations. Large polyps have more mutations, whereas frank colon cancers have even more mutations. This type of genetic information provided the framework for the now widely accepted concept that it is the *stepwise accumulation* of alterations in specific genes that is required for the development of cancer (see Figure 12-10).

Oncogenes and Tumor-Suppressor Genes: Accelerators and Brakes

Passengers and Drivers

The previous discussion refers to the heritable changes in cells as being key in the development of cancer. New technologies that provide massive amounts of information about chromosome and gene structure allow us to see multiple alterations in cancer cells. These methods include massively parallel high-throughput DNA sequencing (the process by which the sequence of nucleotides along a strand of DNA is determined), high-density single-nucleotide polymorphism (SNP), and chromosome copy number analysis (CNA). These approaches confirm that there are a small number of very common genetic alterations in cancer and a very large number of alterations that individually are rare.[10] It is clear that some mutations can contribute to cancer progression (e.g., mutations in *p53* or *RAS*). These mutations are **driver mutations;** they drive the progression of cancer. Conversely, not all mutations in cancer contribute to the malignant phenotype. Some are just random events, and are referred to as **passenger mutations;** they are just along for the ride. The increasing amount of cancer genome analysis data poses the following question: how do we determine which mutations are drivers and which are passengers?

What Are the Driver Mutations? To understand how genetic mutations cause cancer, first it is important to distinguish between

oncogenes and tumor-suppressor genes. Table 12-4 compares the two types of cancer genes. **Oncogenes** are mutant genes that in their normal nonmutant state direct synthesis of proteins that positively regulate (accelerate) proliferation. Conversely, **tumor-suppressor genes** encode proteins that in their normal state negatively regulate (halt, or "put the brakes on") proliferation. Hence, they also have been referred to as anti-oncogenes.

TABLE 12-4 COMPARISON OF CANCER GENE TYPES

GENE TYPE	NORMAL FUNCTION	MUTATION EFFECT
Caretaker	DNA and chromosome stability	Chromosome instability and increased rates of mutation
Dominant oncogenes*	Encode proteins that promote growth (e.g., growth factors)	Overexpression or amplification causes gain of function
Tumor suppressors (recessive oncogenes)	Encode proteins that inhibit proliferation and prevent or repair mutations	Requires loss of function of both alleles to increase cancer risk

*Nonmutant state referred to as proto-oncogene.

In its normal, nonmutant state, an oncogene is referred to as a **proto-oncogene.** An example of a proto-oncogene would be a growth factor (e.g., epidermal growth factor) or a growth factor receptor (e.g., epidermal growth factor receptor). Other positive regulators of proliferation are in the signal transduction pathway that transmits the signal from the growth factor receptor to the cell nucleus. Normally, Ras is a proto-oncogene (Figure 12-11).

Oncogene Addiction. There are a number of common driver mutations in cancer. Cancers that arise because of these mutations often depend on these mutant genes and proteins for their continued growth and survival. If the mutations and abnormal proteins can be returned to their normal states, the cancers often stop growing and even regress. The cancers are addicted to their mutant cancer genes, a concept known as **oncogene addiction.** This also provides a key example of how targeted cancer therapy can work—for example, if the oncogene is a protein kinase (e.g., BCR-ABL, EGFR, HER2, or BRAF) that can be inhibited by a drug, then the cancer can be deprived of the function of the oncogene. Treating the addiction treats the cancer.[11]

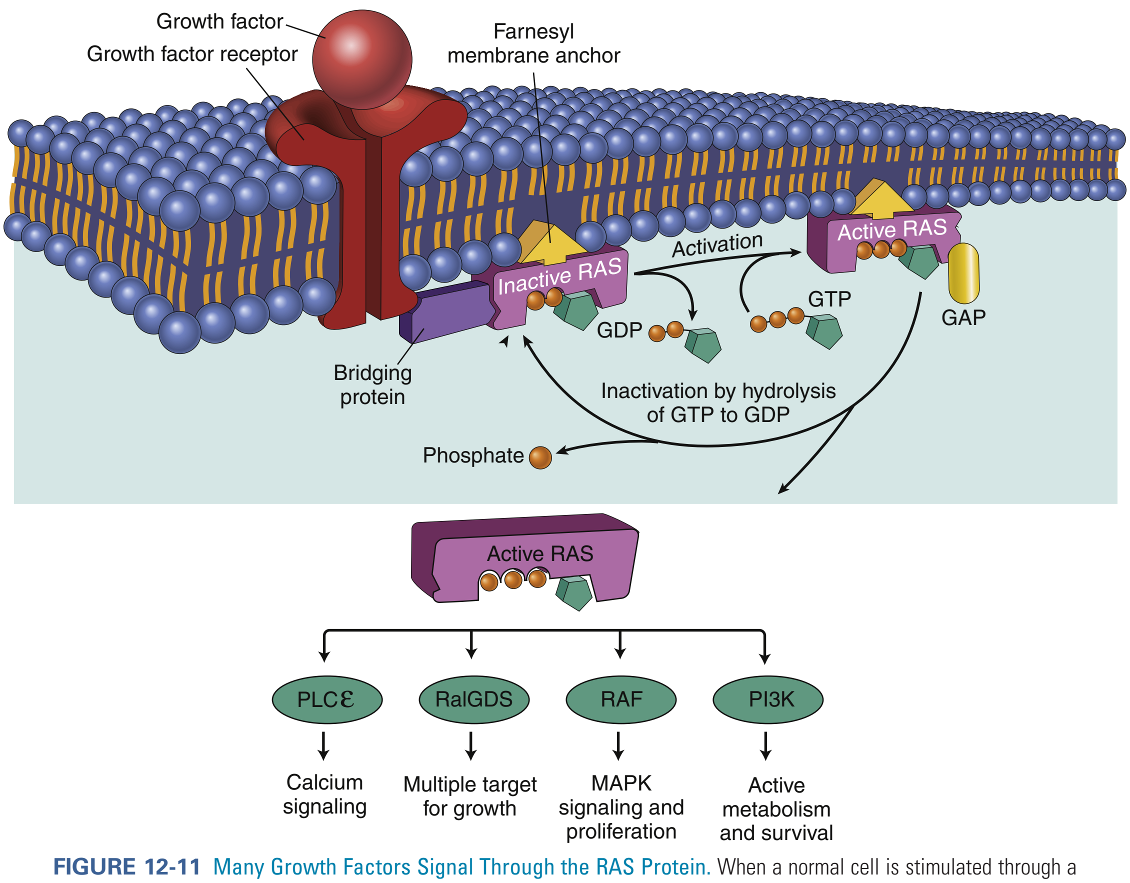

FIGURE 12-11 Many Growth Factors Signal Through the RAS Protein. When a normal cell is stimulated through a growth factor binding to its receptor, inactive RAS exchanges GDP for GTP, becoming active. Active (GTP-bound) RAS sends growth signals throughout the cell by interacting with a number of signaling proteins, including RalGDS, RAF, PLCε, and PI3K. RAS is normally inactivated when it hydrolyzes GTP to GDP. Oncogenic Ras has a mutation that blocks hydrolysis of GTP, thereby locking RAS in the active configuration. *GDP,* Guanosine diphosphate; *GAP,* guanosine triphosphate-activating protein; *GTP,* guanosine triphosphate; *MAPK,* mitogen-activated protein kinase; *PI3K,* phosphoinositide 3-kinase; *PLCε,* phospholipase C-epsilon; *RAF,* serine/threonine-specific protein kinase; *RalGDS,* Ral guanine nucleotide dissociation stimulator; *Ras*, RAS protein. (Adapted from Kumar V, Abbas AK, Aster J: *Robbins basic pathology,* ed 9, Philadelphia, 2013, Saunders.)

Gene Changes That Occur in Cancer

The activation and inactivation of various genes is key in the development of cancer. The following three types of DNA changes occur in cancer: small DNA changes, large DNA changes, and epigenetic changes.

Mutation of Normal Genes into Oncogenes

Point Mutations. Several types of genetic events can activate oncogenes (Box 12-1 and Figure 12-12). Perhaps the most common events are small-scale changes in DNA such as **point mutations,** the alteration of one or a few nucleotide base pairs (see Chapter 4). This type of mutation can have profound effects on the activity of proteins. A point mutation in the *ras* gene converts it from a regulated proto-oncogene to an unregulated oncogene, an accelerator of cellular proliferation. Activating point mutations in *ras* are found in many cancers, especially pancreatic and colorectal cancer.[12] Specialized tests, such as direct DNA sequencing, can detect such point mutations in clinical samples.

BOX 12-1 TYPES OF GENETIC LESIONS IN CANCER

1. Point mutations
2. Subtle alterations (insertions, deletions)
3. Chromosome changes (aneuploidy and loss of heterozygosity)
4. Amplifications
5. Gene silencing (DNA methylation, histone modification, microRNAs)
6. Exogenous sequences (tumor viruses)

Chromosome Translocations and Copy Number Variation. **Chromosome translocations** are large changes in chromosome structure in which a piece of one chromosome is translocated to another chromosome. Translocations can activate oncogenes in one of two distinct mechanisms. First, a translocation can cause excess and inappropriate production of a proliferation factor. One of the best examples is the t(8;14) translocation found in many Burkitt lymphomas;[13] t(8;14) designates a chromosome that has a piece of chromosome 8 fused to a piece of chromosome 14 (see Chapter 29). Burkitt lymphoma is an aggressive cancer of B lymphocytes. The *myc* proto-oncogene found on chromosome 8 is normally activated at low levels in proliferating lymphocytes and is deactivated in mature lymphocytes. The **MYC protein** is part of the positive signal for cell proliferation. If accidental formation of the t(8;14) translocation occurs, the *myc* gene is aberrantly placed under the control of a B-cell immunoglobulin gene *(Ig)* present on chromosome 14. The *Ig* gene is very active in maturing B lymphocytes. The t(8;14) translocation alters the control of *myc;* its normal low level is switched to high levels, as directed by an *Ig* gene promoter. MYC protein, when inappropriately high, drives proliferation and blocks

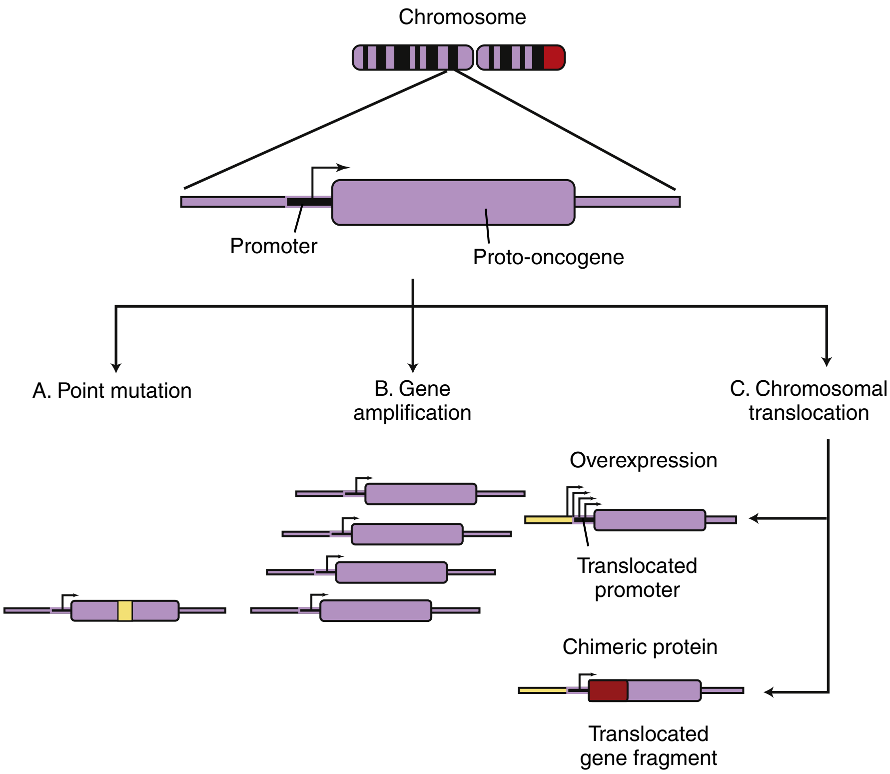

FIGURE 12-12 Oncogene Activation Mechanisms. Cellular genes may become cancerous oncogenes as a result of **(A)** point mutations that alter one or a few nucleotide base pairs, causing the production of a protein that is activated as a result of the altered sequence (e.g., *ras*); **(B)** amplification of the cellular gene, resulting in higher levels of protein expression (e.g., *N-myc* in neuroblastoma); or **(C)** chromosomal translocations that either lead to the juxtaposition of a strong promoter, causing increased protein expression (*c-myc* in Burkitt lymphoma), or produce a novel fusion protein that is derived from gene fragments normally present on different chromosomes (*Bcr-Abl* in chronic myeloid leukemia). (From Haber DA: *Molecular genetics of cancer.* In *ACP medicine,* Danbury, CT, 2004, WebMD.)

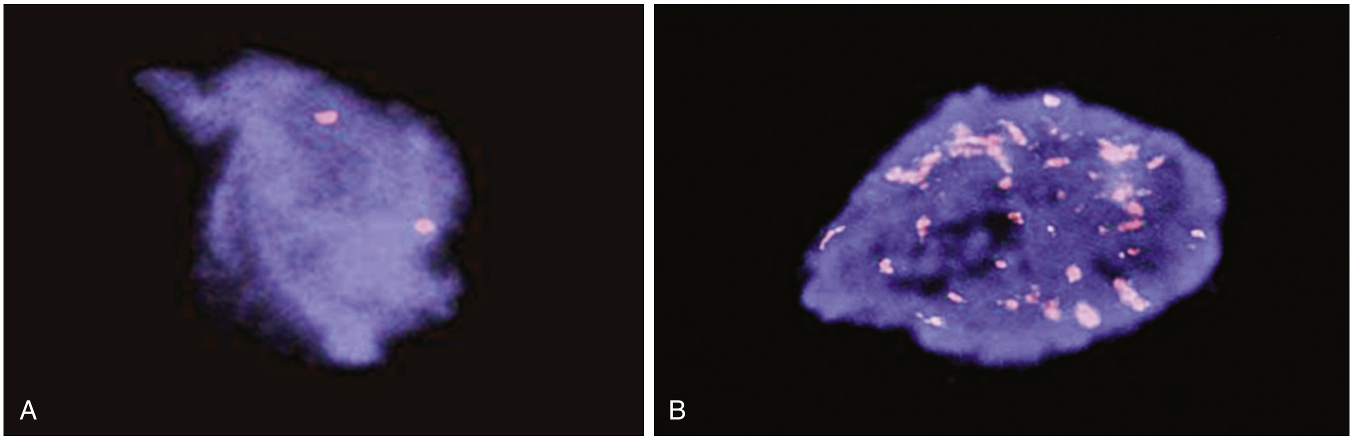

FIGURE 12-13 ***N-myc*** **Gene Amplification in Neuroblastoma.** The *N-myc* gene is detected in human neuroblastoma cells using a technique called FISH (fluorescent in situ hybridization). **A,** A single pair of *N-myc* genes are detected in normal cells and in low-grade neuroblastoma. **B,** Multiple, amplified copies of the *N-myc* gene are detected in some cases of neuroblastoma. Amplification of the *N-myc* gene is strongly associated with a poor prognosis in childhood neuroblastoma. (Courtesy Arthur R. Brothman, PhD, FACMG, University of Utah School of Medicine, Salt Lake City, UT.)

differentiation. Hence, the t(8;14) translocation causes cancer of maturing B cells (see Figure 12-12, *C).*

Second, chromosome translocations also can lead to production of novel proteins with growth-promoting properties. In a different type of leukemia, chronic myeloid leukemia (CML), a specific chromosome translocation is almost always present. This translocation, t(9;22), was first identified in association with CML in Philadelphia in 1960 and so is often referred to as the Philadelphia chromosome.[14] This translocation fuses two chromosomes in the middle of two different genes, *bcr* on chromosome 9 and *abl* on chromosome 22. The result is production of a BCR-ABL fusion protein containing the first half of BCR and the second half of ABL. BCR-ABL is a misregulated protein tyrosine kinase that promotes growth of myeloid cells. Imatinib, a drug that specifically targets this tyrosine kinase, represents the first successful chemotherapy targeted against the product of a specific oncogenic mutation. Imatinib and related tyrosine kinase inhibitors (TKIs) are highly effective in the treatment of CML and, because of their specificity, lack the toxic side effects noted with nonspecific anticancer drugs.[15] However, imatinib is not effective in cancers that do not have the t(9;22) translocation or related mutations. In modern personalized cancer therapy, knowledge of the specific genetic alteration can dictate the optimal drugs for the individual.

Just as single nucleotides can be gained or lost, larger regions of DNA encompassing entire genes can be gained or lost, a phenomenon known as **copy number variation (CNV).**[16] CNV can be inherited and accounts for a significant fraction of human genetic diversity. CNV also can occur in the course of cancer development, where it can amplify oncogenes or delete tumor-suppressor genes.

Gene Amplification. Another type of genetic abnormality that can activate oncogenes is **gene amplification** (see Figures 12-12, *B*, and 12-13). Amplifications are the result of duplication of a small piece of a chromosome over and over again, so that instead of the normal two copies of a gene, tens or even hundreds of copies are present (see Chapter 4). Gene amplification results in increased expression of an oncogene, or in some cases, drug resistance genes. The *N-myc* oncogene is amplified in 25% of childhood neuroblastoma cases and confers a poor prognosis.[17] The epidermal growth factor receptor *erbB2* is amplified in 20% of breast cancers.[18] Individuals whose cancers have *erbB2* amplification respond well to drugs specifically targeted to this oncogene.[19]

TABLE 12-5 SOME FAMILIAL CANCER SYNDROMES CAUSED BY LOSS OF TUMOR-SUPPRESSOR GENE FUNCTION

SYNDROME	GENE
Retinoblastoma	*RB1*
Li-Fraumeni syndrome	*p53 (TP53)*
Familial melanoma	*p16*^{INK4a} (CDKN2A)
Neurofibromatosis	*Neurofibromin (NF1)*
Familial adenomatous polyps	*APC*
Breast cancer	*BRCA1*

Tumor-Suppressor Genes

Tumor-suppressor genes are genes whose major function is to negatively regulate cell growth and prevent mutations. Tumor suppressors may normally slow the cell cycle, inhibit proliferation resulting from growth signals, or stop cell division when cells are damaged. Examples of several tumor suppressors are given in Table 12-5. One of the first discovered tumor-suppressor genes, the **retinoblastoma *(Rb)* gene,** normally strongly inhibits the cell division cycle (see Chapter 1). When it is inactivated, the cell division cycle can proceed unchecked. *Rb* is mutated in childhood retinoblastoma, and in many lung, breast, and bone cancers as well.

Whereas oncogenes are activated in cancers, tumor suppressors must be inactivated to allow cancer to occur (see Table 12-5 and Figure 12-14). A single genetic event can activate an

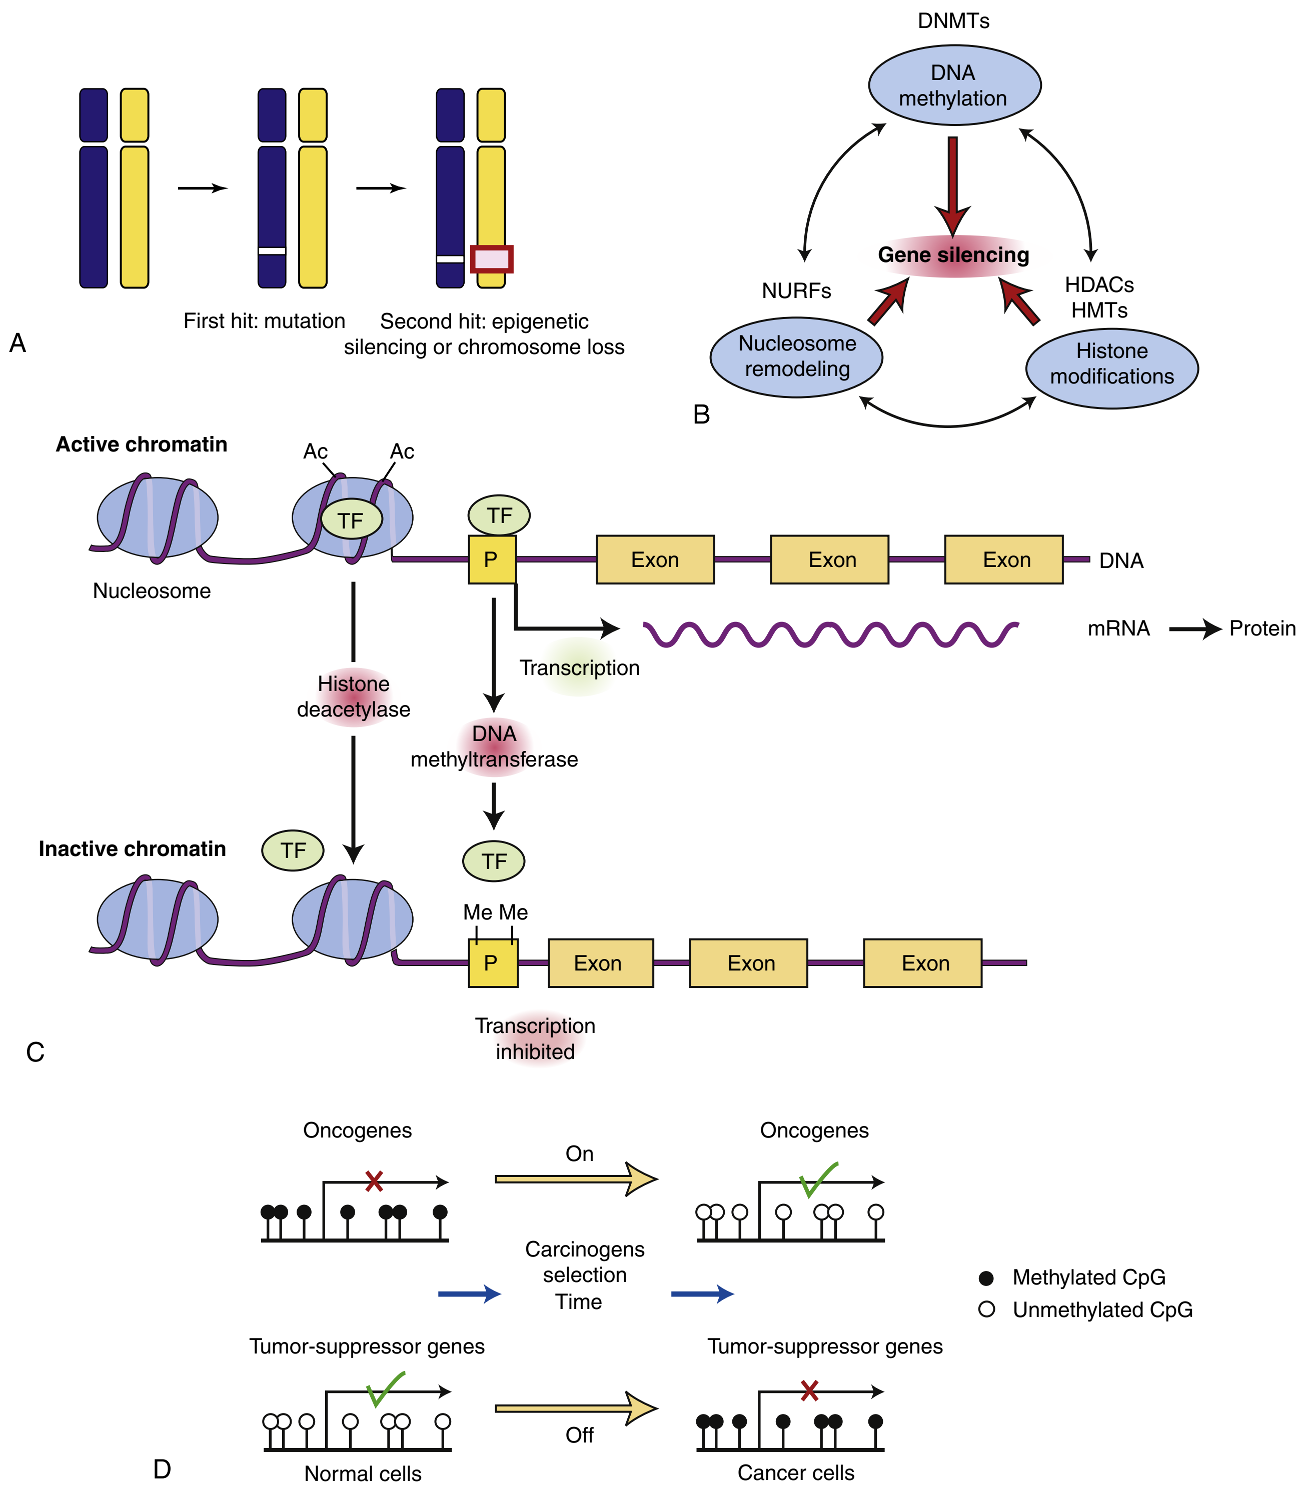

FIGURE 12-14 **Silencing Tumor-Suppressor Genes by Epigenetic Alterations.** Tumor-suppressor genes can be turned off by a variety of mechanisms. **A,** In this example, the first hit is a point mutation in a tumor-suppressor gene *(white box),* followed by either epigenetic silencing or chromosome loss of the second allele *(red box).* **B,** Genes can normally be silenced by a variety of interacting processes including DNA methylation, histone modifications, nucleosome remodeling, and microRNAs (not shown). A number of cellular enzymes contribute to these modifications, including DNA methyltransferases *(DNMTs),* histone deacetylases *(HDACs),* histone methyltransferases *(HMTs),* and complex nucleosomal remodeling factors *(NURFs).* Gene silencing is essential for normal development and differentiation. **C,** Histone modification and promoter methylation regulate gene expression. Genes are transcribed when chromatin is modified by addition of acetyl *(Ac)* groups to specific lysine groups in histones. Gene expression can be turned off when specific acetyl groups are removed by HDACs or when the CpG-rich promoter regions of genes are modified by direct DNA methylation (by DNA methyltransferase). In addition, small endogenous RNA molecules (microRNAs or miRNA) can bind to mRNA and reduce gene expression. **D,** Changes in promoter methylation turn cancer genes off and on. Oncogenes can be turned on by promoter hypomethylation, and tumor-suppressor genes can be turned off by promoter hypermethylation. Each of these changes can produce selective growth and survival advantage for the cancer cell. (**B** adapted from Jones PA, Baylin SB: *Cell* 128:683–692, 2007; **C** from Gluckman PD et al: *N Engl J Med* 359[1]:66, 2008; **D** from Shames DS, Minna JF, Gazdar AF: *Curr Mol Med* 7:85–102, 2007.)

oncogene because it can act in a dominant manner in the cell. However, we have two copies, or alleles, of each gene, one from each parent. It therefore takes two hits to inactivate the two alleles of a tumor-suppressor gene. The first allele of a tumor suppressor is often inactivated by point mutations. For example, the *Rb* gene may be inactivated on one chromosome by a point mutation (e.g., the copy inherited from the father). Because the other copy of the retinoblastoma gene (in this example, the one from the mother) is intact, a functional RB protein can still be made and therefore the cell division cycle can be regulated appropriately. If the remaining gene is mutated or silenced, then all RB function is lost and another step toward cancer occurs (see Chapter 4).

Loss of Heterozygosity. For the function of a tumor suppressor to be lost, both chromosomal copies (alleles) of the gene must be inactivated. This is because they act in a recessive manner at the level of the cell. Although it may seem intuitive that simple inactivating mutations might disrupt both alleles, in fact this is not what usually happens.[20] Instead, the first allele (in the preceding example, the paternal copy) is inactivated by simple mutation, but the second allele (in this example, the maternal copy) is lost because entire regions of the maternal chromosome are epigenetically silenced or a piece of the chromosome is simply lost (see Figure 12-14, *A*). Because humans have two chromosomes, one from each parent, they are always *heterozygous* for nearby multiple genetic markers; loss of one copy (allele) of a chromosome region in a tumor is referred to as **loss of heterozygosity,** or **LOH.** Loss of heterozygosity, like silencing, can unmask inactivating mutations in recessive tumor-suppressor genes. For example, the *Rb* gene resides on chromosome 13, in a region referred to as q14 (13q14). Most individuals with *Rb* mutations have a subtle mutation in one allele and have lost the other copy of *Rb* through loss of the 13q14 chromosome region on the other chromosome.

Turning Off Genes Without Mutation

Epigenetic Silencing. Abnormal gene silencing is emerging as a major cause of cancer. Gene expression can be regulated in a heritable manner (i.e., passed from a parent to a child or from a single cell to its progeny) by an "epigenetic" mechanism called **silencing.** Inheritance of silencing occurs during cell division and does not require mutations or changes in DNA sequence (also see Chapter 6). More simply, the same DNA sequence can produce dramatically different phenotypes depending on chemical modifications that alter the expression of genes. Epigenetic silencing is caused by reversible chemical modification (methylation [addition of a methyl group] or acetylation [addition of an acetyl group]) of histones and related chromatin components, as well as methylation of cytosine residues in DNA (known as **DNA methylation**) (see Figure 12-14, Figures 6-2, 6-3, and Chapter 16). Whole regions of chromosomes are normally shut off by silencing, so that the pattern of gene expression is different than that seen in other cells with the same genes. In this way, the progeny of liver cells remain liver cells, and skin cells remain skin cells. Notably, *global* changes in epigenetic silencing can turn these cells back into stem cells.[21]

Changes in gene silencing contribute to the development of cancer.[22] Many cancers have increased methylation of DNA in the promoter region of tumor-suppressor genes (in CpG islands or C-cytosine and G-guanine, p-phosphodiester bond, rich sequences that are often located near promoter regions; see Chapters 4 and 13). They also have associated changes in the modification of histones in the chromatin, including methylation of lysines 9 and 27 in histone H3. In addition, overexpression of chromosome silencing proteins known as the polycomb complex, and loss of expression of histone deacetylases (enzymes that remove acetyl groups from histone proteins) SIRT1 is seen in human cancers. These changes in chromatin-modifying genes alter the promoter regions of genes leading to their silencing. The boundaries of the normally silenced regions can also spread in cancer cells, thereby inactivating previously active genes. In either case, silencing can shut off critical tumor-suppressor genes in the absence of mutations in the gene. Early in the development of cancer, these changes in gene expression can lead to a selective advantage for affected cells, perhaps leading to their immortalization and clonal expansion. Silencing of tumor suppressors may be a faster way to create cancer cells than mutational or genetic loss of tumor suppressors.[23] Conversely, loss of silencing can contribute to inappropriate expression of oncogenes. Chemotherapeutic drugs that can regulate gene silencing, including histone deacetylase (HDAC) inhibitors and 5-azacytidine (which reverses the effects of DNA methyltransferases [DNMTs]), have proven effective in reactivating silenced tumor-suppressor genes in the treatment of selected cancers[24] (see Figure 12-14).

MicroRNAs, Oncomirs, and Non–coding RNAs. Changes in gene regulation can affect not just single genes, but also entire networks of signaling. Gene expression networks can be regulated by changes in **microRNAs (miRNAs,** or **miRs)** and other non–coding RNAs (ncRNAs). miRNAs are short (approximately 22 nucleotides) RNAs derived from introns of protein coding genes or transcribed as independent genes from regions of the genome previously believed to have no function (erroneously called junk DNA). The human genome encodes more than 1000 miRs. miRs regulate diverse signaling pathways; the miRs that stimulate cancer development and progression are termed **oncomirs.** miRs decrease the stability and expression of other genes by pairing with mRNA in a process that involves the RNA-induced silencing complex, or RISC. A single miR can have multiple mRNA targets. Changes in miR abundance can therefore affect the expression of many genes, making miRs both powerful regulators and challenging subjects to study.[25] Beyond miRs, longer RNAs without apparent protein coding capacity also are implicated in cellular regulation with an emerging appreciation of their role in cancer.[26]

miRs can play both positive and negative roles in cancer. The importance of miRs in cancer was first shown in chronic lymphocytic leukemia (CLL), where a chromosome region encoding miR15 and miR16 was found to be deleted in a large number of individuals. Decreased expression of these two miRs is seen in many cases of CLL, as well as in prostate and several other cancers, and results in increased expression of a

number of oncogenes. Conversely, increased expression of a cluster of miRs (17-18-19-20-92) is seen in some lymphomas and solid tumors, causing the decreased expression of a number of tumor-suppressor genes. miR expression can be easily assessed with microarray technology, leading to the realization that substantial changes in miR expression are seen in many cancers.

Guardians of the Genome

The previous discussion of mutations leads naturally to the question of how mutations occur in the first place. The integrity of genetic information can be compromised at several points: during each round of DNA synthesis, during each mitosis when chromosomes are segregated to daughter cells, and when external mutagens (e.g., chemicals and radiation) alter or disrupt DNA. Multiple mechanisms have evolved to protect and repair the genome.[27] These repair mechanisms are directed by **caretaker genes,** genes that are responsible for the maintenance of genomic integrity. Caretaker genes encode proteins that are involved in repairing damaged DNA, such as occurs with errors in DNA replication, mutations caused by ultraviolet or ionizing radiation, and mutations caused by chemicals and drugs. Loss of function of caretaker genes leads to increased mutation rates. If DNA damage is severe, the cell undergoes programmed cell death, or apoptosis, rather than simply dividing with damaged DNA.

Inherited mutations can disrupt the caretaker genes that protect the integrity of the genome. Examples include the disorder xeroderma pigmentosum (XP); affected individuals have defects in the repair of ultraviolet light–induced DNA damage and should avoid direct sunlight exposure. They have a very high incidence of skin cancer. Hereditary nonpolyposis colorectal cancer (HNPCC) results from an inherited defect in repairing DNA base pair mismatches that occur occasionally during DNA replication. Affected individuals have an increased rate of small insertions and deletions in DNA, leading to a high rate of colon and other cancers.[28] Finally, there are inherited mutations that threaten the integrity of entire chromosomes. Bloom syndrome, caused by mutations in a DNA helicase, and Fanconi aplastic anemia, caused by loss of function of a multiprotein complex required for repair of DNA double-stranded breaks, are autosomal recessive disorders in which affected individuals demonstrate marked chromosomal instability. Chromosome breaks, aberrant fusions, and chromosome loss are common. As a consequence, these individuals have a high risk of developing cancer at an early age.

The rate of individual gene mutation is probably too low to account for the acquisition of many new mutations during the evolution of a malignant cancer clone. In addition to abnormal epigenetic silencing, **chromosome instability** (often referred to as CIN) also appears to be increased in malignant cells.[29] The underlying mechanism of this instability is not clear but may be caused by malfunctions in the cellular machinery that regulates chromosome segregation at mitosis.[30] Chromosome instability results in a high rate of chromosome loss, as well as loss of heterozygosity and chromosome amplification. Each of these events can accelerate the loss of tumor-suppressor genes and the overexpression of oncogenes.

Genetics and Cancer-Prone Families

Genetic events are the primary basis of carcinogenesis. Most of the genetic and epigenetic alterations that cause cancer occur within the somatic tissues during the lifetime of the individual. As previously discussed, the frequency of genetic changes can be increased by exposure to **mutagens,** that is, agents causing mutations, and by defects in DNA repair. Because these genetic events occur in somatic cells as opposed to germ cells, they are not transmitted to future generations. Even though they are genetic events they are not inherited! It is possible, however, for cancer-predisposing mutations to occur in germline cells (cells that produce gametes). Mutations present in germline cells result in the transmission of cancer-causing genes from one generation to the next, producing families with a high incidence of specific cancers. These inherited mutations that predispose to cancer are almost invariably found in tumor-suppressor genes (see Table 12-5).

Although rare, such "cancer families" demonstrate that inheritance of a mutated gene can cause cancer (Figure 12-15).

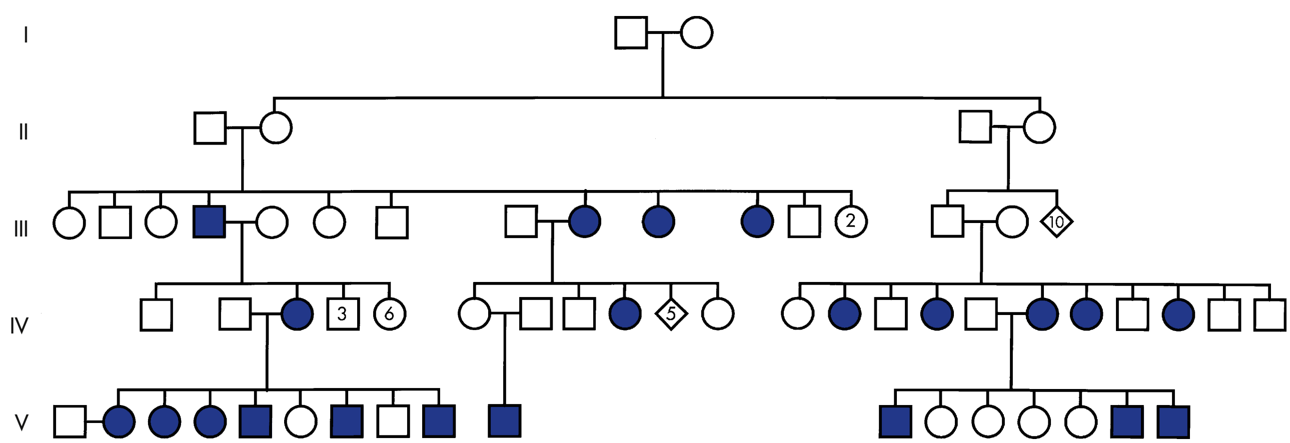

FIGURE 12-15 Familial Colon Cancer Pedigree. Darkened symbols represent individuals diagnosed with colon cancer. One of the individuals in the first generation must have carried a mutation in the *APC* gene. (From Jorde LB et al: *Medical genetics,* ed 4, St Louis, 2010, Mosby.)

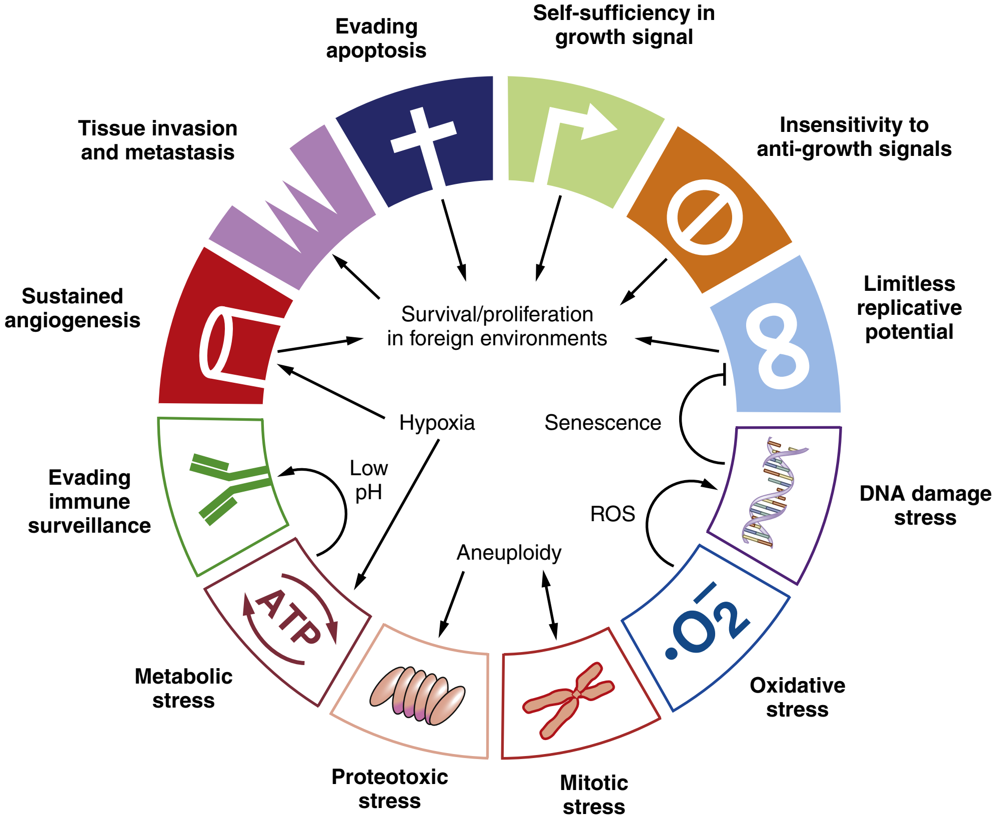

FIGURE 12-16 **Hallmarks of Cancer.** Cancers acquire alterations in specific pathways during their evolution. The six key pathways that must be altered are shown at the top of the circle, and supporting pathways are shown at the bottom of the circle. Mutation in key genes often alters several pathways; for example, *p53* mutations alter both angiogenesis and evasion of apoptosis. ⌒ = Inhibits. (From Luo J, Solimini NL, Elledge SJ: *Cell* 136:823–837, 2009.)

Inheritance of one mutant allele in these families predisposes a person to a specific form of cancer.[31] Individuals who inherit the germline mutant allele will inevitably suffer loss of the normal allele by loss of heterozygosity (LOH) or **epigenetic silencing** (see Figure 12-14) in some cells and eventually develop the tumor. Examples of human cancers that can be inherited are retinoblastoma, a childhood cancer of the eye that can be caused by germline mutations in one allele of the *Rb* gene; Wilms tumor, a childhood cancer of the kidney *(Wt1);* neurofibromatosis *(Nf1);* inherited breast cancer *(BRCA1);* and familial polyposis coli or adenomas of the colon *(APC)*. A specific tumor-suppressor gene has been found in each of these cancers. In many cases, these tumor-suppressor genes also are inactivated in sporadic (as opposed to inherited) cancers. For example, inherited mutations in the *APC* gene are rare and account for only a few percent of all colon cancers. However, 85% of sporadic colon cancers also have acquired mutations of *APC,* which occurred over time in the individual. Characterization of cancer-causing genes and other genetic factors helps identify individuals prone to developing cancer (see Figure 12-15) and contributes to our understanding of sporadic cancers. Individuals known to carry mutations in tumor-suppressor genes (for example, women with a germline *BRCA1* mutation) are offered targeted cancer screening to facilitate early cancer detection and therapy.[32]

Types of Genes Misregulated in Cancer

Alterations in Progrowth and Antigrowth Signals

We now understand that multiple genetic hits are required for the evolution of full-blown cancer. One key question is, what types of genes must be altered to cause a cancer? In 2000, a highly influential paper by Hanahan and Weinberg[33] proposed six specific pathways that must be misregulated for cancer to develop (see Figures 12-10, 12-11, and 12-16). First, cancer cells must have mutations that enable them to proliferate in the absence of external growth signals. To achieve this, some cancers acquire the ability to secrete growth factors that stimulate their own growth, a process known as **autocrine stimulation** (also see Chapter 1). Other cancers have an increase in growth factor receptors; for example, in breast cancer, the epidermal growth factor (EGF) receptor HER2/neu is up-regulated, and likely sends growth signals into the cell even when growth factors are at very low levels. Inhibitors of HER2 and other EGF receptors that block this pathway are effective in treating selected breast and lung cancers.[34] Alternatively, the signal cascade from the cell surface receptor to the nucleus may be mutated in the "on" position. Up to one third of all cancers have an activating mutation in the gene for an intracellular signaling protein called **RAS.** This mutant RAS stimulates cell growth even when growth factors are missing (see Figure 12-11).

Cells also usually receive diverse "antigrowth" signals from their normal milieu. Contact with other cells, with basement

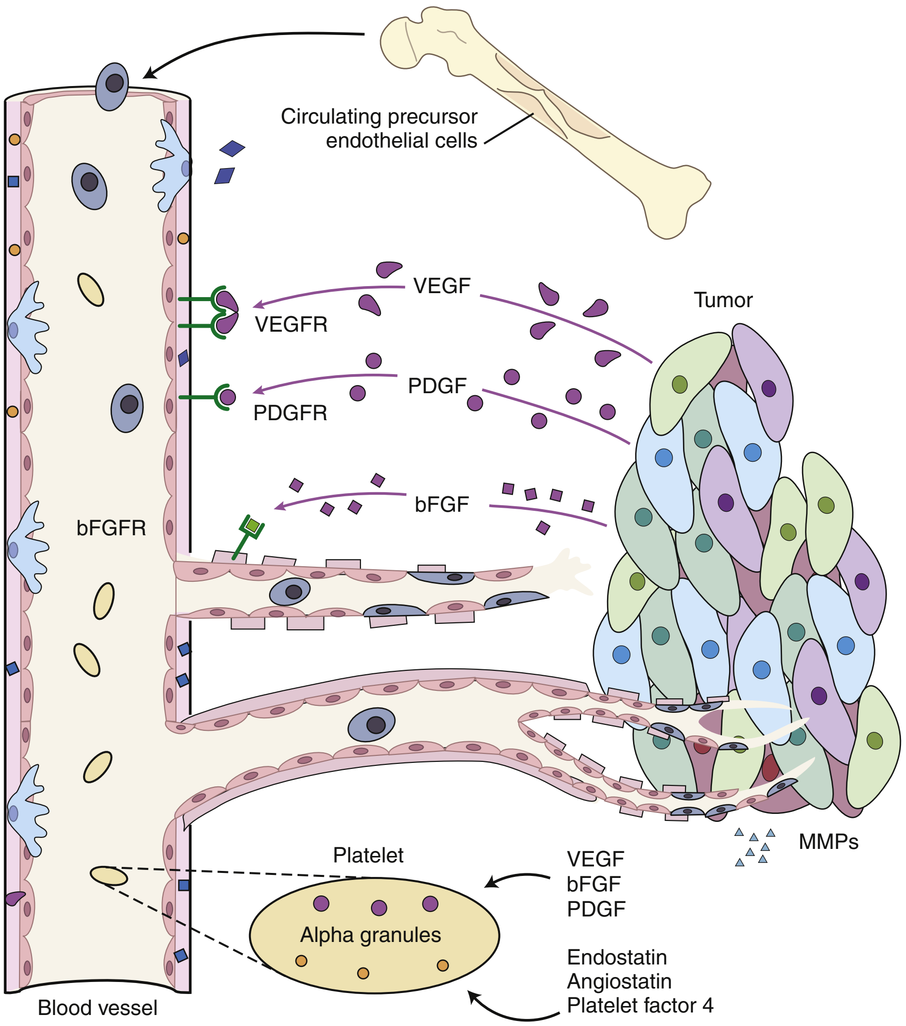

FIGURE 12-17 **Tumor-Induced Angiogenesis.** Malignant tumors secrete angiogenic factors and tissue-remodeling matrix metalloproteinases *(MMPs)* that actively induce formation of new blood vessels. New blood vessels are formed from both local endothelial cells and circulating precursor cells recruited from the bone marrow. Circulating platelets can also release regulatory proteins into the tumor. *bFGF* and *bFGFR,* Basic fibroblast growth factor and its receptor, respectively; *PDGF* and *PDGFR,* platelet-derived growth factor and its receptor, respectively; *VEGF* and *VEGFR,* vascular endothelial growth factor and its receptor, respectively. (Adapted from Folkman J: *Nat Rev Drug Discov* 6[4]:273–286, 2007.)

membranes, and with soluble factors all normally signal cells to stop proliferating. These mechanisms can put a halt to unregulated cell growth. In addition, this normal antigrowth signal must be inactivated or ignored. Common mutations that subvert the antigrowth signal include inactivation of the tumor-suppressor *retinoblastoma* or, conversely, activation of the protein kinases that drive the cell cycle, the *cyclin-dependent kinases* (see Chapter 1). Next, cells have a mechanism that causes them to self-destruct when growth is excessive and cell cycle checkpoints have been ignored. This self-destruct mechanism, called **apoptosis,** is triggered by diverse stimuli, including normal development and excessive growth (see Chapter 2). The pathway to apoptosis is disabled in advanced cancers. The most common mutations conferring resistance to apoptosis occur in the *TP53* gene.

Angiogenesis

If cancers are to grow larger than a millimeter in diameter, they need their own blood supply to deliver oxygen and nutrients. However, in adults new blood vessel growth is normally limited to areas of wound healing and to the uterus during the proliferative phase of the menstrual cycle. Tiny cancers lack the ability to grow new blood vessels and may never grow larger than a grain of sand. More advanced cancers can, however, secrete multiple factors that stimulate new blood vessel growth (called neovascularization or **angiogenesis**). The **angiogenic factors,** such as *vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF),* and *basic fibroblast growth factor (bFGF),* by recruiting new vascular endothelial cells and initiating the proliferation of existing blood vessel cells, allow small cancers to become large cancers.[35] Therapies directed against new vessel growth are in clinical use; these agents include bevacizumab, a monoclonal antibody that inhibits VEGF; erlotinib, sorafenib, and sunitinib, inhibitors of the VEGF and PDGF receptor tyrosine kinases; and thalidomide, which decreases vascular proliferation[36] (Figure 12-17).

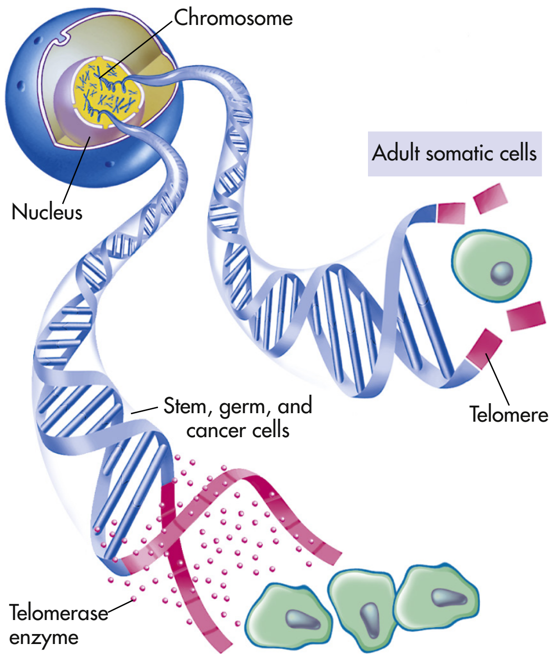

FIGURE 12-18 Control of Immortality: Telomeres and Telomerase. Normal adult somatic cells cannot divide indefinitely because the ends of their chromosomes are capped by telomeres. In the absence of the telomerase enzyme, telomeres become progressively shorter with each division until, when they are critically short, they signal to the cell to stop dividing. In germ cells, adult stem cells, and cancer cells the telomerase gene is "switched on," producing an enzyme that rebuilds the telomeres. Thus, like germ cells, the cancer cell becomes immortal and able to divide indefinitely without losing its telomeres.

Telomeres and Immortality

A hallmark of cancer cells is their immortality. Usually the only cells in the body that are "immortal" are germ cells (those that generate sperm and eggs) and stem cells. Other cells in the body are not immortal and can divide only a limited number of times (known as the Hayflick limit) before they cease dividing. One major block to unlimited cell division (i.e., immortality) is the size of a specialized structure called the *telomere.* **Telomeres** are protective ends, or caps, on each chromosome and are placed and maintained by a specialized enzyme called **telomerase** (Figure 12-18). As you might expect, telomerase is usually active only in germ cells (in ovaries and testes) and in stem cells. All other cells of the body lack telomerase. Therefore, when non–germ cells begin to proliferate abnormally, their telomere caps become smaller and smaller with each cell division. Short telomeres normally signal the cell to cease cell division. If the telomeres become critically small, the chromosomes become unstable and fragment, and then the cells die. Cancer cells, when they reach a critical age, activate telomerase somehow in order to restore and maintain their telomeres and thereby make it possible to divide over and over again.[37] Because telomerase is specifically activated in cancer cells, and potentially in cancer stem cells, it is an attractive therapeutic target.[38]

Finally, it appears genetic differences exist between cells that successfully metastasize and those that do not.[39] Specific genes regulate the ability to metastasize. Decreased cell-to-cell adhesion, the secretion of various proteases that digest surrounding barriers, and the ability to grow in new locations all contribute to successful metastasis[40] (discussed later in this chapter).

Inflammation, Immunity, and Cancer

With the advent of research studies on cancer in inbred mice (genetically identical) in the 1950s, immunologists recognized that many cancers expressed antigens on the cell surface that were not normally expressed on the surface of non–cancer cells from the same tissue. Similar tumor-associated antigens are also expressed on human cancer cells. Two hypotheses arose from these observations. First, immunologists predicted that many developing malignancies were suppressed by an efficient immune surveillance system by which cells expressing tumor-associated antigens were identified, and the resultant immune response destroyed developing malignant cells. Second, when tumors do develop, their tumor-associated antigens could be targets of effective immunotherapy. Immunotherapy could be either active by immunization with tumor antigens to elicit or enhance the immune response against a particular cancer, or passive by injecting the cancer patient with antibodies or lymphocytes directed against the tumor-associated antigens.

The Immune System Protects Us Against Viral-Associated Cancers

The immune system is indeed important in protecting us against cancers caused by specific viral infections. A broad spectrum of viruses has been associated with cancer in animals, and several viruses have been associated with human cancer.[41,42] In humans, *human papillomavirus (HPV), Epstein-Barr virus (EBV)* (also known as *HHV4*), *Kaposi sarcoma herpesvirus (KSHV)* (also known as *HHV8*), and *hepatitis B* and *C viruses (HBV, HCV)* are associated with about 15% of all human cancers worldwide (Table 12-6). Cancer of the cervix and hepatocellular carcinoma account for approximately 80% of the cases of virus-linked cancer.

Virtually all cervical cancer is caused by infection with specific types of HPV, which infects basal skin cells and commonly causes warts. There are more than 120 HPV types, but only about 40 can infect human mucosal tissue, and only a few (HPV16, -18, -31, and -45) are associated with the highest risk for developing cervical, anogenital, and penile cancer (see Chapters 10 and 26). Most HPV infection is handled effectively and rapidly by the immune system and does not cause cancer. Cancer is more common in people with prolonged infection with HPV (a decade or more), during which the viral DNA becomes integrated into the genomic DNA of the infected basal cell of the cervix and directs the persistent production of viral oncogenes. Early oncogenic HPV infection is readily detected by the Papanicolaou (Pap) test, an examination of cervical epithelial scrapings. Early detection of cellular atypia in a Pap test alerts healthcare providers to the possibility of cervical carcinoma in situ, which can be effectively treated. The Pap test is probably the most effective cancer screening test developed to date. Vaccines protecting against the common oncogenic HPV types (HPV16 and HPV18 [types that cause 70% of cervical cancers] and HPV6 and HPV11 [types that cause 90% of genital warts]) were approved for clinical use beginning in

TABLE 12-6 HUMAN VIRUSES ASSOCIATED WITH CANCER

VIRUS FAMILY	TYPE	HUMAN CANCER	COFACTORS
Hepatitis viruses	Hepatitis B	Hepatocellular carcinoma	Alcohol, smoking, aflatoxins
	Hepatitis C	Hepatocellular carcinoma	Alcohol
Herpesviruses	Epstein-Barr	Burkitt lymphoma, nasopharyngeal carcinoma	Malaria
	KSHV/HHV8 immunodeficiency	Kaposi sarcoma	
Papillomaviruses	HPV16, HPV18, HPV31, HPV33, others	Cervical, anogenital	Smoking, oral contraceptives
Retroviruses	HTLV-1	Adult T-cell leukemia/lymphoma	Unknown

Modified from Mendelsohn J et al, editors: *The molecular basis of cancer,* ed 2, Philadelphia, 2001, Saunders.
KSHV/HHV8, Kaposi sarcoma–associated herpesvirus/human herpesvirus-8; *HPV,* human papillomavirus; *HTLV-1,* human T-cell lymphotropic virus type 1.

2006; if these vaccines are administered to young women and men before an initial HPV infection, this is likely to prevent many cases of cervical cancer.[43]

EBV and HHV8 are members of the Herpesviridae family.[44] More than 90% of adults have been infected with EBV, usually as children and without symptoms. EBV infection during adolescence may cause infectious mononucleosis. The virus infects B lymphocytes and stimulates their proliferation; the infection usually remains latent throughout the individual's life. In individuals who are immunosuppressed because of HIV infection or because of drugs given for an organ transplant, persistent EBV infection can lead to the development of B-cell lymphomas. Development of B-cell lymphomas in persons with organ transplants is known as **post-transplant lymphoproliferative disorder (PTLD).**[45] One effective therapy for PTLD is, if possible, to decrease or stop the administration of immunosuppressant drugs and allow the immune system to attack the virus. EBV infection also is associated with Burkitt lymphoma in areas of endemic malaria and with nasopharyngeal carcinoma, a cancer endemic in Chinese populations in Southeast Asia.[46,47] HHV8 is linked to the development of Kaposi sarcoma, a cancer that was once seen primarily in older men but now occurs in a markedly more virulent form in immunocompromised individuals, especially those with acquired immunodeficiency syndrome (AIDS).[48] HHV8 also has been linked to several rare lymphomas.

Human T-cell lymphotropic virus type 1 (HTLV-1) is an oncogenic retrovirus linked to the development of adult T-cell leukemia and lymphoma (ATLL).[49] HTLV is transmitted vertically (that is, inherited by children from infected parents) and horizontally (e.g., by breast-feeding, sexual intercourse, blood transfusions, and exposure to infected needles). Infection with HTLV may be asymptomatic, and only a small fraction of infected individuals develop ATLL, often many years after acquiring the virus.

Chronic hepatitis B infections are common in parts of Asia and sub-Saharan Africa and confer up to a 200-fold increased risk of developing liver cancer. Chronic hepatitis C infections have become increasingly recognized in Western countries. Up to 80% of liver cancer cases worldwide are associated with chronic hepatitis caused either by HBV or by HCV. The initial infection with hepatitis B or C is not associated with cancer; instead, it is acquisition of a chronic viral hepatitis that markedly increases cancer risk.[50] In both cases, it appears that a lifetime of chronic liver inflammation predisposes to the development of hepatocellular carcinoma. Widespread use of the HBV vaccine is expected to significantly decrease the incidence of chronic hepatitis B and hence hepatocellular carcinoma. Unfortunately, a vaccine for HCV is not yet available.

The immune surveillance hypothesis would predict that compromise of the immune system, either by administration of immunosuppressive drugs or by development of genetic or acquired immunodeficiencies, would result in increased incidences of all types of cancer. However, defective immune responses generally only increase the risk for lymphoid cancers, many of which are associated with viral infections.[51] For instance, individuals taking chronic powerful immunosuppressive drugs, such as those given for kidney, heart, or liver transplant, have a much higher risk of developing viral-associated cancers, with a 10-fold increased risk of non-Hodgkin lymphoma (caused by Epstein-Barr virus) and up to a 1000-fold increased risk of Kaposi sarcoma (caused by human herpesvirus 8 [HHV8]). The same immunosuppressed individuals, however, have only a slight increase in the risk of common cancers such as lung and colon cancer (and this could well be because of increased inflammation at those sites), and no increase in the risk of breast or prostate cancer.[52,53] Although the immune system is indeed important in protecting us against cancers caused by specific viral infections, it does *not* effectively protect us against most common cancers.

Inflammation as a Cause of Cancer

Although the immune surveillance theory remains controversial the general opinion remained that an immune or inflammatory response to malignancy is a detrimental condition that successful tumors have evolved methods of evading. We now realize that the relationship between a cancer and the immune and inflammatory systems is much more complex. Inflammatory and immune responses may create a local environment in which cells can develop into a malignant phenotype and may even benefit progression and spread of malignancies.[54] In fact, chronic inflammation has been recognized for close to 150 years as being an important factor in the development of cancer.[55] Epidemiologic studies strongly support the conclusion that chronic inflammation predisposes to cancer. Chronic inflammations may result from many causes; for example, solar irradiation, asbestos exposure (mesothelioma), pancreatitis, and infection (Table 12-7). Additionally, some organs appear to

TABLE 12-7 CHRONIC INFLAMMATORY CONDITIONS AND INFECTIOUS AGENTS ASSOCIATED WITH NEOPLASMS

INFLAMMATORY CONDITION	ASSOCIATED NEOPLASM(S)
Asbestosis, silicosis	Mesothelioma, lung carcinoma
Bronchitis	Lung carcinoma
Cystitis, bladder inflammation	Bladder carcinoma
Gingivitis, lichen planus	Oral squamous cell carcinoma
Inflammatory bowel disease, Crohn disease, chronic ulcerative colitis	Colorectal carcinoma
Lichen sclerosus	Vulvar squamous cell carcinoma
Chronic pancreatitis, hereditary pancreatitis	Pancreatic carcinoma
Reflux esophagitis, Barrett esophagus	Esophageal carcinoma
Sialadenitis	Salivary gland carcinoma
Sjögren syndrome, Hashimoto thyroiditis	MALT lymphoma
Skin inflammation	Melanoma
INFECTIOUS AGENT	**ASSOCIATED NEOPLASM(S)**
AIDS (HIV, herpesvirus type 8)	Non-Hodgkin lymphoma, squamous cell carcinomas, Kaposi sarcoma
Chronic cholecystitis	Gallbladder cancer
Chronic cystitis (schistosomiasis)	Bladder, liver, rectal carcinoma; follicular lymphoma of the spleen
Gastritis, gastric ulcers *(Helicobacter pylori)*	Gastric adenocarcinoma, MALT
Hepatitis	Liver carcinoma
Mononucleosis (Epstein-Barr virus)	B-cell non-Hodgkin lymphoma, Burkitt lymphoma
Opisthorchis, cholangitis (liver flukes, bile acids)	Cholangiosarcoma, colon carcinoma
Osteomyelitis	Skin carcinoma in draining sinuses
Pelvic inflammatory disease, chronic cervicitis (HPV, gonorrhea, chlamydia)	Ovarian carcinoma, cervical/anal carcinoma

HIV, Human immunodeficiency virus; *HPV,* human papillomavirus; *MALT,* mucosa-associated lymphoid tissue.

be more susceptible to the oncogenic effects of chronic inflammation; for example, the gastrointestinal (GI) tract, prostate, thyroid gland, pancreas, urinary bladder, pleura, and skin.

Individuals who have suffered with ulcerative colitis for 10 years or more have up to a 30-fold increase in the risk of developing colon cancer. Chronic viral hepatitis caused by hepatitis B virus (HBV) or hepatitis C virus (HCV) infection markedly increases the risk of liver cancer. One large study found a 66% increase in the risk of lung cancer among women with chronic asthma, an inflammatory disease of the airways (see Chapter 35).

Inflammation and cancer have much in common.[56] In both cancer and inflammation (e.g., after injury and during infection), inflammatory cells, including neutrophils, lymphocytes, and macrophages, migrate to the site of injury and release cytokines and growth and survival factors that stimulate local cell proliferation and new blood vessel growth to promote wound healing by tissue remodeling (Figure 12-19) (see Chapter 5). These factors combine in chronic inflammation to promote continued proliferation.[57] In addition, inflammatory cells release compounds such as reactive oxygen species (ROS) and other reactive molecules that can promote mutations and block the cellular response to DNA damage. Notably, an increased abundance of the enzyme cyclooxygenase-2 (COX-2), which generates prostaglandins during acute inflammation, has been associated with colon and some other cancers. Meta-analyses of multiple clinical studies have concluded that long-term high-dose use of nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, that inhibit COX-2 can reduce the risk of colon cancer by as much as 20% (see Chapter 5).[58]

A specific example is the association between gastric inflammation induced by infection with the bacterium *Helicobacter pylori (H. pylori)* and the risk for gastric cancer. *H. pylori* is a bacterium that infects more than half of the world's population. Chronic infection with *H. pylori* is an important cause of peptic ulcer disease and is strongly associated with gastric carcinoma, a leading cause of cancer deaths worldwide. It is also associated with a less common cancer, gastric mucosa–associated lymphoid tissue (MALT) lymphomas. *H. pylori* infection is often acquired in childhood and disproportionately affects lower socioeconomic classes. Although most infections are asymptomatic, prolonged chronic inflammation can lead to increased gastric acid secretion, atrophic gastritis, and duodenal ulcers, or to benign cellular proliferation that can, in a small fraction of individuals, progress to dysplastic changes and finally frank gastric adenocarcinoma. *H. pylori* infection can both directly and indirectly produce genetic and epigenetic changes in infected stomachs, including mutations in *p53* and alterations in the methylation of specific genes.[59,60] Eradication of *H. pylori* from infected individuals before the development of dysplasia may prevent the development of cancer.[61] However, there is no expert consensus on the value of population screening and treatment strategies.

Inflammation, Immunity, and Progression of Cancer

Once cells with malignant phenotypes have developed, additional complex interactions occur between the tumor and the

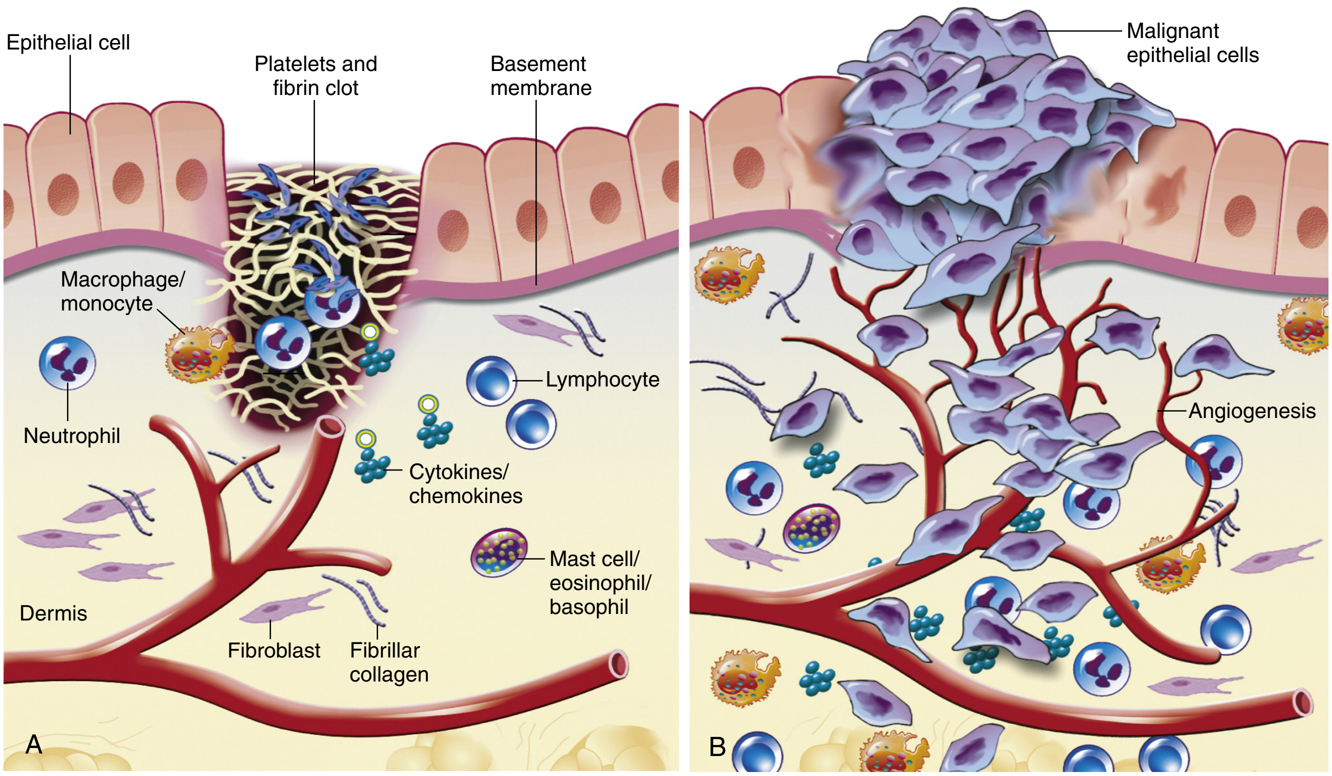

FIGURE 12-19 Wound Healing vs. Invasive Tumor Growth. **A,** Wounds simulate a local inflammatory response. With tissue injury, a blood clot with activated platelets forms, releasing multiple factors that stimulate wound healing. Chemotactic factors such as transforming growth factor-beta and platelet-derived growth factor, derived from activated platelets, initiate granulation tissue formation, activation of fibroblasts, and secretion of proteolytic enzymes (including matrix metalloproteinases) necessary for remodeling of the extracellular matrix. Signaling from many cell types in the wound, including stromal cells, facilitates healing. Once the wound is healed, the signals presumably stop. **B,** Invasive carcinomas act as disorganized wounds. Neoplastic cells produce angiogenic factors, cytokines, and chemokines that are mitogenic and/or chemoattractants for numerous cells. In return, activated fibroblasts and infiltrating inflammatory cells also secrete proteolytic enzymes, cytokines, and chemokines, which are mitogenic for neoplastic cells as well as for endothelial cells involved in neoangiogenesis. These factors, which in the normal situation promote wound healing, now can stimulate tumor growth and angiogenesis, induce fibroblast migration and maturation, and promote metastatic spread through the venous or lymphatic networks. (Adapted from Coussens LM, Werb Z: *Nature* 420[6917]:860–867, 2002.)

surrounding stroma and cells of the immune and inflammatory systems (Figure 12-20). Normal tissues contain a complex mixture of cell types, including fibroblasts, vascular cells, adipocytes, mesenchymal cells (including mesenchymal stem cells), inflammatory cells, and immune cells, and a supporting extracellular matrix. Cancers disrupt this environment, initiate or enhance inflammation, and in turn recruit local and distant cells (macrophages, lymphocytes, and other cellular components of inflammation). The acute inflammatory response related to infection, instead of cancer, undergoes several phases; the initial phase is protective and focused on destruction of the contaminating infectious agents, whereas the later phases are focused on the initiation and progression of healing, as well as preventing the development of autoimmune responses against the normal cellular debris of tissue destruction and regeneration (see Chapter 7). Successful tumors appear capable of manipulating cells of the inflammatory and immune responses towards the phenotypes associated with wound healing and tissue regeneration, which is a process that includes induction of cellular proliferation, neovascularization, and local immune suppression. These activities benefit cancer progression, as well as increase resistance to chemotherapeutic agents.[62]

One of the key cells that promote tumor survival is the tumor-associated macrophage, or TAM.[63] Many tumors produce cytokines and chemokines that are chemotactic factors for monocytes/macrophages (for example, colony-stimulating factor-1 [CSF-1; also known as macrophage colony stimulating factor or M-CSF], vascular endothelial growth factor [VEGF], the chemokine ligand 2 [CCL2; also known as monocyte chemotactic protein-1 or MCP-1]). These chemotactic factors, especially CCL2, are commonly expressed by human tumors (for example, levels of CCL2 in human breast and cancers of the esophagus are related to the degree of macrophage infiltration and progression of the tumor). Thus monocytes are attracted from the blood and into the tumor, where they mature into macrophages. Monocytes have the capacity to differentiate into several macrophage phenotypes, depending upon the conditions in the microenvironment. The classical pro-inflammatory macrophage (M1) is the primary macrophage in the acute inflammatory response and is responsible for removal and

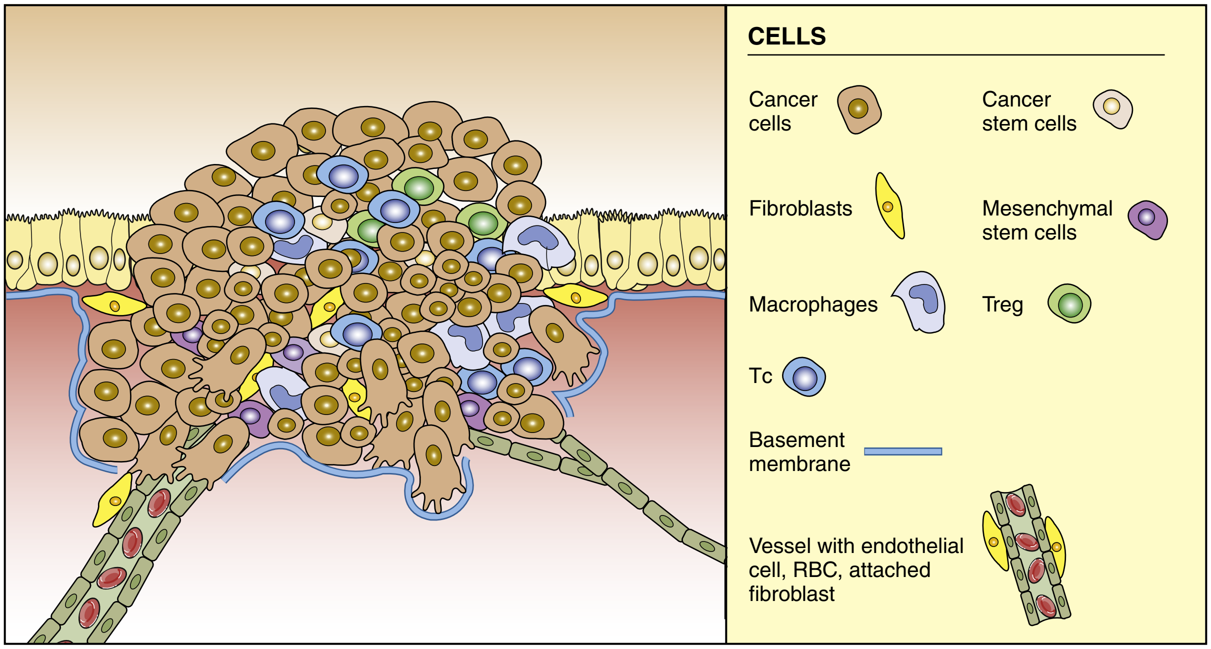

FIGURE 12-20 **Cancers Live in a Complex Microenvironment.** This diagram represents aspects of the complex microenvironment of a high-grade epithelial neoplasm. The tumor cells produce angiogenic factors that induce neovascularization and invasion by inflammation-related cells from neighboring tissue and from the blood. Individual cancer cells have undergone diverse phenotypic changes, including the formation of cancer stem cells (CSCs). Cytokines and chemokines produced by vascular endothelial cells (ECs) directly affect the proliferation and spread of cancer cells. Cancer-associated fibroblasts originate from fibroblasts associated with blood vessels or invasion from surrounding tissues and produce factors that primarily affect tumor cell proliferation and breakdown of the underlying extracellular matrix. Circulating monocytes invade the tumor and differentiate into tumor-associated macrophages (macrophages) (TAMs) of the M2 phenotype. TAMs produce factors that affect most other cells in the microenvironment. T lymphocytes infiltrate the tumor in the form of CD8+ cytotoxic cells (Tc) and CD4+ regulatory cells (Treg). The Tc cells are suppressed through the combined effect of cytokines and chemokines produced by Treg cell, TAMs, and tumor cells.

destruction of infectious agents. During healing, however, a different phenotype (M2) produces anti-inflammatory mediators to suppress ongoing inflammation and induce cellular proliferation, angiogenesis, and wound healing.[64] TAMs appear to phenotypically mimic the M2 phenotype. The transition to the M2 phenotype is under control of Th2 cytokines (for example, tumor necrosis factor-alpha [TNF-α], colony-stimulating factor-2 [CSF2; also known as granulocyte/macrophage colony stimulating factor or GM-CSF], interleukin-4 [IL-4], IL-10, IL-13).

TAMs have diminished cytotoxic response, and develop the capacity to block cytotoxic T-cell and NK cell functions and produce cytokines that are advantageous for tumor growth and spread. TAMs secrete cellular growth factors (for example, TGF-β and fibroblast growth factor [FGF-2]) that favor tumor cell proliferation, angiogenesis, and tissue remodeling, similar to their activities in wound healing. They also secrete angiogenesis factors (for example, VEGF) that induce neovascularization and matrix metalloproteinase (MMP) that degrade intercellular matrix. The overall effect is increased tumor growth, increased oxygen delivered to the tumor, invasion of the blood vessels, and invasion through the degraded matrix into the local tissue. Most tumors have large numbers of TAMs, whose presence frequently correlates with reduced survival (for instance, in individuals with breast cancer, some forms of lung cancer, and Hodgkin lymphoma). Therapies targeting the nonmalignant TAMs are effective at slowing cancer progression.[65]

Many tumors also have an abundance of tumor-infiltrating lymphocytes. Although the immune cells frequently found in tumors were once thought to be futile attempts at an antitumor response, instead it appears that cancers actively recruit an immune and stromal response to assist in remodeling of tissues, formation of new blood vessels, and promotion of metastasis[66] (see Figure 12-20) cells are generally in low amounts in tumors. The predominant lymphocytes are regulatory T (Treg) cells.[67] Treg cells are CD4+ cells that differentiate under the control of specific cytokines, primarily TGF-β, and express CD25 (the α-chain of the IL-2 receptor) and are thus frequently designated CD4+, CD25+ Treg cells. The role of Treg cells during wound healing is to control or limit the immune response to protect the host's own tissues against autoimmune reactions. Their role in tumors is manipulated to prevent a destructive antitumor immune response and provide cytokines that facilitate tumor cell proliferation and spread.[68] Treg cells and TAMs, as well as stromal cells, produce very high levels of TGF-β and IL-10, an immunosuppressive cytokine, which generally decrease Th1 and Th2 activity, suppress antigen recognition and cell proliferation by Th cells, and suppress the capacity of CD8+ cytotoxic T (Tc) cells to recognize, proliferate in response to antigen, and kill tumor cells. Increased levels of Treg cells in blood and

lymph nodes and also infiltrating the tumor correlate with poor outcomes in breast and GI tumors.[69]

In several conditions the release of immunosuppressive factors into the tumor microenvironment increases resistance of the tumor to chemotherapy and radiotherapy.[70] In advanced non–small cell lung cancer an elevated ratio of Treg to Tc cells is related to a poor response to platinum-based chemotherapy. Other cytokines appear to increase the cancer cells' resistance to apoptosis. For example, the Th2 cytokine IL-4 increases the resistance of thyroid cancer to chemotherapy; IL-6 produced by adipocytes and fibroblasts activates survival pathways in breast cancer leading to resistance to radiotherapy; and adipocytes enhance the transcription of the anti-apoptotic factor Bcl-2 in leukemia cells.[71]

A major component of wound healing is angiogenesis—the process of establishing new blood vessels within the tissue undergoing repair. Access to a blood supply is a major benefit to the growth and spread of cancer. Vascular endothelial growth factor (VEGF), an extremely potent inducer of angiogenesis, is secreted by most cells in the tumor microenvironment, including tumor-infiltrating monocytes, endothelial cells, adipocytes, cancer-associated fibroblasts, and some tumor cells. Tumor cells may also have VEGF receptors. VEGF may, thus, induce increased resistance to chemotherapy. For instance, in soft tissue sarcomas VEGF induces increased expression of anti-apoptotic proteins (survivin, Bcl-2) and activation of Pi3K/Akt-mediated survival pathways. The use of angiogenic inhibitors targeting VEGF signaling can inhibit angiogenesis and diminish tumor growth.

Tumor growth and progression is enhanced by, and perhaps is dependent upon, interactions with cells in the microenvironment. Suppression of tumor-enhancing inflammatory/immune responses may provide powerful adjunctive approaches to traditional antitumor therapeutic regimens, such as chemotherapy and radiation therapy.[72] Tumor-infiltrating cells, such as TAM and Treg cells, express cell-specific surface markers. Antibodies directed against those markers can induce apoptosis of these cells. Additionally, the effects of specific cytokines, chemokines, and other tumor-enhancing mediators produced in the tumor microenvironment may be neutralized by specific antagonists.[73] These are also usually in the form of monoclonal antibodies. For instance, TNF-α antagonist has been used effectively in rheumatoid arthritis to inhibit production and neutralize the effects of TNF-α, including reduction of angiogenesis, leukocyte infiltration, and production of metalloproteinases. Trials are currently underway to assess the effects of TNF-α antagonists on the progress of cancer. Other antagonists are under investigation, including those against IL-1β, TGF-β, CSF-1 (M-CSF), VEGF, IL-6, IL-10, and metalloproteinases. Chemokine antagonists are also under development. A potential complication of adjunctive therapy directed against cellular or molecular products of inflammation concerns the importance of these constituents in normal inflammatory/immune responses. If the proposed antagonists were administered systemically, suppression of responses elsewhere in the body may increase the individual's susceptibility to infection. Delivery systems that concentrate the antagonists proximal to the tumor environment may be the most effective means of administration.

CANCER INVASION AND METASTASIS

Metastasis is the spread of cancer cells from the site of the original tumor to distant tissues and organs through the body. Metastasis is a defining characteristic of cancer, contributes significantly to the pain and suffering from cancer, and is the major cause of death from cancer. Cancer that has not metastasized can often be cured by a combination of surgery, chemotherapy, and radiation. These same therapies are frequently ineffective against cancer that has metastasized. For example, in appropriately treated women with low-stage breast cancer, the 5-year survival rate is often greater than 90%.[74] Tragically, less than 30% of women with metastatic breast cancer are alive 5 years after diagnosis.[75] A growing body of basic and clinical research is defining the biologic principles of metastasis, with the hope that this improved understanding will lead to novel diagnostic approaches and better therapies to prevent and treat metastatic cancers.[76]

Invasion, or local spread, is a prerequisite for metastasis and is the first step in the metastatic process. In its earliest stages local invasion may occur by direct tumor extension. Eventually, however, cells migrate away from the primary tumor and invade the surrounding tissues. Mechanisms important in local invasion include recruitment of macrophages and other cell types to the primary tumor, where they promote digestion of connective tissue capsules and other structural barriers by secreted proteases; changes in cell-to-cell adhesion, often by changes in the expression of cell adhesion molecules such as cadherins and integrins, making the cancer cells more slippery and mobile; and increased motility of individual tumor cells[77] (Figure 12-21). Tumors that are encased in a capsule, such as breast ductal carcinoma, must breakdown the capsule in order to initiate local spread.[78] The capsule consists of layers of epithelial cells and myoepithelial cells in contact to the tumor and contained by a basement membrane (see Figure 24-43). The myoepithelial cells may be tumor suppressive; they produce proteins that are tumor suppressors (e.g., TGF-α, IL-6), as well as angiogenesis inhibitors and proteinase inhibitors.[79] The mechanism of capsular dissolution is unclear, but may result from production of enzymes by the tumor or the influx of leukocytes.[80] Information about mechanical stress and associated tumor cell response is contained in What's New? Mechanical Stress and Tumors.

To transition from local to distant metastasis, the cancer cells must also be able to invade local blood and lymphatic vessels, a task facilitated by stimulation of neoangiogenesis and lymphangiogenesis by factors such as VEGF. Finally, a successful metastatic cell must be able to survive in the circulation, attach in an appropriate new microenvironment, and multiply to produce an entire new tumor, similar to the characteristics of a cancer stem cell. Different cancers have different patterns of spread, determined by a combination of factors. Cancers often spread first to regional lymph nodes through the lymphatics and then to distant organs through the bloodstream. A cancer's ability

WHAT'S NEW?

Mechanical Stress and Tumors

Cells, whether in isolation or in tissues, often face and respond to a wide variety of external stimuli. These environmentally induced changes, called *perturbations,* can be chemical or physical and responses can be physiologic, such as cellular homeostatic activities or tissue development movements, or pathologic, such as malignant transformation or inflammation. Cellular responses to chemical signals have been studied in great detail, but the elements involved in the recognition of physical stresses (e.g., hypoxia, osmotic shock, ionizing radiation, or mechanical stretching) and the mechanisms related to cell responses to these stimuli remain barely analyzed. These responses include a variety of conserved adaptive behaviors, such as wound healing, cell migration, extravasation, secretion, and necrotic or apoptotic death.[1]

Mechanical stress is a key physical stimulus sensed by cells. At the cellular level, mechanical cues or stressors can modulate almost all aspects of cell behavior, including growth, differentiation, migration, gene expression, protein synthesis, and apoptosis,[2] many of them of important clinical interest (e.g., cancer metastasis, stem cell proliferation, and differentiation and wound healing). Mechanical cues control specific physiologic processes, such as sound sensation, by cells of the inner ear or blood flow across the endothelium.[2] Importantly in some cases, organs and tissues adapt their structures and functions in response to acute or chronic mechanical stress (e.g., pressure overload causes cardiovascular hypertrophy and muscle disuse results in atrophy).

For tumor biology, the cell surface integrin family act as critical mechanosensors.[3] Integrin-mediated cell adhesion and signaling are crucial events for numerous cell fates and include morphogenesis, differentiation, cell growth, the immune response, and cell survival.[4] *Integrins* function as noncovalent transmembrane receptors that are organized in focal adhesions (FAs) and link the extracellular matrix (ECM) to the actin cytoskeleton; they do not directly interact with actin filaments. A number of actin-binding proteins, including talin, α-actinin, and filamin, have been identified as intermediates.[5] Integrins can mediate the sensing of mechanical properties of the ECM by changing their affinity, conformation, clustering, and recruitment and by transducing these signals to the activation of downstream signaling cascades. The molecular architecture of FAs suggests that mechanical force is, itself, essential for focal adhesion formation and maintenance. From stretch-induced recruitment, talin may serve as a molecular ruler that specifies focal adhesion molecular architecture.[6]

Investigators are studying the relationships of cues from the microenvironment and tumor behavior. For example, recent work showed the mechanical tone of nontumorigenic host epithelium directs the phenotype of tumor cells.[7] Investigators established a three-dimensional ex vivo model of both normal and malignant mammary epithelial growth to test the importance of the ECM in regulating local migration of tumor cells and dissemination.[8] From their studies, they determined that breaks in the basement membrane could induce invasion and dissemination from the resulting direct contact between cancer cells and collagen I.[8] Uncontrolled growth in a confined space generates compressive forces. To understand how this may affect tumor behavior, investigators from various fields, including chemical engineering and radiation oncology, found that compressive stress accumulated during tumor growth can enable coordinated migration of cancer cells by stimulating formation of leader cells and enhancing cell–substrate adhesion.[9] This novel mechanism represents a potential target for the prevention of cancer cell migration and invasion. Overall, the research on mechanical stress and associated tumor cell response is just beginning.

to establish a metastatic lesion in a new location requires that the cancer both attach to specific receptors and survive in the specific environment. Because metastasis requires successful completion of each and every step, there may be many opportunities to interrupt this potentially lethal pathway.

Only Rare Cells in a Cancer Are Able to Metastasize

Metastasis is a highly inefficient process. A landmark clinical review examined a group of women with advanced ovarian cancer.[81] These unfortunate women had accumulated a large amount of peritoneal fluid filled with malignant ovarian cancer cells (malignant ascites). To relieve the pressure caused by the ascites, the fluid was surgically shunted into the venous circulation. This palliative procedure relieved the abdominal pressure but had the side effect of moving millions of ovarian cancer cells an hour directly into the bloodstream. Despite this direct injection of billions of cancer cells into the circulation, these women unexpectedly had no increased number of metastases when they died. The conclusion from this clinical study is that most cancer cells cannot successfully cause metastases, a conclusion that has been supported by many other clinical and laboratory studies.[82] The reason lies both in the seed and in the soil. Cancer cells (the seeds) must surmount multiple physical and physiologic barriers in order to spread, survive, and proliferate in distant locations, and the destination (the soil) must be receptive to the growth of the cancer. It has been suggested that the metastatic cell must, like a decathlon champion, be successful in every event to allow a cancer to spread.[82]

How do cancer cells develop the ability to metastasize? The same heritable changes that occur to cause the primary cancer, including gene mutations, deletions, translocations, epigenetic silencing, and changes in miRNA expression, all work to provide genetic heterogeneity in the tumor cells as they proliferate. As this diversity increases, this increases the number of cells in the cancer mass with new abilities that can facilitate metastasis.

Detachment and Invasion

In order for cells to move away from their normal niche, they must be able to detach from the stroma and migrate. Cells are normally attached to extracellular matrix (ECM). To facilitate cancer spread, many tumors and their associated inflammatory cells secrete proteases and protease activators, such as the matrix metalloproteinases (MMPs) and plasminogen activators. Active proteases digest the extracellular matrix and basement membranes, creating pathways through which cells can move, while releasing bioactive peptides as digestion products that further

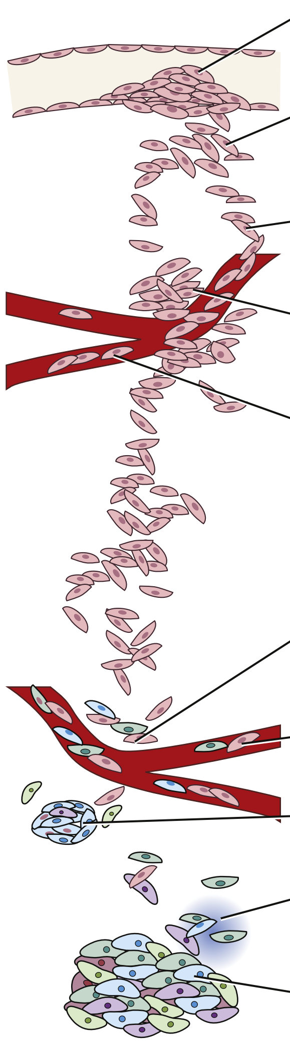

FIGURE 12-21 Multistep Nature of Metastasis. (From Gupta GP, Massagué J: *Cell* 127[4]:697–708, 2006.)

stimulate tumor growth and mobility. However, the production of metalloproteinases alone is inadequate to explain the metastatic process.

The process by which neoplastic cells dissociate from the primary tumor, spread into the lymphatics and blood vessels, and establish macrometastases in foreign microenvironments is a fascinating, and yet not fully understood, utilization of pathways that are more commonly observed in embryonic and fetal development. Carcinomas originate from highly differentiated and polarized epithelial cells that form structured sheets stabilized by multiple adherences to neighboring cells and to a basement membrane (an extracellular meshwork of collagens and other connective tissue proteins) along the cells' basal surface. Although the degree of malignant transformation resulting in a primary tumor may be adequate for local expansion of the tumor, neoplastic cells in the primary carcinoma usually retain some epithelial-like characteristics that prevent dissociation from the extracellular matrix and preclude successful metastasis to distal sites. A greater degree of cellular "dedifferentiation" is necessary to produce the "seeds" that can separate from the primary tumor and flourish in a potentially hostile secondary site. This results from a programmed transition of the still partially epithelial-like carcinoma to a more undifferentiated mesenchymal-like phenotype (**epithelial-mesenchymal transition [EMT]**) (Figure 12-22).[83] A similar process occurs with tumors of endothelial origin (endothelial-mesenchymal transition).[84]

EMT is a process that occurs normally in embryonic development (for example, cell movement related to morphogenesis during gastrulation and neural crest formation) and implantation, as well as wound healing and tissue repair. Generally, cells that have transitioned into a mesenchymal-like phenotype have suppressed expression of adhesion molecules with a loss of polarity, increased migratory capacity, elevated resistance to apoptosis, and the potential to redifferentiate into other cell types. These properties permit the tumor cells to dissociate from the primary tumor and be transported to a distal site. The degree of dedifferentiation may be variable, but most cells undergoing EMT acquire stem cell traits that facilitate initial growth in a new microenvironment.[85] The EMT is not a stable transition; the metastatic tumor tends to regain some characteristics of the primary tumor, thus reverting to some extent to its epithelial origins.

The transition to a mesenchymal-like phenotype is, in most cases, driven by cytokines and chemokines produced within the tumor microenvironment (see Figure 12-22). IL-8 is an effective driver of carcinoma cells into EMT. TGF-β induces loss of E-cadherin (an integral component of tight junctions) and β_4-integrin in mammary gland tumor cells. The loss of E-cadherin in particular allows cells to detach from extracellular matrix and migrate more readily.

Genetic changes associated with the EMT are under the control of a variety of transcription factors, for example, Snail, Slug, and Twist.[86] Most are repressors of transcription, so that expression of adhesion molecules such as E-cadherin is greatly diminished. The translational factor Slug also represses transcription of Bcl-2 antagonists, resulting in increased Bcl-2 expression and increased resistance to apoptosis.

Survival and Spread in the Circulation

Normal cells, when separated from their ECM, undergo *anoikis*, a form of apoptosis (see Chapter 2). The process of EMT frequently results in increased resistance to apoptosis. In addition, tumor cells that have already adapted to a hypoxic environment have already been selected for resistance to apoptosis, often by loss of normal cell death pathways. For example, neuroblastomas with loss of the pro-apoptotic caspase-8 genes are able to avoid apoptosis after loss of integrins, and are more able to metastasize than the same cells with normal levels of caspase-8. Accordingly, individuals whose neuroblastomas have low levels of caspase-8 have a poor prognosis[87] (see Chapter 2).

Selective Adherence in Favorable Sites

After release from the ECM and digestion of basement membranes, cancer cells gain access to the circulation through new tumor-associated blood vessel growth or angiogenesis (described earlier), also known as neovascularization. Mobile tumor cells are able to enter the circulation, perhaps facilitated

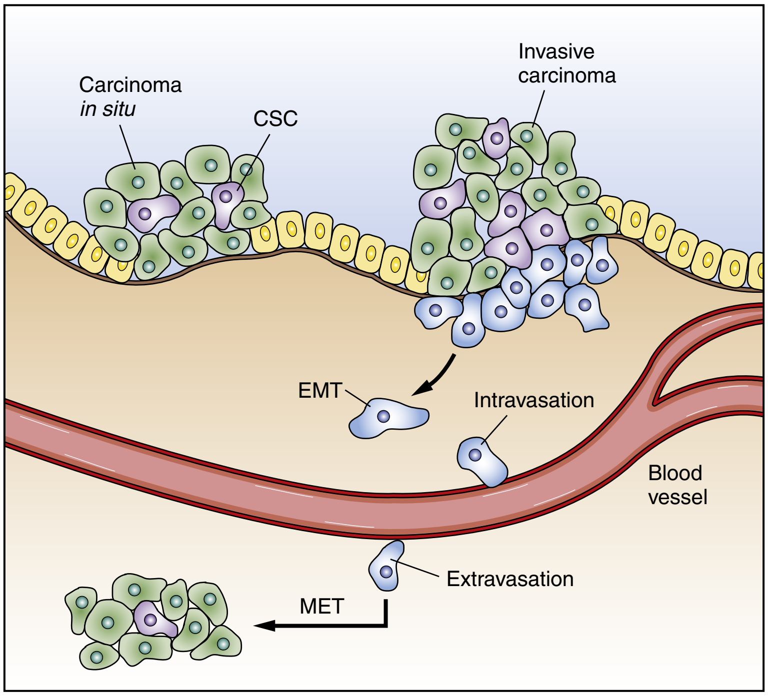

FIGURE 12-22 **Epithelial-Mesenchymal Transition (EMT).** Tumors of epithelial origin usually retain epithelial-like characteristics that preclude spread into adjacent tissues and metastasis to distal sites. As seen in this diagram, cells within carcinoma in situ or non-invasive carcinoma (not shown) retain adhesion to adjacent cells and the underlying basement membrane (BM). The process of transition to mesenchymal-like cells is driven by cytokines within the tumor microenvironment and induction of a family of EMT-inducing transcription factors. The outcome included dedifferentiation of the tumor cell, potentially to a cancer stem cell phenotype, loss of adhesion-related molecules, breakdown of the BM, and increased resistance to apoptosis, which result in a locally invasive carcinoma and release into the bloodstream or lymphatic vessels of cells capable of relocalization, redifferentiation (potentially through a reverse mesenchymal-to-epithelial transition process; MET), and formation of a metastasis. *CSC*, Cancer stem cell. (From Craene BD, Berx G: *Nat Rev Cancer* 13[2]:97–110, 2012.)

by the leaky newly made vessels and attraction of the cells because of chemoattractants coming from these new vessels. Once in the circulation, metastatic cells must be able to withstand the physiologic stresses of travel in the blood and lymphatic circulation, including high shear rates and exposure to immune cells. One mechanism is for tumor cells to bind to blood platelets, giving them a protective coat of nonmalignant blood cells that both shields the tumor cells and creates a small tumor embolus, or cancer clot, that can promote cancer cell survival in distant locations.

The patterns of metastasis are dictated by the interaction between the cancer cells and the microenvironments in which they land. Two distinct mechanisms give rise to patterns of distant spread. First, cancer cells spread through vascular and lymphatic pathways, as well as natural tissue planes. The **neovascularization** of a cancer offers malignant cells direct access into the venous blood, and draining lymphatics can carry malignant cells to regional lymph nodes. Single cells, clumps, and even tumor fragments can disseminate by these routes. Anatomic patterns of lymphatic and venous blood flow help determine how colon cancers spread to the liver, liver cancers spread through the portal vein to the lungs, lung cancers spread through the systemic circulation to the brain, and breast cancer spreads through lymphatics to axillary lymph nodes (Figure 12-23). There is also a major yet poorly understood selectivity of different cancers for different sites. Thus metastatic breast cancer often spreads through the bloodstream to bones but rarely to kidney or spleen, whereas lymphomas often spread to the spleen but uncommonly spread to bone. In a key study, Schackert and Fidler[88] injected different types of cancer cells into the carotid artery of mice. Despite identical blood flow–mediated distribution of the cancer cells, each cancer cell type produced cancers in very different parts of the brain. This tissue selectivity is likely caused by specific interactions between the cancer cells and specific receptors on the small blood vessels in different organs (Table 12-8). Experimental metastasis studies in mice are beginning to reveal additional molecular reasons for this tissue specificity (Figure 12-24). Examples include interaction between $\alpha 3\beta 1$ integrins binding to laminin-5 receptors in the lung, and the chemokine receptor CXCR4 on breast cancer cells promoting homing to lung tissues expressing the ligand CXCL12.[89]

Escape from the Circulation and Development of a New Microenvironment

As the study with women with ovarian cancer illustrates, pumping millions of cancer cells in the bloodstream does not necessarily cause metastatic disease. Cancer cells may arrive in a new location and survive but not proliferate to form a clinically relevant metastasis. The tumor cells that do not make the transition from simple survival to robust proliferation in a new

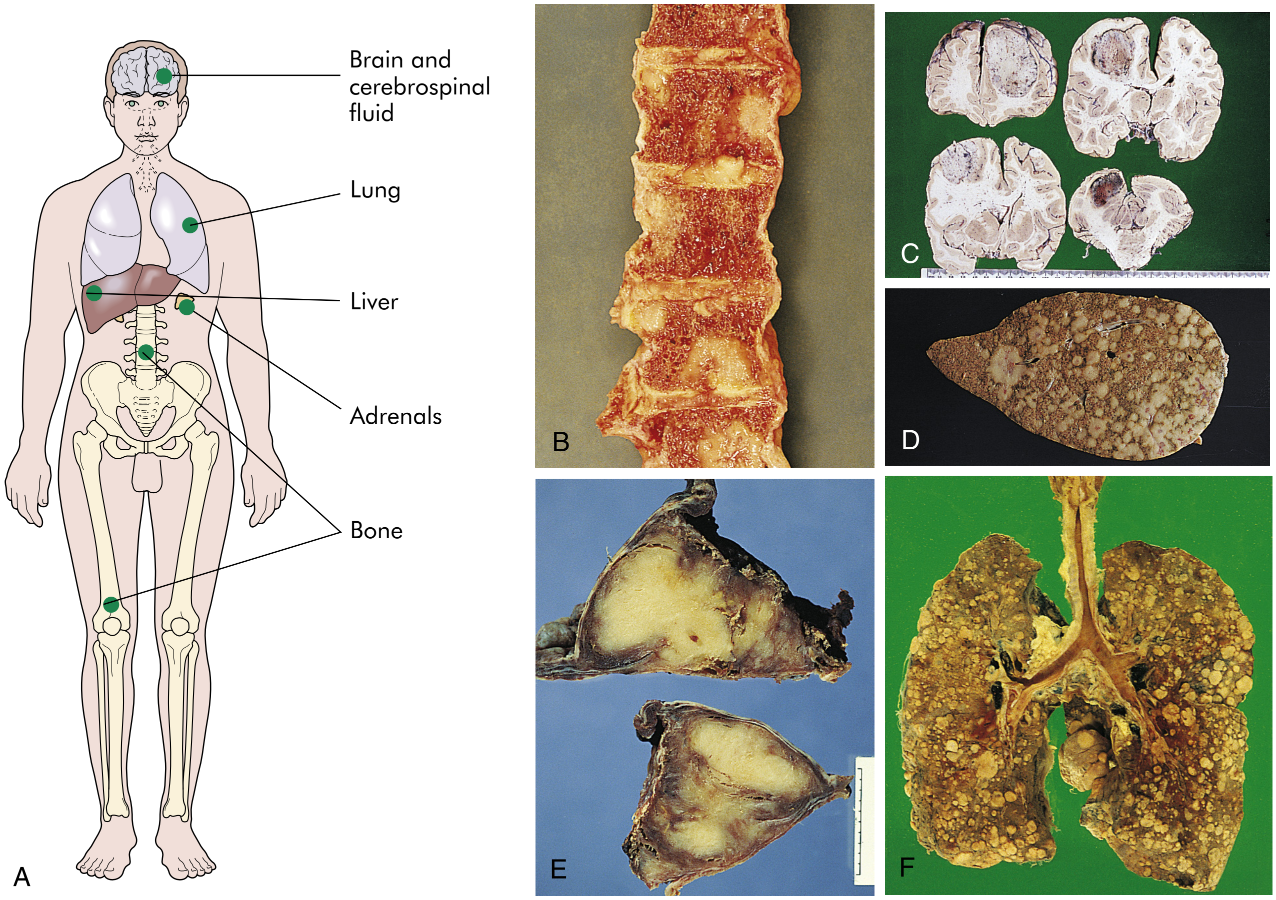

FIGURE 12-23 **Patterns of Metastatic Spread. A,** Sites of hematogenous metastasis. Blood-borne tumor metastasis leads to growth of secondary tumors in several main sites. The macroscopic appearance of bone metastasis is shown in **B,** where lesions are seen in vertebrae. **C,** Numerous metastases from a neoplasm of the stomach are seen in the brain. **D,** The liver is the most common site for metastases from tumors in the gastrointestinal tract that arose from a colonic neoplasm. **E,** Metastatic tumor has replaced both adrenal glands, as is commonly seen with spread from lung and breast tumors. **F,** The lung is the most common site for blood-borne metastases from tumors outside the spinal tract, particularly mesenchymal tumors.

TABLE 12-8 COMMON SITES OF METASTASIS

PRIMARY TUMOR	MAJOR ANATOMIC PATHWAY	COMMON SITE OF DISTANT METASTASIS
Lung	Pulmonary vein, left ventricle	Multiple organs, including brain
Colorectal	Mesenteric lymphatics, portal venous system	Liver
	Inferior vena cava, right ventricle, pulmonary artery	Lungs
Testicular	Lymphatics to periaortic area to subclavian veins to right ventricle	Lungs, liver, brain
Prostate	Regional lymphatics and veins, which drain to Batson plexus of presacral veins	Bones (especially lumbar spine), liver
Breast	Axillary, transpectoral, and internal mammary lymphatics	Bones, lung, brain, liver
Head and neck	Direct extension	Lymphatics, liver, bones
Ovarian	Direct extension, peritoneal seeding, mesenteric veins	Peritoneal surfaces, diaphragm, omentum, liver
Sarcoma (extremity)	Inferior vena cava, right ventricle, pulmonary artery	Lungs
Melanoma	Regional lymphatics	In transit lymphatics, lung, liver, brain, gastrointestinal tract

location are said to be in a state of *dormancy*. This dormancy may account for the observation that solitary tumor cells can be detected in the blood years after a complete clinical remission in individuals, and that many people with detectable micrometastases will not develop clinically obvious metastases.[88,90] One of the factors that allow proliferation of cancer cells in the new environment may be cancer's recruitment of normal cells from local and circulating bone marrow stem cells. One developing concept is that successful metastatic tumor cells secrete factors that recruit circulating mesenchymal stem cells to the metastatic

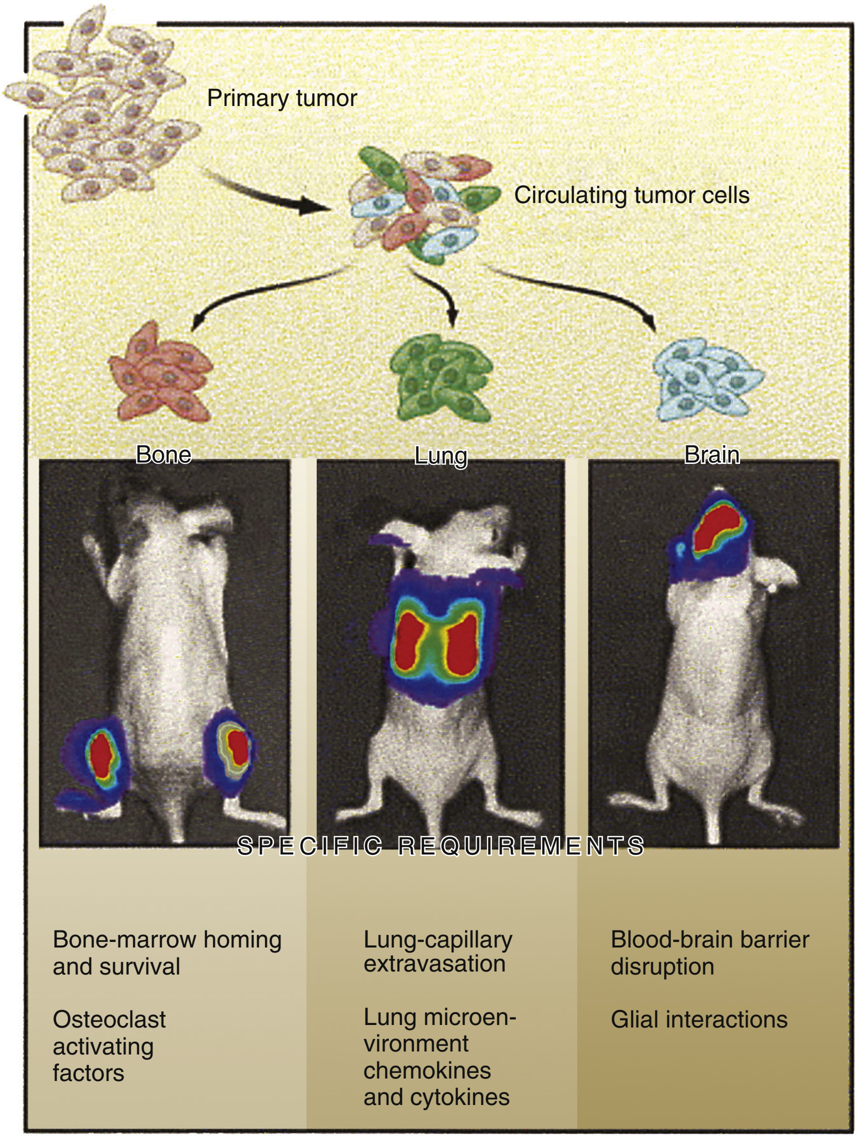

FIGURE 12-24 **Clues Regarding How the Patterns of Metastatic Spread Are Determined.** Different cancer cells from the same cancer can spread to different locations. This is because tumors are heterogeneous mixtures of cells, with variations in the genes that are turned on and off. Different anatomic locations favor different types of cells. Studies with mice illustrated here show that expression of specific factors such as adhesion molecules, chemokines, and host factors such as blood-brain barrier disruption can favor the spread of specific cancer cells to different locations. In this example, cancer cells were visualized by genetically tagging cells with firefly luciferase for bioluminescent imaging. (From Gupta GP, Massagué J: *Cell* 127[4]:679–695, 2006.)

site (see Figure 12-17). These newly recruited stem cells then differentiate into tumor-supporting stroma and new blood vessels. One area of research is aimed at understanding why some micrometastases remain dormant; new therapies might block their progression to clinically important disease.

CLINICAL MANIFESTATIONS AND TREATMENT OF CANCER

Clinical Manifestations of Cancer

Diagnosis and Staging

Cancer can be discovered in many ways: after screening tests, from routine exams, and after investigation of symptoms (see What's New? Screening Mammography: Why It Has Not Lived Up to Expectations). The symptoms a cancer produces are as diverse as the types of cancer. The location of the cancer can determine symptoms by physical pressure, obstruction, and loss of normal function, or a cancer can cause problems far away from its source by pressing on nerves or secreting bioactive compounds. Whatever the initial complaint, once the diagnosis is suspected and a tumor has been identified, it is essential that tumor tissue be obtained to establish a definitive diagnosis and correctly classify the disease. Various methods of obtaining tissue are described in Table 12-9.

Once tissue is obtained, it is examined microscopically by the pathologist for the histologic hallmarks of cancer detailed

WHAT'S NEW?

Screening Mammography: Why It Has Not Lived Up to Expectations

Screening mammograms illustrate many of the difficulties that arise from population-based screening tests. The goal of screening tests is early and accurate detection of a treatable disease without causing false alarms (a low false-positive rate) or missing a diagnosable disease (a low false-negative rate). We also do not want to detect disease or conditions that are insignificant and do not require treatment, known as overdiagnosis. Recently, investigators examined the extent of overdiagnosis of breast cancer. Various databases were examined to study breast cancer trends between 1976 (just before screening mammography was introduced) and 2008. During this interval the incidence of ductal carcinoma in situ (DCIS) and localized disease (early stage cancers) doubled from 112 to 234 per 100,000 women, an increase of 122 cases per 100,000 women.[1] During the same interval, the annual incidence of late stage cancers decreased minimally from 102 to 94 per 100,000 women, a decrease of 8 per 100,000 women. The higher increase in early stage cases compared to late stage cases (112 vs. 8 per 100,000) suggests substantial overdiagnosis.[2] The investigators estimate that, as a result of breast cancer overdiagnosis, more than 1 million U.S. women have been presumably treated unnecessarily (overtreatment) with approaches including surgery, radiotherapy, and chemotherapy during the last 30 years.[1] These authors also conclude that the improvement in breast cancer mortality during those years is mainly because of treatment and not screening. This question, however, is debated. The Cochrane reviewers analyzed tumor sizes and stages and reported that screening has not lowered the rate of advanced cancers and recent observational studies of breast cancer mortality have failed to find an effect related to mammography screening.[3] Results from the Norwegian screening program found 15% to 25% of cases of breast cancer are overdiagnosed.[4] The Nordic Cochrane Center found that 13 years of breast screening had no measurable effect on breast cancer mortality in Norway.[5] An independent expert panel in the United Kingdom estimated the risks and benefits of screening for breast cancer in women 50 to 70 years of age invited for mammography every 3 years in the UK. They found for every 180 women who are screened, 1 life is saved but 3 women are diagnosed and treated for cancer that would not otherwise have become apparent in their lifetimes.[6] A study involving women from 30 European countries showed that the mean decrease in breast cancer mortality between 1989 and 2005 among women less than 50 years of age was 37%; the corresponding decrease was 21% among women aged 50 to 69 years.[7] The declines in mortality, however, began before the start of organized screening programs in many countries and may possibly be the result of tamoxifen treatment.[3] Another study compared three pairs of similar neighboring countries where screening was introduced 10 to 15 years apart.[8] The pairs were Northern Ireland and the Republic of Ireland, the Netherlands and Belgium, and Sweden and Norway. There was no relationship between the start of screening mammography and reduction in breast cancer mortality.[8]

Authors state that most publications on mammography screening have examined the effects on mortality separately from harms, such as overtreatment.[9] The Canadian Task Force on Preventive Health Care has new recommendations for screening for breast cancer in women at average risk aged 40 to 74 years.[10] These new guidelines are cautious, advising against routine screening in women aged 40 to 49 years. This Task Force recommends screening women aged 50 to 69 years every 2 to 3 years, admitting that this is a weak recommendation based on moderate-quality evidence, and screening women aged 70 to 74 years on the same schedule based on low-quality evidence.[11] This Task Force suggested that women who do not place a high value on a small reduction in breast cancer mortality from screening and those who are concerned about false-positives on mammography and overdiagnosis may decline screening.[10] The United States Preventive Services Task Force (USPSTF) recommendations include the following:

- The USPSTF recommends biennial screening mammography for women aged 50 to 74 years.
  Grade: B Recommendation
- The decision to start regular, biennial screening mammography before the age of 50 years should be an individual one and take the woman's context into account, including the woman's values regarding specific benefits and harms.
  Grade: C Recommendation
- The USPSTF concludes that the current evidence is insufficient to assess the additional benefits and harms of screening mammography in women 75 years or older.
  Grade: I Statement
- The USPSTF recommends against teaching breast self-examination (BSE).
  Grade: D Recommendation
- The USPSTF concludes that the current evidence is sufficient to assess the additional benefits and harms of clinical breast examination (CBE) beyond screening mammography in women 40 years or older.
  Grade: I Statement
- The USPSTF concludes that the current evidence is insufficient to assess the additional benefits and harms of either digital mammography or magnetic resonance imaging (MRI) instead of film mammography as screening modalities for breast cancer.
  Grade: I Statement
- Overall, considering benefits, overdiagnosis, overtreatment, and potential harms, including unnecessary surgery, radiotherapy, increased number of biopsies, and administration of toxic drugs, *all* of which may contribute to the biology of breast carcinogenesis, there will be continued debate regarding the role of screening mammography in decreasing breast cancer mortality.

in the beginning of this chapter. The classification of the cancer can be further facilitated by a variety of clinically available tests, including immunohistochemical stains, flow cytometry, electron microscopy, chromosome analysis, and nucleic acid–based molecular studies.

If the diagnosis of cancer is established, it is critical to determine if the cancer has spread, known as the **stage** of the cancer. Staging initially involves determining the size of the tumor, the degree to which it has locally invaded, and the extent to which it has spread (metastasized) (Figure 12-25). Specific molecular

TABLE 12-9 OBTAINING TISSUE—THE BIOPSY

PROCEDURE	PURPOSE	EXAMPLE
Excisional biopsy	Complete removal, usually with a margin of normal tissue	Full resection (e.g., mastectomy, partial colectomy)
Incisional biopsy	Removal of a portion of a lesion	Lymph node biopsy, muscle mass biopsy
Core needle biopsy	Often performed with direct vision, or guided with ultrasound or computed tomography (CT)	Needle biopsy of prostate or liver mass
Fine needle aspiration	Obtains dissociated cells for cytologic study but does not preserve tissue structure	Thyroid, breast mass
Exfoliative cytology	Cells shed from the surface, for example, from cervix, sputum (lung) or urine	Brushings from lung or colon endoscopy

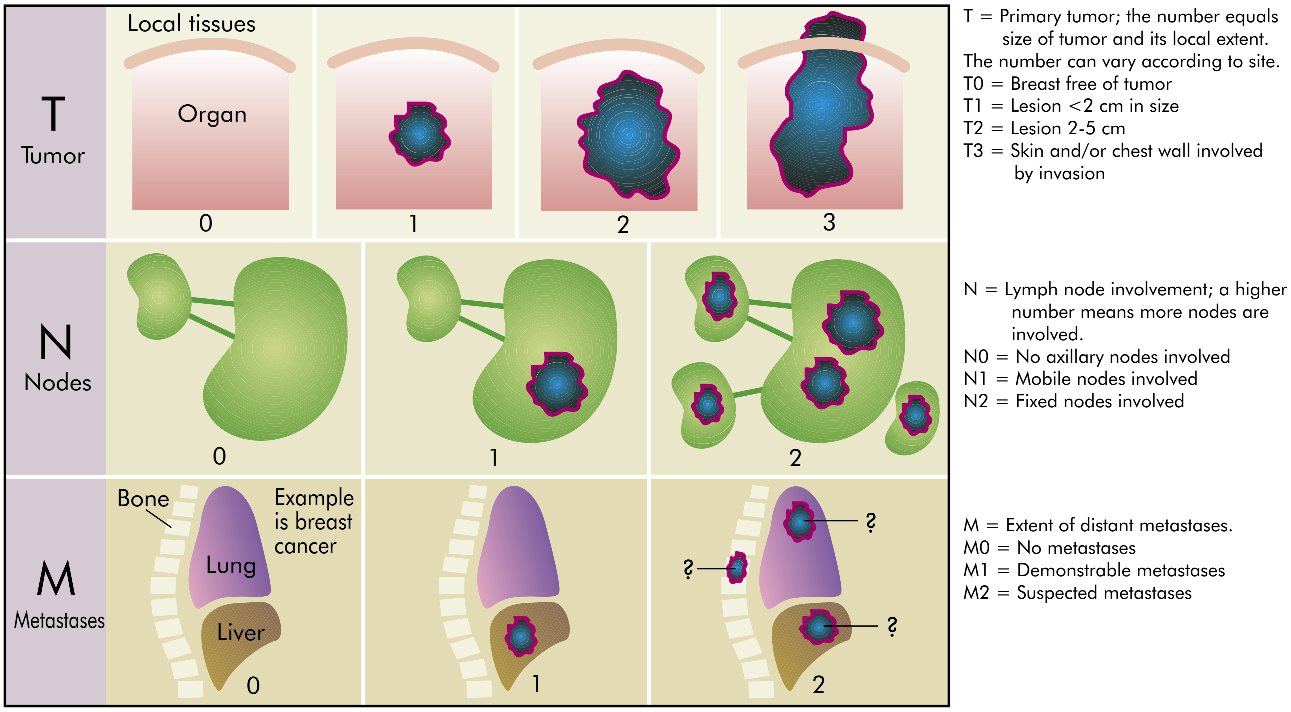

FIGURE 12-25 **Tumor Staging by the TNM System.** Example of staging for breast cancer.

tests are increasingly used in staging as well. Diverse schemes are used for staging different tumors. In general, a four-stage system is used, with carcinoma in situ regarded as a special case. Cancer confined to the organ of origin is stage 1; cancer that is locally invasive is stage 2; cancer that has spread to regional structures, such as lymph nodes, is stage 3; and cancer that has spread to distant sites, such as a liver cancer spreading to the lung or a prostate cancer spreading to bone, is stage 4. One common scheme for standardizing staging is the World Health Organization's TNM system: *T* indicates tumor spread, *N* indicates node involvement, and *M* indicates the presence of distant metastasis (see Figure 12-25). The prognosis generally worsens with increasing tumor size, lymph node involvement, and metastasis (Table 12-10). Staging also may alter the choice of therapy, with more aggressive therapy being delivered to more invasive disease.

TABLE 12-10 CANCER SURVIVAL DEPENDS ON TUMOR TYPE AND STAGE OF DISEASE

	STAGE			
DISEASE	I	II	III	IV
Colon cancer	>90	75	50	<10
Hodgkin disease	99	95	85	70
Pancreatic cancer	37	26	10	1

Comment: Estimated percentage of individuals surviving 5 years for selected tumors, by stage at diagnosis. Additional factors such as age, molecular lesions, histologic subtypes, and type of treatment modify the outcome as well.

Paraneoplastic Syndromes

Paraneoplastic syndromes are symptom complexes that are triggered by a cancer but are not caused by direct local effects of the tumor mass. They are most commonly caused by biologic substances released from the tumor (e.g., hormones) or by an immune response triggered by the tumor. For example, a small fraction of carcinoid tumors release hormones, including serotonin, into the bloodstream that cause flushing, diarrhea,

TABLE 12-11 **PARANEOPLASTIC SYNDROMES**

CLINICAL SYNDROMES	MAJOR FORMS OF UNDERLYING CANCER	CAUSAL MECHANISM
Endocrinopathies		
Cushing syndrome	Small cell carcinoma of lung Pancreatic carcinoma Neural tumors	ACTH or ACTH-like substance
Syndrome of inappropriate antidiuretic hormone (SIADH) secretion	Small cell carcinoma of lung; intracranial neoplasms	Antidiuretic hormone or atrial natriuretic hormones
Hypercalcemia	Squamous cell carcinoma of lung Breast carcinoma Renal carcinoma Adult T-cell leukemia/lymphoma Ovarian carcinoma	Parathyroid hormone–related protein (PTHRP), TGF-α, TNF, IL-1
Hypoglycemia	Fibrosarcoma Other mesenchymal sarcomas Hepatocellular carcinoma	Insulin or insulin-like substance
Carcinoid syndrome	Bronchial adenoma (carcinoid) Pancreatic carcinoma Gastric carcinoma	Serotonin, bradykinin
Polycythemia	Renal carcinoma Cerebellar hemangioma Hepatocellular carcinoma	Erythropoietin
Nerve and Muscle Syndrome		
Myasthenia	Bronchogenic carcinoma	Immunologic
Disorders of central and peripheral nervous systems	Breast carcinoma	
Dermatologic Disorders		
Acanthosis nigricans	Gastric carcinoma Lung carcinoma Uterine carcinoma	Immunologic; secretion of epidermal growth factor
Dermatomyositis	Bronchogenic, breast carcinoma	Immunologic
Osseous, Articular, and Soft Tissue Changes		
Hypertrophic osteoarthropathy and clubbing of the fingers	Bronchogenic carcinoma	Unknown
Vascular and Hematologic Changes		
Venous thrombosis (Trousseau phenomenon)	Pancreatic carcinoma Bronchogenic carcinoma Other cancers	Tumor products (mucins that activate clotting)
Nonbacterial thrombotic endocarditis	Advanced cancers	Hypercoagulability
Anemia	Thymic neoplasms	Unknown
Others		
Nephrotic syndrome	Various cancers	Tumor antigens, immune complexes

wheezing, and rapid heartbeat. A number of cancers trigger an antibody response that attacks the nervous system, causing a variety of neurologic disorders that can precede other symptoms of cancer by months.[91]

Although infrequent, paraneoplastic syndromes are significant because they may be the earliest symptom of an unknown cancer and, in affected individuals, can be serious, often irreversible, and sometimes life-threatening. Table 12-11 presents the classifications of paraneoplastic syndromes. Other clinical manifestations of cancer are summarized in Box 12-2.

Cancer Treatment

The diagnosis of cancer has a profound effect on individuals and their families. Responses range from depression to resigned fatalism to an aggressive no-holds-barred pursuit of therapy. The choice of therapy should be based on a full consideration of the individual's diagnosis, prognosis, and therapeutic options by the individual, the family, and the medical team. Many types of cancer can be effectively treated with chemotherapy, radiotherapy, surgery, and combinations of these modalities. Caregivers must recognize that many individuals seek additional

BOX 12-2 SUMMARY OF OTHER CLINICAL MANIFESTATIONS OF CANCER

Pain: There is little or no pain during the early stages of malignant disease. Significant pain can occur in many individuals who are terminally ill with cancer. Direct pressure, obstruction, invasion of a sensitive structure, stretching of visceral surfaces, tissue destruction, infection, and inflammation all can cause pain.

Fatigue: The most frequently reported symptom of cancer and cancer treatment. The exact mechanisms that produce fatigue are poorly understood. Suggested causes include sleep disturbances, various biochemical changes secondary to disease and treatment, numerous psychosocial factors, level of activity, nutritional status, and other environmental and physical factors.

Cachexia: A syndrome that includes many symptoms including anorexia, early satiety (filling), weight loss, anemia, asthenia (marked weakness), taste alterations, and altered protein, lipid, and carbohydrate metabolism. It is the most severe form of malnutrition associated with cancer and results in wasting, emaciation, and decreased quality of life. Cytokines and metabolites from the tumor may contribute to cachexia.

Anemia: Commonly associated with malignancy, with 20% of persons diagnosed with cancer having hemoglobin concentrations less than 9 g/dl (normal value = 15 g/dl). Mechanisms of anemia include chronic bleeding (resulting in iron deficiency), severe malnutrition, cytotoxic chemotherapy, and malignancy in blood-forming organs. Chronic bleeding and iron deficiency can accompany colorectal or genitourinary malignancy. Iron also is malabsorbed in individuals with gastric, pancreatic, or upper intestinal cancer.

Leukopenia and Thrombocytopenia: Causes can include many chemotherapeutic drugs because they are toxic to the bone marrow, often causing granulocytopenia and thrombocytopenia. Granulocytopenia also can result from radiation therapy if it encompasses significant areas of the bone marrow. Thrombocytopenia is a major cause of hemorrhage in people with cancer and is often treated with platelet transfusions. Thrombocytopenia is a disorder of disseminated intravascular coagulation that occurs in individuals with acute promyelocytic leukemia and severe infections.

Infection: The most significant cause of complications and death in patients with malignant disease. When the absolute granulocyte count falls below 500 cells per μL, the risk of serious microbial (bacterial and fungal) infection increases. Advanced disease can predispose to infection and immunosuppression from the underlying cancer and the radiotherapy and chemotherapy used to treat it. (Factors that predispose individuals with cancer to infection are summarized in Table 12-12.) The prevalence of hospital-acquired (nosocomial) infections increases because of indwelling medical devices, inadequate wound care, and the introduction of microorganisms from visitors and other individuals.

Gastrointestinal Tract (GI): The GI tract relies on rapidly growing cells to produce an effective barrier to trauma and infection and to provide an absorptive surface for nutrients. Chemotherapy and radiation therapy may cause a decreased cell turnover, thereby leading to oral ulcers (stomatitis), malabsorption, and diarrhea. The disruption of barrier defenses also increases the risk for infection, especially invasion by a person's own GI flora.

Hair Loss (Alopecia) and Skin: Results from chemotherapy effects on hair follicles. It is usually temporary, although hair may regrow with a different texture initially. Not all chemotherapeutic agents cause alopecia. Decreased renewal rates of the epidermal layers in the skin may lead to skin breakdown and dryness, altering the normal barrier protection against infection. Radiation therapy may cause skin erythema (redness) and contribute to breakdown.

Data from Miller AH et al: *J Clin Oncol* 26(6):971–982, 2008; Pachman DR et al: *J Clin Oncol* 30(30):3687–3695, 2012.

non–science-based explanations and therapies and often use alternative therapies, either concurrently or sequentially. Alternative therapies can be biologically harmless or harmful; rarely is there any evidence they are medically effective and in the worst cases they can be expensive, delay the use of effective therapies, and produce unknown side effects. A challenge for the medical team is to provide the same level of psychosocial comfort and support that alternative therapies can provide, while also providing scientifically rational evidence-based therapies.

Chemotherapy

The era of modern chemotherapy began with the observation in World War II that mustard gas exposure caused suppression of the bone marrow. Related compounds, such as nitrogen mustard and cyclophosphamide, were then tested and produced clinical responses in hematologic malignancies, including lymphomas. Also in the late 1940s, based on the remarkable clinical observation that the vitamin folic acid could *increase* leukemia growth, anti–folate drugs were developed (leading ultimately to methotrexate) that produced remissions in previously untreatable leukemias.[92]

All chemotherapeutic agents take advantage of specific vulnerabilities in target cancer cells. Antimetabolites, such as methotrexate and L-asparaginase, block normal growth pathways in all cells, but leukemia and other cancer cells are exquisitely sensitive to folic acid and asparagine deprivation, whereas nonmalignant cells are far less sensitive. Similarly, some cancer cells are highly sensitive to DNA-damaging agents, such as cyclophosphamide and anthracyclines, because of the oncogenic mutations that accelerate the cell cycle and DNA synthesis. Cellular checkpoints prevent normal cells treated with microtubule-directed drugs, such as vincristine and the taxanes, from undergoing mitosis, whereas cancer cells treated with these agents lack normal checkpoints, continue through mitosis, and undergo mitotic catastrophe (see Chapter 1).

Single chemotherapeutic agents often shrink cancers, but these drugs given alone rarely if ever provide a cure. Hence, chemotherapy drugs are usually given in combinations designed to attack a cancer from many different weaknesses at the same time and to limit the dose and therefore the toxicity of any single agent. Cancers contain a very large number of cells, and commonly a small fraction of those cells may be resistant to a particular drug. However, those cells are likely to be sensitive to the second or third drug in a chemotherapy cocktail. Scheduling of drug administration is also very important, with many studies showing cancers are more likely to develop drug resistance if there are significant delays between planned courses of chemotherapy.

The newest highly targeted agents used to treat cancer exploit specific vulnerabilities uncovered by molecular analysis in specific diseases. These new drugs are still used in combination with conventional chemotherapy and to be effective they must be used in diseases in which the molecular target is present. For example, imatinib is a competitive inhibitor of

TABLE 12-12 FACTORS PREDISPOSING INDIVIDUALS WITH CANCER TO INFECTION

FACTOR	BASIS
Age	Many common malignancies occur mostly in older age. Immunologic functions decline with age. General debility reduces immunocompetence. Immobility predisposes to infection. Far-advanced cancer often results in immobility and general debility that worsens with age. Elderly persons are predisposed to nutritional inadequacies. Malnutrition impairs immunocompetence.
Tumor	Nutritional derangements can result. Sites and circumstances favorable to growth of microorganisms (obstruction, serous or blood effusion, ulceration) can be created. Far-advanced disease predisposes patients to debility and immobility. Humoral or cellular immune defects may result. Metastasis to bone marrow may cause leukopenia or other defects in immunity.
Leukemias	Inadequate granulocyte production (impaired phagocytosis) results. Thrombocytopenia (bleeding, breaks in skin integrity) can occur. Late effect: Chronic lung disease from *Pneumocystis jiroveci* pneumonia can develop during therapy.
Lymphomas and other mononuclear phagocyte malignancies	Humoral and cellular immune defects (anergy, altered immunoglobulin production) result. Late effect: Splenectomy in children can cause increased susceptibility to infection.
Surgical treatment	Invasive procedure interrupts first lines of defense. Radical nature of surgery (removal of large blocks of tissue in lengthy procedures) causes hemorrhage, decreased tissue perfusion, creation of dead spaces, devitalization of tissues. Procedure may be "dirty" surgery (bowel, infected or contaminated areas). Surgery patients are often older and at poor risk. Long preoperative hospitalization often precedes surgery. Patients may have received previous adrenocorticosteroid therapy. Patients may have infections at sites remote from operative area. Nutritional derangements (especially important in head and neck surgery) may result. Lymph node dissection may predispose patient to local infection and impair containment to area. Gynecologic surgery may result in fistulae. Lung surgery may cause bronchopleural fistulae. Debility and immobility may result.

Data from Donovan MI, Girton SF: *Cancer care nursing,* ed 2, New York, 1984, Appleton-Century-Crofts; Murphy GP, Lawrence W, Lenhard RE: *Clinical oncology,* ed 2, New York, 1994, American Cancer Society.

tyrosine kinases, primarily the BCR-ABL tyrosine kinase. It is highly effective in treating CML and gastrointestinal stromal tumor (GIST) but ineffective in virtually all other cancers. Several monoclonal antibodies directed against cellular receptors or cell surface antigens are in use or being evaluated. These include antibodies against the CD20 antigen expressed on some B-cell lymphomas, the epidermal growth factor (EGF) receptor on colon cancers and head and neck cancers, and the HER2 EGF receptor on breast cancer. Fortunately, because these drugs are so tightly targeted they have much less toxicity than conventional chemotherapies that have targets in virtually all cells.

Chemotherapy can be used for several distinct purposes. **Induction chemotherapy** seeks to cause shrinkage or disappearance of tumors. In Hodgkin disease, for example, chemotherapy alone can be used in some cases to cure the disease. In other settings, chemotherapy may shrink the tumor and improve symptoms without ultimately providing a cure. **Adjuvant chemotherapy** is given after surgical excision of a cancer with the goal of eliminating micrometastases. **Neoadjuvant chemotherapy** is given before localized (surgical or radiation) treatment of a cancer. As with induction chemotherapy, the effectiveness, or lack thereof, of neoadjuvant therapy can be measured (for example, with follow-up scans). Neoadjuvant therapy can shrink a cancer so that surgery may spare more normal tissue. For example, in the bone cancer *osteogenic sarcoma,* neoadjuvant therapy often converts a large tumor mass into a much smaller mass, allowing the surgeon to perform a limb-sparing excision rather than an amputation.

Radiation Therapy

Radiation therapy is used to kill cancer cells while minimizing damage to normal structures. Ionizing radiation damages cells by imparting enough energy to cause molecular damage, especially to DNA. The damage may be lethal, in which the cell is killed by radiation; potentially lethal, in which the cell is so severely affected by radiation that modifications in its environment will cause it to die; or sublethal, in which the cell can subsequently repair itself. Cellular compartments with rapidly renewing cells are, in general, more radiosensitive. Effective cell killing by radiation also requires good local delivery of oxygen,

something not always present in large cancers. Radiation produces slow changes in most cancers and irreversible changes in normal tissues as well. Because of these irreversible changes, each tissue has a maximum lifetime dose of radiation it can tolerate. Radiation is well suited to treat localized disease in areas that are hard to reach surgically, for example, in the brain and pelvis. A number of radiation delivery methods are available, with external beam being the most common. Radiation sources, such as small ^{125}I-labeled capsules (also called seeds), can also be temporarily placed into body cavities, a delivery method termed **brachytherapy.** Brachytherapy is useful in the treatment of cervical, prostate, and head and neck cancers.

Radiation therapy and chemotherapy may affect the gametes, leading to varying degrees of decreased fertility and premature menopause. These effects are dose and age dependent, with the prepubertal gonad thought to be more resistant to damage. The potential for harm also is dependent on the agent used, with the alkylating category of chemotherapies carrying the greatest risk. Craniospinal irradiation for central nervous system tumors also may affect the hypothalamus or pituitary gland, with subsequent secondary gonadal failure because of lack of production of gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimulating hormone. The potential for reproductive harm should be addressed before therapy, if possible, with provisions made for sperm or embryo banking.

Surgery

Surgery plays many roles in the care of individuals with cancer. The multiple approaches to obtaining tissue for diagnosis have been discussed. Surgery is often the definitive treatment of cancers that do not spread beyond the limits of surgical excision. It is also indicated for the relief of symptoms, such as those caused by tumor mass obstruction. In selected high-risk diseases, surgery plays a role in the prevention of cancer. For example, individuals with familial adenomatous polyposis because of germline mutations of the *APC* gene have close to a 100% lifetime risk of colon cancer, so a prophylactic colectomy is indicated. Similarly, women with *BRCA1/2* mutations have a markedly increased risk of breast and ovarian cancer, and often choose prophylactic mastectomy or bilateral salpingo-oophorectomy (removal of ovaries and fallopian tubes), or both.[93]

Key principles apply specifically to cancer surgery, including obtaining adequate surgical margins during a resection to prevent local recurrences, placing needle tracks and biopsy incision scars (that may be contaminated with cancer cells) carefully so they can be removed in subsequent incisions, avoiding the spread of cancer cells during surgical procedures through careful technique, and paying attention to obtaining adequate tissue specimens during biopsies so that the pathologist can be confident of the diagnosis. Additionally, the surgeon provides critical staging information by inspection, sampling, and removal of local and regional lymph nodes during procedures.

SUMMARY REVIEW

Cancer Characteristics and Terminology

1. Benign tumors are usually encapsulated and well differentiated and do not spread to distant locations.
2. Malignant tumors, compared with benign tumors, have more rapid growth rates, specific microscopic alterations (anaplasia, loss of differentiation), absence of normal tissue organization, and no capsule; they invade blood vessels and lymphatics and have distant spread.
3. Carcinomas arise from epithelial tissue, and leukemias are cancers of blood-forming cells. CIS refers to preinvasive epithelial tumors of glandular or squamous cell origin.
4. Localized cancer is considered low stage, whereas cancer that has spread regionally and distantly is termed stage 3 and stage 4, respectively.
5. Cancer cells are characterized by anaplasia, or loss of differentiation, and autonomy, or independence, from normal cellular controls.
6. In the adult, undifferentiated cells not committed to a specific function are known as pluripotent cells, precursor cells, or adult stem cells. Cancerous growth depends on derangements of cell differentiation.
7. Tumor markers are substances (i.e., hormones, enzymes, genes, antigens, antibodies) found in cancer cells and in blood, spinal fluid, or urine. They are used to screen and identify individuals at high risk for cancer, to help diagnose specific types of tumors, and to follow the clinical course of cancer.

The Genetic Basis of Cancer

1. Genetic events are the primary basis of carcinogenesis. Mutations in cancer-causing genes accumulate with age, causing the increasing risk of cancer with advanced age.
2. Epidemiologic and molecular data suggest it takes five or six distinct mutations in different signaling pathways to produce cancer. Mutations activate growth-promotion pathways, block antigrowth signals, prevent apoptosis, turn on telomerase and new blood vessel growth, and allow tissue invasion and distant metastasis.
3. In rare families, cancer is inherited in an autosomal dominant fashion as a result of mutations in tumor-suppressor genes such as *TP53, RB1,* and *BRCA1.*
4. Proto-oncogenes encode for growth factors (e.g., PDGF), growth factor receptors (e.g., HER2), signal transducers (e.g., RAS), and nuclear growth–promoting proteins (e.g., MYC).
5. Three key genetic mechanisms have a role in human carcinogenesis: (a) activation of proto-oncogenes resulting in hyperactivity of growth-related gene products (such genes are called *oncogenes*); (b) mutation of genes resulting in loss or inactivity of gene products that normally would inhibit growth (such genes are called *tumor-suppressor genes*); and (c) mutation of genes resulting in overexpression of products that prevent normal cell death, or apoptosis, thus allowing continued growth of tumors.
6. Tumor-suppressor genes encode for proteins that act as inhibitors of growth factor stimulation. Tumor-suppressor gene proteins block specific phases of the cell cycle, induce

SUMMARY REVIEW — cont'd

end-stage (e.g., terminal) differentiation, and stimulate cell senescence or death.

7. Carcinogenesis, or the development of cancer, involves both inactivation of tumor-suppressor genes (usually by loss of heterozygosity, or by "silencing") and activation of oncogenes.
8. Epigenetic changes in genes by DNA methylation and covalent histone modification can mimic mutation by heritably inactivating tumor-suppressor genes.
9. Like many normal adult tissues, cancers can contain rare stem cells. To fully eradicate a cancer, it may be necessary to target the cancer stem cell.
10. Caretaker genes are responsible for maintaining genomic integrity. Inherited mutations can disrupt caretaker genes and cause chromosome instability.
11. A number of viruses can cause cancer. Human cervical cancer is caused by papillomavirus infection. Kaposi sarcoma is caused by infection with HHV8, a member of the Herpesviridae family. Chronic hepatitis infection with HBV or HCV is the leading cause of liver cancer.
12. Defects in the immune system increase the risk of viral-associated cancers but have a minimal effect on the risk of other cancers.
13. Active inflammation predisposes to cancer by stimulating a wound-healing response that includes proliferation and new blood vessel growth.
14. Vaccinations can prevent hepatitis B–associated liver cancer and many human papillomavirus-caused cervical cancers.
15. Chronic *H. pylori–associated inflammation* causes stomach cancer and a rare lymphoma.
16. Metastasis is the major cause of death from cancer.
17. Cancers metastasize by several routes, including direct invasion and spread through lymphatics and veins.
18. Metastasis is a complex process that requires cells to have many new abilities, including the ability to invade, survive, and proliferate in a new environment and recruit new blood vessel growth.
19. Carcinomas undergo a process of epithelial-mesenchymal transition (EMT) during which many epithelial-like characteristics are lost (e.g., polarity, adhesion to basement membrane) resulting in increased migratory capacity, increased resistance to apoptosis, and dedifferentiation to a stem cell–like state that favors growth in foreign microenvironments and establishment of metastatic disease.

Clinical Manifestations

1. Clinical manifestations of cancer include fatigue, pain, cachexia, anemia, leukopenia, thrombocytopenia, and infection.
2. Paraneoplastic syndromes are rare symptom complexes often caused by release of active substances from or stimulation of an immune response by a cancer that causes symptoms not directly produced by the local effects of the cancer.
3. Pain is generally associated with the late stages of cancer. It can be caused by pressure, obstruction, invasion of a structure sensitive to pain, stretching, tissue destruction, and inflammation.
4. Fatigue is the most frequently reported symptom of cancer and cancer treatment.
5. Cachexia (loss of appetite, early satiety, weakness, inability to maintain weight, taste alterations, altered metabolism) leads to protein-calorie malnutrition and progressive wasting.
6. Anemia associated with cancer usually occurs because of malnutrition, chronic bleeding and resultant iron deficiency, chemotherapy, radiation, and malignancies in the blood-forming organs.
7. Leukopenia is usually a result of chemotherapy (which is toxic to bone marrow) or radiation.
8. Infection may be caused by leukopenia, immunosuppression, or debility associated with advanced disease. It is the most significant cause of complications and death.

Cancer Treatment

1. Cancer is treated with surgery, radiation therapy, chemotherapy, and combinations of these modalities.
2. The theoretic basis of chemotherapy is the vulnerability of tumor cells in various stages of the cell cycle. The goal of chemotherapy is to eradicate enough tumor cells so the body's natural defenses can eradicate remaining cells.
3. Modern chemotherapy uses combinations of drugs with different targets and different toxicities.
4. A new generation of specific targeted drugs attacks targets identified by the molecular analysis of cancers.
5. Ionizing radiation causes cell damage, so the goal of radiation therapy is to damage the tumor without causing excessive toxicity or damage to undiseased structures.
6. Surgical therapy is used for nonmetastatic disease, for which cure is possible by removing the tumor, and as a palliative measure to alleviate symptoms.

CHAPTER OUTLINE

Although cancer arises from a complicated and an interacting web of multiple etiologies, avoiding high-risk behaviors and exposure to individual **carcinogens,** or cancer-causing substances, will prevent many types of cancer (Figure 13-1).[1-3] Research has shown that lifestyle behaviors, dietary and environmental factors (such as exposure to ultraviolet radiation and infections), and occupational exposure contribute to the number of cancer cases and deaths.[4-6] In this context, any of the following factors can contribute to the development of cancer[7-9]:

- Lifestyle choices, such as nutritional intake, smoking, or alcohol use
- Environmental conditions, including exposure to sunlight, natural and medical radiation, workplace exposures, and involuntary or unknown exposures
- Lack of physical exercise and overweight/obesity
- Sexual practices
- Prescribed and illicit medications
- Socioeconomic factors that affect exposures and susceptibility
- Carcinogenic substances present in air, water, and soil

The question of estimating the environmentally attributable risk for cancer is deceptive because such estimates vary tremendously as a result of the definition of the environment used. Therefore, another way of examining what portion of cancer risk is attributable to the environment involves asking, "What is not attributable to the environment?"[10] In this context, it is usually those cancers caused by highly penetrant genes; inherited mutations very rarely predispose us to cancer.[11-14] The International Agency for Research on Cancer (IARC) completed a review of the more than 100 chemicals, occupations, physical

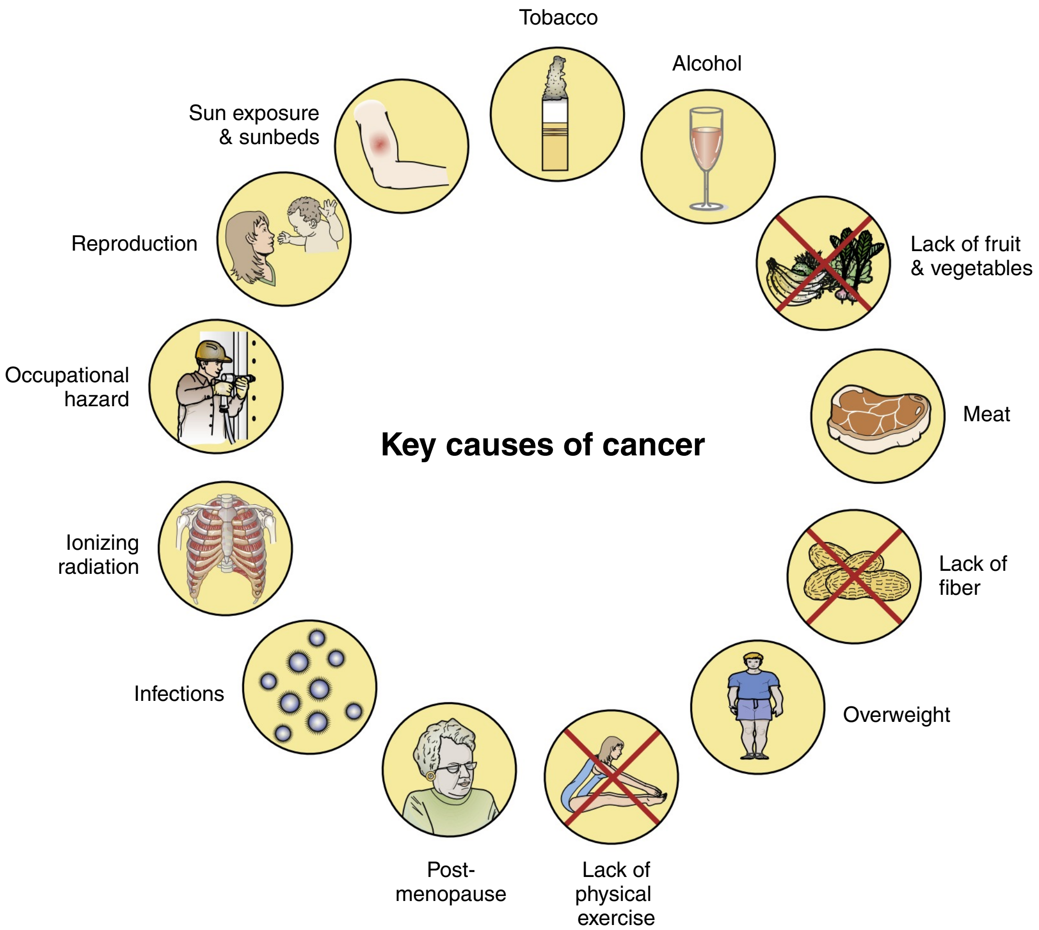

FIGURE 13-1 Key Causes of Cancer. Tobacco, diet and alcohol, obesity, lack of physical activity, hormones, infections, ionizing radiation, occupational hazards, reproductive factors, and ultraviolet light are key causes of cancer.

agents, biologic agents, and other agents classified as carcinogenic to humans.[7] Simplified tables with a list of classifications by cancer sites with sufficient or limited evidence in humans are contained in Table 13-1.

GENETICS, EPIGENETICS, AND TISSUE

Cancers are caused by environmental-lifestyle behaviors and by exposures and genetic factors. Cancer is driven by genetic alterations and epigenetic abnormalities (see Chapter 12).[15-18] These changes are mitotically and meiotically heritable[19,20] (see Chapter 4). Although driver and passenger genetic alterations are key, a wealth of data now indicate the importance of epigenetic processes, especially those with resultant gene silencing (not broken, but mute) of key regulatory genes (see Chapters 6 and 12 and Figure 13-2).

There has been intense scrutiny of the biology of aberrant gene silencing and associated environmental factors. Much research has focused on the abnormal appearance of an epigenetic alteration—DNA methylation (the addition of a methyl group [CH_3])—in the proximal promoter regions of associated genes (see Figure 13-2, *B*). Some of these genes are known as key tumor-suppressor genes.[15-18,21] The promoter DNA hypermethylation and gene silencing (i.e., epigenetic alterations) cause a loss of function and this loss facilitates tumor initiation and progression[15-18,21] (see Chapter 11).

Cancer development and progression involves the tissue microenvironment or stroma (see Chapter 12). The microenvironment participates in a complex signaling process that facilitates tumor promotion and metastasis because stromal tissue has various immune cells. Extensive clinical and experimental evidence shows that infiltrating immune cells cause chronic inflammation and, therefore, create a permissive tumor-progressing environment. Chronic inflammation also can *precede* and presumably initiate malignant change, as for example in inflammation-induced colon cancer.[22] It is well documented that chronic inflammation induced by bacteria, viruses, autoimmune processes, and toxins promotes common types of cancer, including colon, liver, and lung cancer. Inflammation can be caused by numerous environmental factors, for example, inhaling tobacco smoke, asbestos fibers, or fine particles in the air from diesel engine exhaust and industrial sources. These sources are major factors in lung and other respiratory tract cancers.[23,24] Cancer development in the presence of chronic inflammation involves the continuous presence of cytokines, chemokines, reactive oxygen species (ROS), oncogenes, cyclooxgenase-2 (COX-2), 5-lipoxygenase (5-LOX), and matrix metalloproteinases (MMPs) as well as the activation of essential transcription factors, such as nuclear factor κB (NF-κB).

TABLE 13-1 LIST OF CLASSIFICATIONS BY CANCER SITES WITH SUFFICIENT OR LIMITED EVIDENCE IN HUMANS

CANCER SITE	CARCINOGENIC AGENTS WITH SUFFICIENT EVIDENCE IN HUMANS	AGENTS WITH LIMITED EVIDENCE IN HUMANS
Lip, Oral Cavity, and Pharynx		
Lip		Solar radiation
Oral cavity	Alcoholic beverages	
	Betel quid with tobacco	
	Betel quid without tobacco	
	Human papillomavirus type 16	
	Tobacco, smokeless	
	Tobacco smoking	
Salivary gland	X-radiation, γ-radiation	Radioiodines, including iodine-131
Tonsil	Human papillomavirus type 16	
Pharynx	Alcoholic beverages	Asbestos (all forms)
	Betel quid with tobacco	Mate drinking, hot
	Human papillomavirus type 16	Printing presses
	Tobacco smoking	Tobacco smoke, secondhand
Nasopharynx	Epstein-Barr virus	
	Formaldehyde	
	Salted fish, Chinese-style	
	Wood dust	
Digestive tract, upper	Acetaldehyde associated with consumption of alcoholic beverages	
Digestive Organs		
Esophagus	Acetaldehyde associated with consumption of alcoholic beverages	Dry cleaning
	Alcoholic beverages	Mate drinking, hot
	Betel quid with tobacco	Pickled vegetables (traditional Asian)
	Betel quid without tobacco	Rubber production industry
	Tobacco, smokeless	Tetrachloroethylene
	Tobacco smoking	
	X-radiation, γ-radiation	
Stomach	*Helicobacter pylori*	Asbestos (all forms)
	Rubber production industry	Epstein-Barr virus
	Tobacco smoking	Lead compounds, inorganic
	X-radiation, γ-radiation	Nitrate or nitrite (ingested) under conditions that result in endogenous nitrosation
		Pickled vegetables (traditional Asian)
		Salted fish (Chinese style)
Colon and rectum	Alcoholic beverages	Asbestos (all forms)
	Tobacco smoking	*Schistosoma japonicum*
	X-radiation, γ-radiation	
Anus	Human immunodeficiency virus type 1	Human papillomavirus types 18, 33
	Human papillomavirus type 16	
Liver and bile duct	Aflatoxins	Androgenic (anabolic) steroids
	Alcoholic beverages	Arsenic and inorganic arsenic compounds
	Clonorchis sinensis	Betel quid without tobacco
	Estrogen-progestogen contraceptives	Human immunodeficiency virus type 1
	Hepatitis B virus	Polychlorinated biphenyls
	Hepatitis C virus	*Schistosoma japonicum*
	Opisthorchis viverrini	Trichloroethylene
	Plutonium	X-radiation, γ-radiation
	Thorium-232 and its decay products	
	Tobacco smoking (in smokers and in smokers' children)	
	Vinyl chloride	
Gallbladder	Thorium-232 and its decay products	
Pancreas	Tobacco, smokeless	Alcoholic beverages
	Tobacco smoking	Thorium-232 and its decay products
		X-radiation, γ-radiation
Digestive tract, unspecified		Radioiodines, including iodine-131

TABLE 13-1 LIST OF CLASSIFICATIONS BY CANCER SITES WITH SUFFICIENT OR LIMITED EVIDENCE IN HUMANS—cont'd

CANCER SITE	CARCINOGENIC AGENTS WITH SUFFICIENT EVIDENCE IN HUMANS	AGENTS WITH LIMITED EVIDENCE IN HUMANS
Respiratory Organs		
Nasal cavity and paranasal sinus	Isopropyl alcohol production	Carpentry and joinery
	Leather dust	Chromium (VI) compounds
	Nickel compounds	Formaldehyde
	Radium-226 and its decay products	Textile manufacturing
	Radium-228 and its decay products	
	Tobacco smoking	
	Wood dust	
Larynx	Acid mists, strong inorganic	Human papillomavirus type 16
	Alcoholic beverages	Mate drinking, hot
	Asbestos (all forms)	Rubber production industry
	Tobacco smoking	Sulfur mustard
		Tobacco smoke, secondhand
Lung	Aluminum production	Acid mists, strong inorganic
	Arsenic and inorganic arsenic compounds	Art glass, glass containers, and pressed ware (manufacture of)
	Beryllium and beryllium products	Biomass fuel (primarily wood), indoor emissions from household combustion of
	Bis(chloromethyl) ether; chloromethyl methyl ether (technical grade)	Bitumens, oxidized, and their emissions during roofing
	Cadmium and cadmium compounds	Bitumens, hard, and their emissions during mastic asphalt work
	Chromium (VI) compounds	Carbon electrode manufacture
	Coal, indoor emissions from household combustion	α-Chlorinated toluenes and benzyl chloride (combined exposure)
	Coal gasification	Cobalt metal with tungsten carbide
	Coal-tar pitch	Creosotes
	Coke production	Engine exhaust, diesel
	Hematite mining (underground)	Frying, emissions from high-temperature
	Iron and steel founding	Insecticides, nonarsenical (occupational exposures in spraying and application)
	MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture)	Printing processes
	Nickel compounds	2,3,7,8-Tetrachlorodibenzo-*para*-dioxin
	Painting	Welding fumes
	Plutonium	
	Radon-222 and its decay products	
	Rubber production industry	
	Silica dust, crystalline	
	Soot	
	Sulfur mustard	
	Tobacco smoke, secondhand	
	Tobacco smoking	
	X-radiation, γ-radiation	
Bone, Skin, and Mesothelium, Endothelium, and Soft Tissue		
Bone	Plutonium	Radioiodines, including iodine-131
	Radium-224 and its decay products	
	Radium-226 and its decay products	
	Radium-228 and its decay products	
	X-radiation, γ-radiation	
Skin (melanoma)	Solar radiation	
	Ultraviolet-emitting tanning devices	
Skin (other malignant neoplasms)	Arsenic and inorganic arsenic compounds	Creosotes
	Azathioprine	Human immunodeficiency virus type 1
	Coal-tar distillation	Human papillomavirus types 5 and 8 (in individuals with epidermodysplasia verruciformis)
	Coal-tar pitch	Nitrogen mustard
	Cyclosporine	Petroleum refining (occupational exposures)
	Methoxsalen plus ultraviolet A	Ultraviolet-emitting tanning devices
	Mineral oils, untreated or mildly treated	Merkel cell polyomavirus (MCV)
	Shale oils	
	Solar radiation	
	Soot	
	X-radiation, γ-radiation

TABLE 13-1 LIST OF CLASSIFICATIONS BY CANCER SITES WITH SUFFICIENT OR LIMITED EVIDENCE IN HUMANS—cont'd

CANCER SITE	CARCINOGENIC AGENTS WITH SUFFICIENT EVIDENCE IN HUMANS	AGENTS WITH LIMITED EVIDENCE IN HUMANS
Mesothelium (pleura and peritoneum)	Asbestos (all forms) Erionite Painting	
Endothelium (Kaposi sarcoma)	Human immunodeficiency virus type 1 Kaposi sarcoma herpesvirus	
Soft tissue		Polychlorophenols or their sodium salts (combined exposures) Radioiodines, including iodine-131 2,3,7,8-Tetrachlorodibenzo-*para*-dioxin
Breast and Female Genital Organs		
Breast	Alcoholic beverages Diethylstilbestrol Estrogen-progestogen contraceptives Estrogen-progestogen menopausal therapy X-radiation, γ-radiation	Estrogen menopausal therapy Ethylene oxide Shiftwork that involves circadian disruption Tobacco smoking
Vulva	Human papillomavirus 16	Human immunodeficiency virus type 1
Vagina	Diethylstilbestrol (exposure in utero) Human papillomavirus 16	Human immunodeficiency virus type 1
Uterine cervix	Diethylstilbestrol (exposure in utero) Estrogen-progestogen contraceptives Human immunodeficiency virus type 1 Human papillomavirus types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59 Tobacco smoking	Human papillomavirus types 26, 53, 66, 67, 68, 70, 73, 82 Tetrachloroethylene
Endometrium	Estrogen menopausal therapy Estrogen-progestogen menopausal therapy Tamoxifen	Diethylstilbestrol
Ovary	Asbestos (all forms) Estrogen menopausal therapy Tobacco smoking	Talc-based body powder (perineal use) X-radiation, γ-radiation
Male Genital Organs		
Penis	Human papillomavirus type 16	Human immunodeficiency virus type 1 Human papillomavirus type 18
Prostrate		Androgenic (anabolic) steroids Arsenic and inorganic arsenic compounds Cadmium and cadmium compounds Rubber production industry Thorium-232 and its decay products X-radiation, γ-radiation
Testis		Diethylstilbestrol exposure in utero
Urinary Tract		
Kidney	Tobacco smoking X-radiation, γ-radiation	Arsenic and inorganic arsenic compounds Cadmium and cadmium compounds Printing processes
Renal pelvis and ureter	Aristolochic acids, plants containing phenacetin Phenacetin, analgesic mixtures containing Tobacco smoking	Aristolochic acids
Urinary bladder	Aluminum production 4-Aminobiphenyl Arsenic and inorganic arsenic compounds Auramine production Benzidine Chlornaphazine Cyclophosphamide Magenta production 2-Naphthylamine	4-Chloro-*ortho*-toluidine Coal-tar pitch Coffee Dry cleaning Engine exhaust, diesel Hairdressers and barbers (occupational exposure) Printing processes Soot Textile manufacturing

TABLE 13-1 LIST OF CLASSIFICATIONS BY CANCER SITES WITH SUFFICIENT OR LIMITED EVIDENCE IN HUMANS—cont'd

CANCER SITE	CARCINOGENIC AGENTS WITH SUFFICIENT EVIDENCE IN HUMANS	AGENTS WITH LIMITED EVIDENCE IN HUMANS
	Painting	
	Rubber production industry	
	Schistosoma haematobium	
	Tobacco smoking	
	ortho-Toluidine	
	X-radiation, γ-radiation	
Eye, Brain, and Central Nervous System		
Eye	Human immunodeficiency virus type 1	Solar radiation
	Ultraviolet-emitting tanning devices	
	Welding	
Brain and central nervous system	X-radiation, γ-radiation	Radiofrequency electromagnetic fields (including from wireless phones)
Endocrine Glands		
Thyroid	Radioiodines, including iodine-131	
	X-radiation, γ-radiation	
Lymphoid, Hematopoietic, and Related Tissue		
Leukemia and/or lymphoma	Azathioprine	Bis(chloroethyl)nitrosourea (BBCNU)
	Benzene	Chloramphenicol
	Busulfan	Ethylene oxide
	1,3-Butadiene	Etoposide
	Chlorambucil	Hepatitis B virus
	Cyclophosphamide	Magnetic fields, extremely low frequency (childhood leukemia)
	Cyclosporine	Mitoxantrone
	Epstein-Barr virus	Nitrogen mustard
	Etoposide with cisplatin and bleomycin	Painting (childhood leukemia from maternal exposure)
	Fission products, including strontium-90	Petroleum refining (occupational exposures)
	Formaldehyde	Polychlorophenols or their sodium salts (combined exposures)
	Helicobacter pylori	Radioiodines, including iodine-131
	Hepatitis C virus	Radon-222 and its decay products
	Human immunodeficiency virus type 1	Styrene
	Human T-cell lymphotropic virus type 1	Teniposide
	Kaposi sarcoma herpesvirus	Tetrachloroethylene
	Melphalan	Trichloroethylene
	MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture)	2,3,7,8-Tetrachlorodibenzo-*para*-dioxin
	Phosphorus-32	Tobacco smoking (childhood leukemia in smokers' children)
	Rubber production industry	Malaria (caused by infection with *Plasmodium falciparum* in holoendemic areas)
	Semustine (methyl-CCNU)	
	Thiotepa	
	Thorium-23 and its decay products	
	Tobacco smoking	
	Treosulfan	
	X-radiation, γ-radiation	
Multiple or Unspecific Sites		
Multiple sites (unspecified)	Cyclosporine	Chlorophenoxy herbicides
	Fission products, including strontium-90	Plutonium
	X-radiation, γ-radiation (exposure in utero)	
All cancer sites (combined)	2,3,7,8-Tetrachlorodibenzo-*para*-dioxin

Note: This table does not include factors not covered in the IARC Monographs, notably genetic traits, reproductive status, and some nutritional factors.

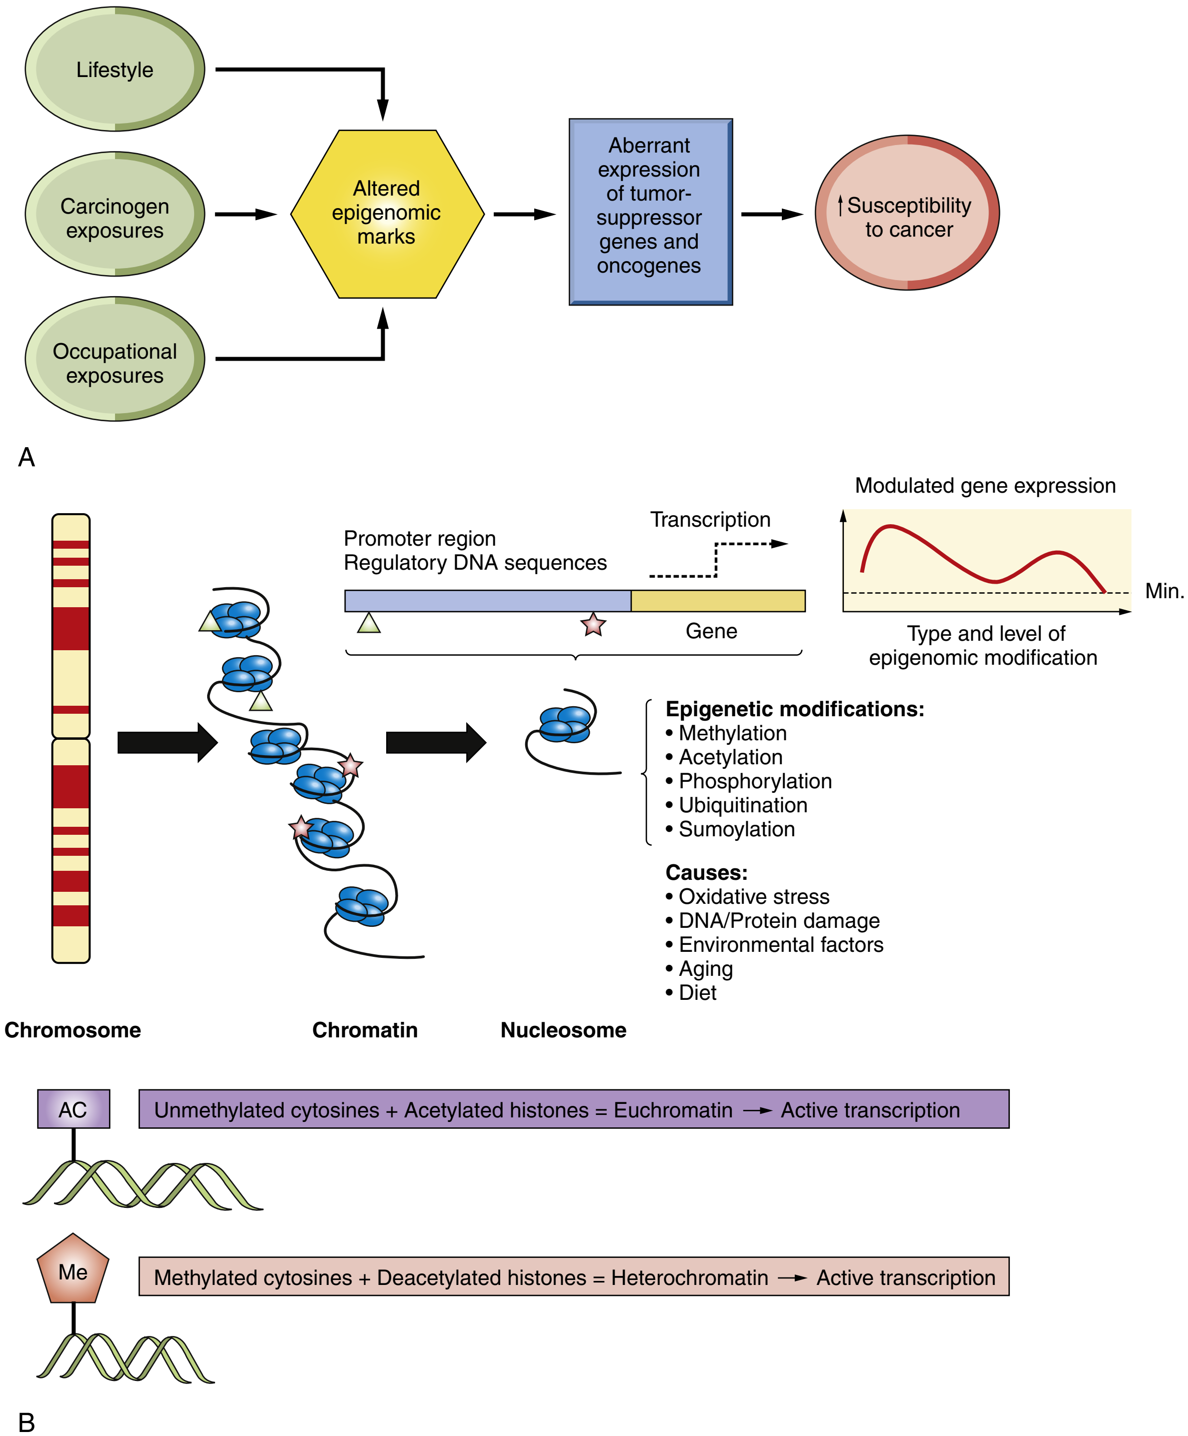

FIGURE 13-2 Epigenetic Modulation and Modifications. **A,** Overview of the potential role of epigenetic modulation by dietary and other environmental factors in cancer development. **B,** Epigenetic modulations' model according to current knowledge. The different types of chemical modifications, such as methylation or acetylation, of promoter regions and/or other regulatory DNA sequences outside the gene can have severe impact on gene transcription and translation and a resultant high modulation of gene expression and product (protein) functionality. (From World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

Investigators are working hard to understand and connect the complex and intricate relationships between genotype, phenotype, and the environment in order to understand a person's chances of developing cancer (see Figure 13-2, *A* and *B*). The root cause of cancer is more than inherited or acquired genetic mutations and involves epigenetic changes that frequently precede and induce cancer-causing genetic mutations.[25] The past decade has highlighted the major role epigenetic processes play in cancer initiation, progression, and treatment.[25] Additionally, if these early epigenetic alterations can be detected and reversed, cancer

may be prevented. In the 1980s, cancer biologist Stephen Baylin hypothesized that if a tumor-suppressor gene is hypermethylated its activity would decrease or stop entirely. Firm evidence came in 1994 when Baylin and oncologist James Herman showed that 20% of the individuals with the noninherited form of renal cell carcinoma (RCC) did not have a mutation in von Hippel-Lindau and their genes were silenced not by a mutation but rather by epigenetic hypermethylation.[26] These and many other investigators' stunning experiments and observations have changed the biology of cancer dramatically! *The paradigm shift from a genetic to an epigenetic model is critical for prevention strategies because these changes are potentially reversible and may precede genetic mutations.* Investigators are linking epigenetic abnormalities to mutations in genes that control DNA methylation, the packaging and the function of DNA in chromatin, and metabolism[25] (see Chapter 12). We know that environmental contaminants can damage the immune system, altering signaling processes that facilitate tumor proliferation. At the interface of environment and genetics is chronic inflammation. Inflammation has been linked with increased DNA methylation, an epigenetic alteration. A notable example is found in persons with ulcerative colitis, who can develop colon cancer at an age younger than the 60- to 70-year average. The epigenetic changes that occur in colon cancer, including DNA hypermethylation and gene silencing, are accelerated and appear in the inflamed tissue before the actual cancer.[27-29]

INCIDENCE AND MORTALITY TRENDS

Incidence Trends

Cancer is reported to become a major cause of morbidity and mortality in the coming decades in all regions of the world (What's New? Global Cancer Transitions).[30] In the National Cancer Institute's 2011 annual report to the nation, trends were reported for all cancers combined, for childhood cancers, and for the top 15 cancers for each of the major racial and ethnic groups by gender.[31] The report also presents incidence of malignant and nonmalignant brain tumors in children and adults by race, gender, age group, and histologic type. Overall, cancer incidence rates for all racial and ethnic groups combined decreased by 0.8% per year during the most recent study period, 2003 to 2007. A significant decrease of 0.6% per year was noted in women and a nonsignificant decrease of 0.8% per year was noted in men influenced by a nonsignificant increase in prostate cancer incidence (2005 to 2007).[31] The most frequently diagnosed cancers, prostate and breast, showed possible changing trends. Cancer of the prostate showed a nonsignificant annual increase of 3.0% for the period 2005 to 2007 after a significant decrease for the period 2001 to 2005. Breast cancer showed a decrease from 1999 to 2007 after a sharp decrease in 2002 to 2003; the lower rates thereafter remained stable. The cancer rates among children (from birth to age 19 years) showed an increase of 0.6% per year for the entire period of 1992 to 2007. The long-term increase in cancer incidence rates in children is possibly related to increases in lymphoid leukemias and a smaller increase in other childhood cancers[31] (see Chapter 14).

From the period 2003 to 2007, 5 of the 15 most common cancers among men—lung and bronchus (lung), colorectal, oral and pharynx (oral), stomach, and malignant brain tumors—showed a significant decrease. Significant increases among men in the period 2003 to 2007 included melanoma of the skin, kidney and renal pelvis (kidney), pancreas, and liver and intrahepatic bile duct (liver). Cancers that had neither an increase nor a decrease in the period 2003 to 2007 included prostate (see preceding paragraph), bladder, esophageal cancers, leukemia, myeloma, and non-Hodgkin lymphoma.

Significant, increasing trends among women were noted in three of the four cancers increasing in men (kidney, pancreas, and melanoma of the skin); leukemia and thyroid cancer also increased.[31] Significant decreasing trends occurred with cancers

WHAT'S NEW?

Global Cancer Transitions

The United Nations has estimated that the global population will reach 7 billion by 2012 and 8.3 billion by 2030. Population aging and growth will be greatest in low- and middle-income countries. Researchers used four levels of a Human Development Index [HDI] (low, medium, high, and very high), as an indicator of life expectancy, education, and gross domestic product per head, to present an overview of global patterns of cancer incidence and mortality. This important report is the first of its kind to present this global overview. These statistics may translate to a global incidence of 20.3 million new cancer cases by 2030 (compared with an estimated 12.7 million cases in 2008) and a predicted 13.2 million cancer-related deaths worldwide by 2030, an increase from the 7.6 million cancer-related deaths in 2008. In both high HDI and very high HDI regions, four cancers (female breast, lung, colorectal, and prostate cancers) explain almost half of the overall cancer burden. In medium HDI regions, lung and female breast cancers are the most common types of cancer along with stomach and liver cancers. In low HDI regions, female breast and liver cancers also are common, as well as the infection-related cancers cervical cancer and Kaposi sarcoma. In these low HDI regions, cervical cancer was more common than both breast cancer and liver cancer. Across 184 countries, 9 different cancers were most commonly diagnosed in men, including the 3 most common—prostate, lung, and liver cancers. Breast and cervical cancers were the most common in women. In medium HDI and high HDI settings, the decreases in incidence of cervical and stomach cancers seem to be offset by the rising increases in incidence of female breast, prostate, and colorectal cancers. The reduction in infection-related cancers appears to be offset by simultaneous increases in cancers related to the "western lifestyle" and changes in tobacco consumption and the effect on lung and other cancers.

Targeted interventions can substantially reduce the incidences of cancers worldwide and include primary prevention strategies to decrease or eliminate certain lifestyle factors—including tobacco avoidance and cessation of smoking, reduction in the number of obese individuals, reduction in alcohol intake, increase in physical activity, and implementation of vaccination programs for liver and cervical cancer as well as effective early detection programs for colorectal, breast, and cervical cancer. Reductions in mortality could be implemented that increase access to curative treatment because provision of palliative care for those individuals dying of cancer will help to reduce population inequities.

Data from Bray F et al: *Lancet Oncol* 13(8):790–801, 2012; Ferlay J et al: *Int J Cancer* 127:2893–2917, 2010.

of the breast, lung, colon or rectum, uterus, cervix, bladder, and oral cavity. No significant trends were observed in non-Hodgkin lymphoma, ovarian cancer, and malignant brain tumors.[31]

This current analysis shows the relative stability of long-term trends of malignant brain tumors of the neuroepithelial tissue. From the period 1980 to 2007, brain tumors increased 1.9% per year during 1980 to 1987 followed by a decrease of 0.4% per year during the remaining 20 years. Yet, marked differences occurred for histologic groups of brain tumors because of changing diagnostic methods, pathologic coding schemes, and classifications. Better classifications have enabled progress in understanding the pathogenesis of malignant gliomas.[31] The trends in nonmalignant tumors are not now known because they only became reportable on a national level in 2004.[31]

Mortality Trends

Since the mid-1970s, cancer death rates have decreased for children. Long-term (1975 to 2007) trends in death rates continued to decrease in children, although at a slower rate in the recent decade[31] (see Chapter 14). Death rates from the periods 1998 to 2007 and from 2003 to 2007 continued to decrease for 7 of the top 15 cancer types in both men and women (colorectal, brain, stomach, and kidney cancers; non-Hodgkin lymphoma; leukemia; and myeloma).[31] Decreasing death rates for men also included lung, prostate, and oral cavity, and for women breast and bladder cancers. Overall, however, death rates continued to increase for cancers of the liver and pancreas among men and women, for uterine cancer in women, and for melanoma of the skin in men.[31] Importantly, lung cancer death rates in women showed a significant decrease during the period 2003 to 2007, following long-term increases during the period 1975 to 2003.

IN UTERO AND EARLY LIFE CONDITIONS

From studies of the etiology of certain cancers, it is widely accepted that a long latency period precedes the onset of adult cancers. Accumulating data suggest early life events influence later susceptibility to certain chronic diseases.[32] Throughout in utero development, the placenta plays a major role in controlling growth and development.[33] Because the placenta is a regulator of the intrauterine environment and can be influenced by exposures throughout pregnancy,[33] much research is being done with DNA methylation linking environmental cues to placental pathologies and adult life (Figure 13-3).

Children may be affected by prenatal exposures, parental exposures before conception, and exposure to breast milk. **Developmental plasticity** is the degree to which an organism's development is contingent on its environment. It requires stable gene expression that in part appears to be modulated by epigenetic processes such as DNA methylation and histone modification (Figure 13-4).[32] Sensitivity to environmental-lifestyle factors influences the mature phenotype and is dependent on the interactions of both the genome and the epigenome. Abnormal DNA hypermethylation in cancer is noted in many genes important to embryonic development.[25] Although the developing embryo is protected from the physical and chemical toxins or dangers of the outside environment by the uterine environment, elements of the maternal diet, drugs, or accidentally ingested and/or inhaled toxins can be delivered to the embryo through the maternal circulation.[34] Known environmental effects include drugs, such as valproic acid (VPA, an anti-epileptic),[35] or the effects of high maternal alcohol consumption.[36,37]

Perhaps one of the best examples of early life events and future cancer is the chemical exposure to diethylstilbestrol (DES), a synthetic estrogen. This medication was prescribed between 1938 and 1971 to attempt to prevent multiple pregnancy-related problems, such as miscarriage, premature birth, and abnormal bleeding.[38] By the 1950s it became clear that DES interfered with the *development* of the reproductive system in the fetus and it did not prevent miscarriage. Recent data suggest that DES-associated increase in clear cell adenocarcinoma is elevated throughout a woman's reproductive years.[39] More recent studies have revealed that daughters of women who took DES during pregnancy may have a slightly increased risk of breast cancer before age 40 (i.e., 1.9 times the risk compared with unexposed women at age 40).[40] For every 1000 DES-exposed women ages 45 to 49 it is estimated that 4 will be diagnosed with breast cancer.

Research from animal studies has demonstrated a relationship between DES exposure and an increased rate of a rare type of testicular cancer (rete testis) and prostate cancer.[41,42] In terms of in utero exposures, testicular cancer has been linked to exposure to abnormal levels of estrogen,[43] and testicular cancer is a risk factor for men with undescended testicles, a factor in some studies correlated with DES exposure. However, studies in humans determining the risk of testicular or prostate cancer and DES exposure are unclear and continuing.[44]

Additionally, investigators are studying diet during pregnancy. Recently, a striking experiment in mice demonstrated how extra vitamin doses during pregnancy in the mother's diet changed the fur color of her pups.[45] This was the first study to show maternal nutrition and subsequent phenotype changes. The nutrients (B_{12}, folic acid, choline, and betaine) silenced the gene that rendered mice fat and yellow but did not alter its DNA sequence. Silencing, or switching the gene off, linked prenatal diet to such diseases as diabetes, obesity, and cancer. These concepts, called the developmental basis of health and disease, are defining the hypothesis of disease onset. Subsequently, the focus of disease prevention and intervention needs to include the decades before onset—that is, during the in utero and neonatal periods.

In summary, epidemiologic and animal studies reveal that small changes in the developmental environment can alter phenotypic changes, resulting in individual responses in adulthood. Continuing evidence indicates that epigenetic mechanisms are responsible for tissue-specific gene expression during cellular differentiation and that these mechanisms modulate developmental phenotypic changes. The phenotypic effects of epigenetic modifications during development may need long latency periods, such as in cancer, thus manifesting later in life. In addition, epigenetic effects may help explain transgenerational effects (Tables 13-2 and 13-3).

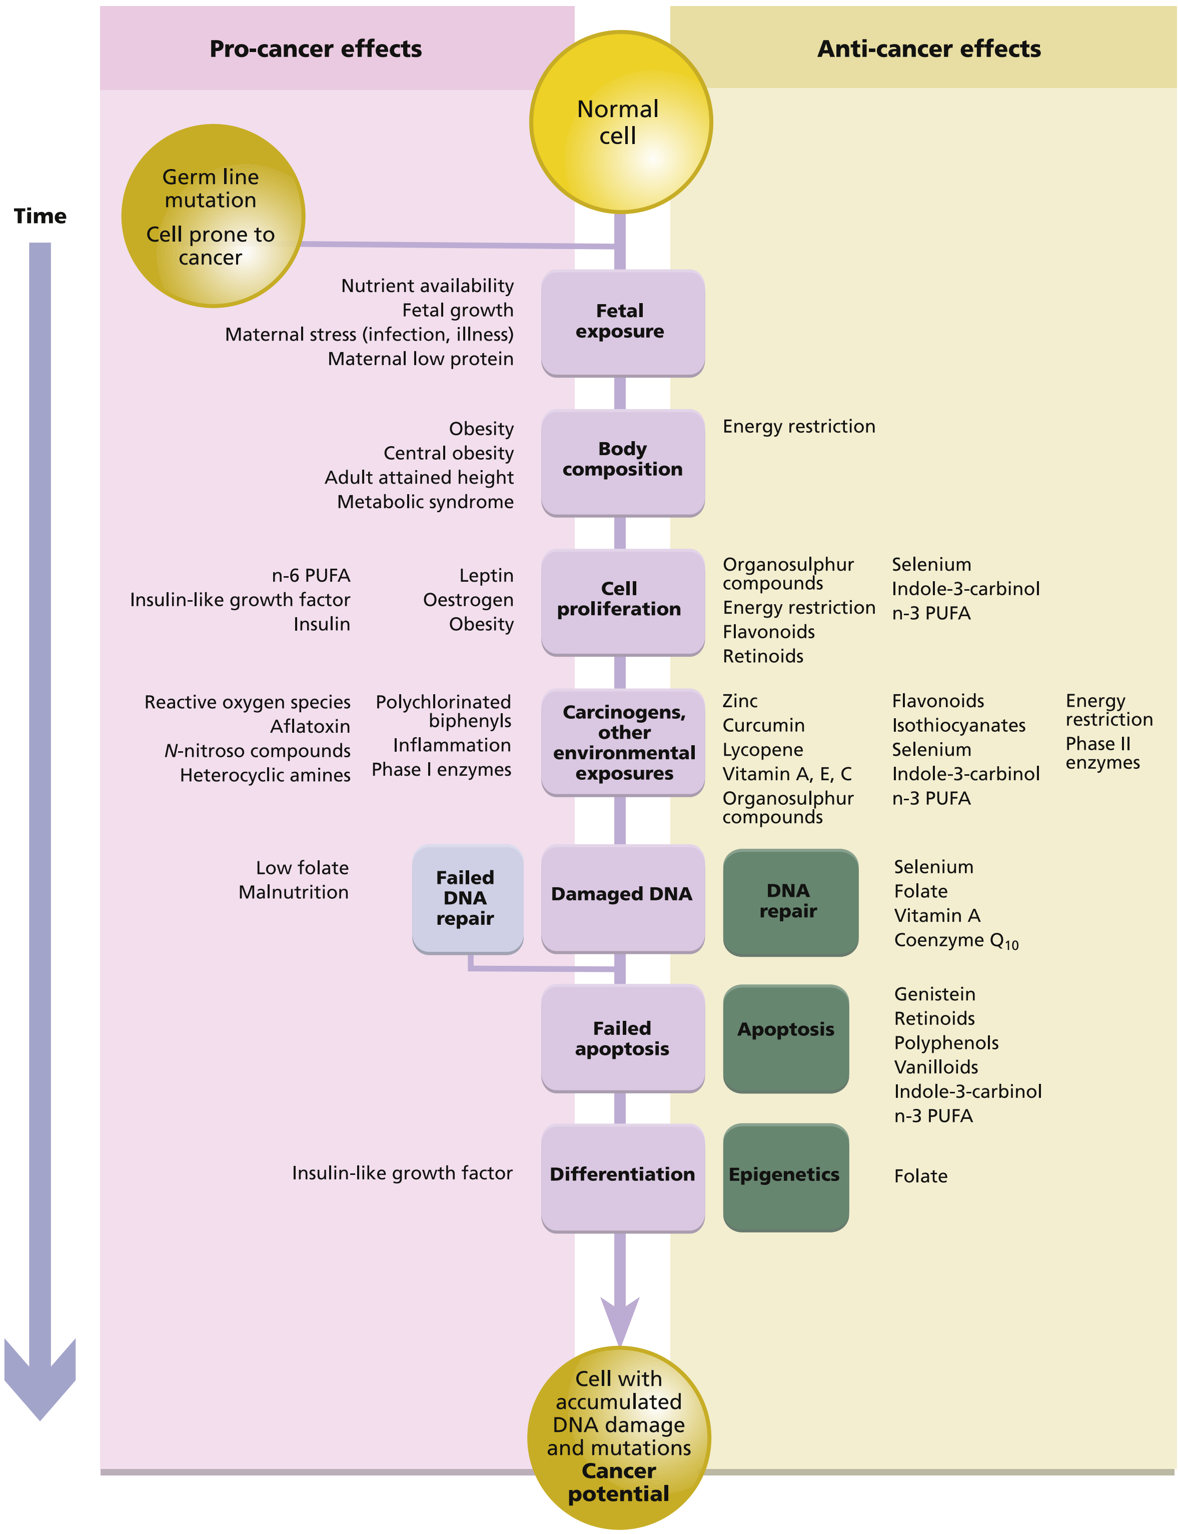

FIGURE 13-3 Pro- and Anti-Cancer Effects. (From World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

It should be noted that lifestyle habits are modifiable and that changing them can translate to reduced cancer risk, but a critical question is whether we are intervening early enough in life to achieve benefits.[1] Protective measures in very young and young people—for example, avoiding sun exposure during peak hours (10 AM to 3 PM) and covering the skin whenever possible, increasing physical exercise, and avoiding high-risk sexual practices, will reduce cancer incidence. Understanding that it takes years to develop tumors, cancer prevention beginning early in life will help reduce the burden of cancer on individuals and society[1] (see What's New? Preventing Cancer—Protecting the Health of Current and Future Generations).

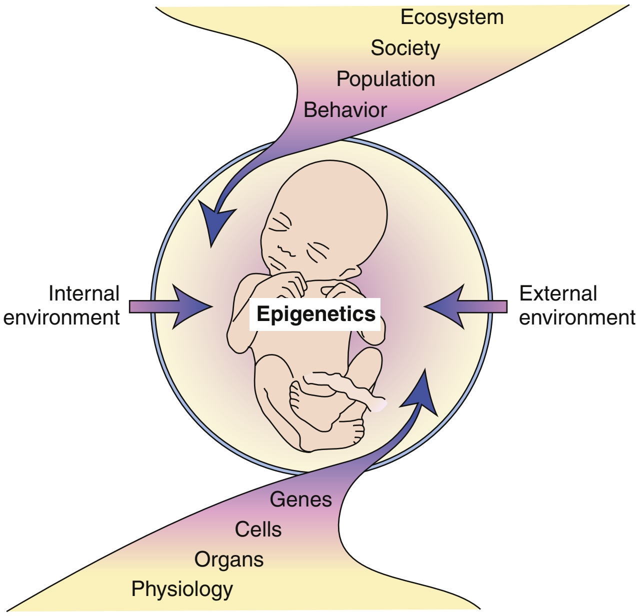

FIGURE 13-4 Fetal Vulnerability to External and Internal Environments. The fetus is particularly vulnerable to changes in the external and internal environments, which can have immediate and lifelong consequences. Such environmentally induced changes can occur at multiple levels, including molecular and behavioral. Ultimately these alterations may be epigenetic, inducing mitotically heritable alterations in gene expression without changing the DNA. (Adapted from Crews E, McLachlan JA: *Endocrinology* 147[6 Suppl]:S4–S10, 2006.)

TABLE 13-2 DIFFERENCES BETWEEN MULTIGENERATIONAL AND TRANSGENERATIONAL PHENOTYPES

PHENOTYPE	EXPOSURE	DEFINITION
Multigenerational	Direct	Simultaneous exposure of multiple generations to an environmental factor
Transgenerational	Initial germline exposure (ancestral)	Transgenerational phenotype is transmitted to future generations through germline inheritance

TABLE 13-3 SOMATIC VS. GERM CELL INHERITANCE

CELL TYPE	BIOLOGIC RESPONSE
Somatic cells	Critical for adult-onset disease in exposed individual; not transmitted to future generations as transgenerational effect
Germ cells	Allow transmission between generations; promote transgenerational phenotype

WHAT'S NEW?

Preventing Cancer—Protecting the Health of Current and Future Generations

- Essentials for preventing cancer include eliminating smoking, decreasing obesity, promoting exercise, eliminating infections, and avoiding an unhealthy diet.
- Interventions targeting lifestyle behaviors for cancer prevention are crucial. Continued efforts are needed to educate students and clinicians to target high-risk patients and promote prevention in pregnant women and in women, men, and children.
- Additionally, efforts must also focus more broadly than just smoking, lifestyle behaviors, and chemopreventive interventions.
- Establish a national cancer prevention strategy and redirect accordingly both research and policy agendas.
- Create a more integrated, coordinated, and transparent system for promulgating and enforcing environmental contaminant policy and regulations, driven by science and free of political or industry influence.
- Set tangible goals for reducing or eliminating toxic environmental exposures in cancer causation.
- The Kids Safe Chemical Act is an important first step toward a precautionary chemicals' management policy.
- Shift the burden of proving safety to chemical manufacturers before new chemical approval.
- Thoroughly assess workplace chemicals and other exposures. Previous occupational risks are outdated.*
- Increase concordance of exposure measures and standards to facilitate interagency and international regulatory policy and enforcement.
- Increase information sharing among the public, researchers, regulatory agencies, industry, and other appropriate groups.
- Involve environmental and public health advocates in developing environmental cancer research, policy agendas, and information dissemination.
- Strengthen research on workplace exposures and on the impact of in utero and childhood exposures that appear to have multigenerational effects.
- Accelerate the development of new research models and endpoints to better quantify exposures at individual, occupational, and population levels.
- Scientists disagree about cancer risk attributable to various environmental exposures. The unequal burden of exposure to known and suspected carcinogens must be addressed.
- Cancer risk should include geographic areas and vulnerable populations (including, but not limited to, children, migrant and other farm workers, cancer "hotspots," socioeconomic differences).
- Actions to minimize radiation exposure from medical sources include the education of healthcare providers, radiology technicians, and the public about the extent of radiation exposure from commonly used imaging and nuclear medicine examinations. Radiation dose–lowering techniques and inspection of radiation-emitting equipment must be implemented.
- Healthcare providers, especially physicians, nurse practitioners, and physicians' assistants, should routinely query patients about their previous and current workplace and home environments.
- Public health messages need development and dissemination to raise awareness of environmental cancer risks.

*Data from 2008-2009 Annual Report, President's Cancer Panel: *Reducing environmental cancer risk. What we can do now* (Suzanne H. Reuben for the President's Cancer Panel), U.S. Department of Health and Human Services, NIH, NCI, April 2010.

ENVIRONMENTAL-LIFESTYLE FACTORS

Tobacco Use

Cigarette smoking is carcinogenic and remains the most important cause of cancer. Tobacco accounts for nearly one in five deaths,[46] yet it is the single most preventable cause of death and disease in the United States.[47] The risk is greatest in those who begin to smoke when young and continue throughout life. Globally, tobacco use accounts for 80% of the worldwide lung cancer burden in males and about 50% in females.[48,49] Male lung cancer death rates are decreasing in most Western countries and increasing in China and several other Asian and African countries. However, the highest lung cancer incidence rates are still found in North America, Northern Europe, and Australia/New Zealand.[50] Rates in females are increasing in many countries including Spain, France, Belgium, and the Netherlands and are now plateauing in the United States, Canada, and the United Kingdom. Overall, lung cancer rates in females lag behind males where females started smoking later than males.[50] Half of all long-term smokers die prematurely from smoking-related causes, and for every person who dies from tobacco use another 20 people suffer with at least 1 serious tobacco-related illness.[51] The prevalence of current smoking among U.S. adults declined from 24.7% in 1997 to 18.9% in 2011.[52] Non-Hispanic white adults were the most likely to be current smokers followed by non-Hispanic black adults and Hispanic adults.[52]

Forms of tobacco used in the United States include cigarettes, cigars, pipes, and imported nonconventional cigarettes (e.g., bidis and clove cigarettes). Besides lung cancer, tobacco use increases the risk for cancers of the mouth, lips, nasal cavity and sinuses, larynx, pharynx, esophagus, stomach, pancreas, kidney, bladder, uterus, cervix, colorectum, and ovaries as well as acute leukemia.[46] The relationship between breast cancer and smoking has been the subject of much controversy and conflicting epidemiologic reports published since 2002, partially from confounding with alcohol use. Reanalyses of evidence from recent cohort studies suggest an increased risk of breast cancer related to smoking independent of alcohol use.[53] In younger premenopausal women an increased risk of breast cancer was related to exposure to passive smoke.[53] Biologic mechanistic studies also support a positive association between cigarette smoking and breast cancer.[53] A 2009 Report from the Canadian Expert Panel on Tobacco Smoke and Breast Cancer Risk concluded from epidemiologic and toxicologic studies and biologic understandings that both pre- and postmenopausal breast cancers are consistent with causality.[54] In addition, smoking causes *even more* deaths from vascular diseases (e.g., coronary heart disease, peripheral vascular disease, abdominal aortic aneurysm), respiratory diseases (e.g., emphysema, bronchitis, airway obstruction), and other diseases than from cancer.

Secondhand smoke, also called **environmental tobacco smoke (ETS),** is the combination of sidestream smoke (burning end of a cigarette, cigar, or pipe) and mainstream smoke (smoke exhaled by the smoker). More than 4000 chemicals have been identified in mainstream tobacco smoke (250 chemicals as toxic),[55] of which 60 are considered carcinogenic.[56] Nonsmokers who live with smokers are at greatest risk for lung cancer as well as numerous noncancerous conditions.[57] One in vitro study supported a relationship between nicotine and genotoxic effects in fetal cells.[58] Other studies are emerging on the relationship of both maternal and paternal smoking and in utero effects. Smoking during pregnancy causes lower birth rates, an increased incidence of spontaneous abortion and preterm birth, increased placental pathology, and increased stillbirth rates.[59]

Cigar or pipe smoking, or both, is strongly and causally related to cancers of the oral cavity, oropharynx, hypopharynx, larynx, esophagus, lung, and probably the pancreas.[60] Pipe smokers have an increased risk of dying from cancers of the lung, throat, esophagus, larynx, pancreas, and colorectum.[61] Smoking bidi, a small amount of tobacco wrapped in the leaf of another plant (used in South Asia), delivers higher amounts of nicotine per gram of tobacco and comparable or greater amounts of tar compared with cigarettes.[62] Bidi smokers have the same risks of cancers and higher risks of heart attacks and chronic bronchitis than those found in nonsmokers.[62] Several types of cancers have been linked to hookah or water pipe smoking.[62]

United Kingdom researchers reported for the first time that starting smoking results in epigenetic changes associated with the development of cancer.[63] These researchers showed that smoking increased DNA methylation. Figure 13-5 illustrates a working model of carcinogenesis by cigarette smoke. Measures

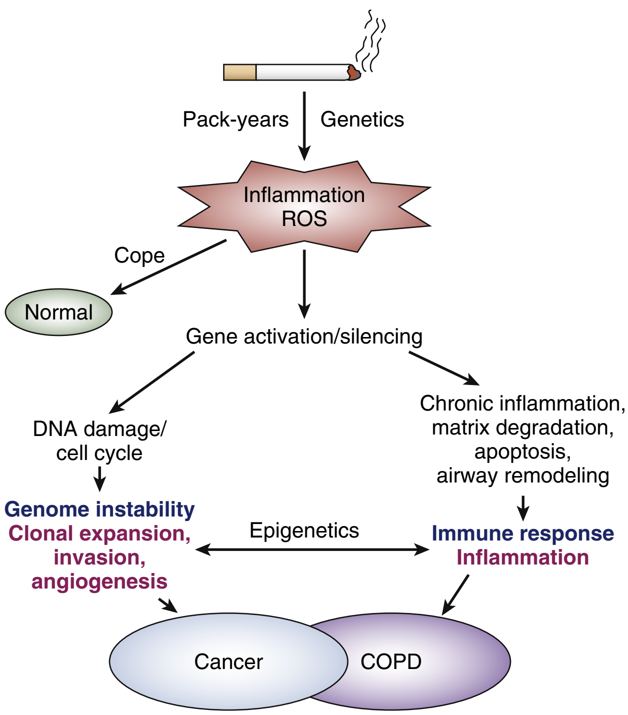

FIGURE 13-5 Working Model of Carcinogenesis by Cigarette Smoke. The major inducer of both lung cancer and COPD is cigarette smoke. Nonsmokers may develop these diseases caused by other environmental or genetic/epigenetic factors. Cigarette smoke induces an inflammatory response and causes an increase in reactive oxygen species (ROS), causing oxidative stress. Oxidative stress is a risk factor for many diseases because it can alter many cellular proteins. A combination of immune-inflammatory signals and epigenetic events may increase the risk for individuals with COPD developing lung cancer. (From Adcock IM et al: *Respiration* 81[4]:265–284, 2011.)

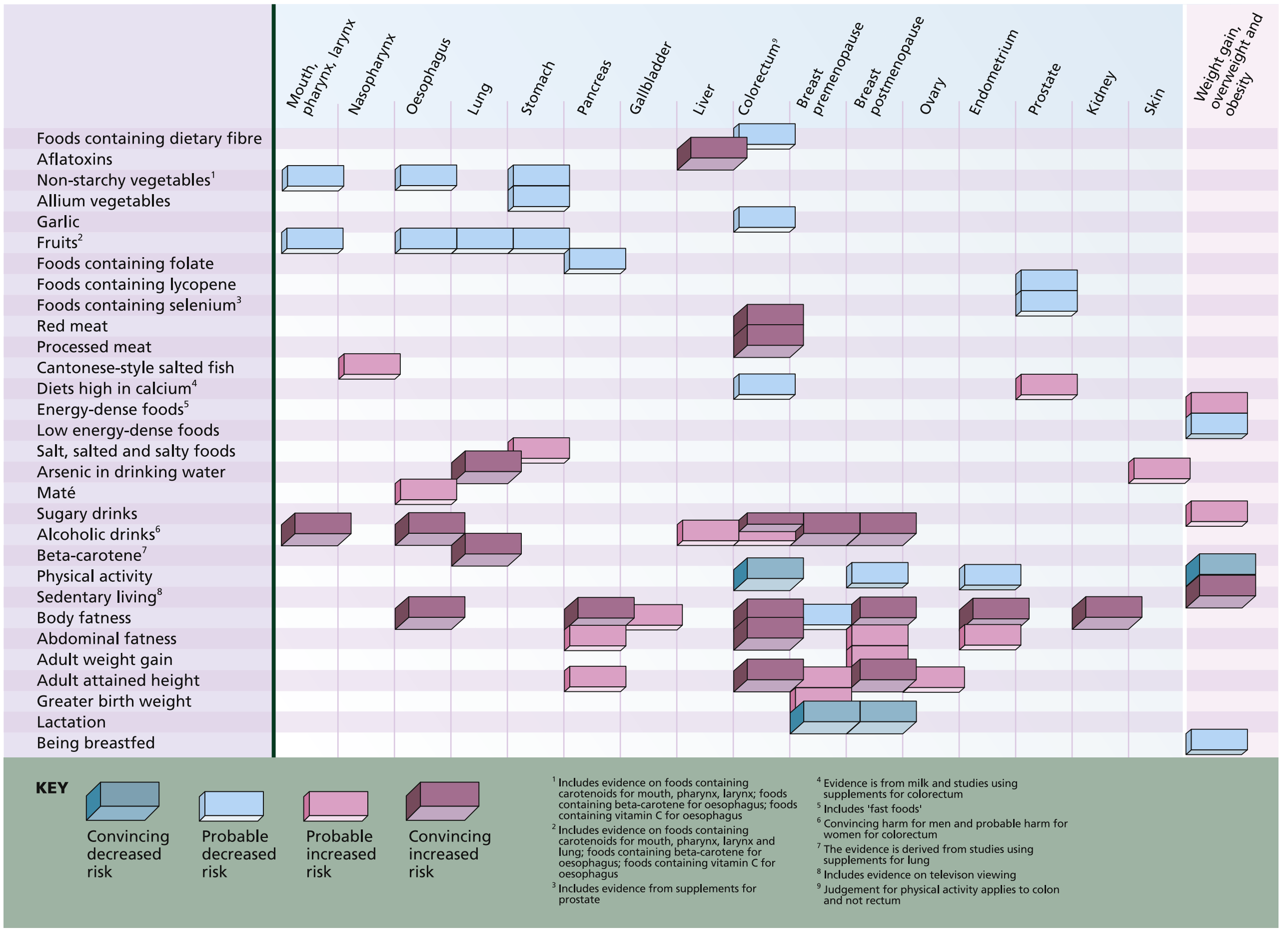

FIGURE 13-6 **Summary of Convincing and Probable Judgments.** (From World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

that prevent young adults from starting smoking would substantially avoid future disease burden. A strong public health approach is one that *prevents* young people from *starting* smoking and helps others *stop* smoking.

Diet

Understanding dietary factors that increase the risk for cancer can be difficult. The ways in which diet affects one's likelihood of developing cancer are complicated by the variety of foods consumed, the many constituents of foods, the metabolic consequences of eating, and the temporal changes in the patterns of food use. Cancer risks in older adults may depend as much on diet in early life as on current eating practices. In addition, studies in humans targeting diet and disease associations face a variety of challenges including measurements of specific nutrients, food types, and dietary patterns.

Dietary sources of carcinogenic substances include compounds produced in the cooking of fat, meat, or protein, and naturally occurring carcinogens associated with plant food substances, such as alkaloids or mold byproducts.[64] Figure 13-6 is a summary of convincing and probable judgments related to food and physical activity risk factors and the prevention of cancer.[64] Dietary components can act directly as mutagens or interfere with mutagen elimination. Abundant evidence exists

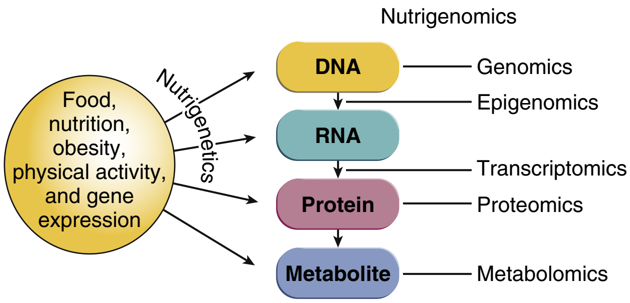

FIGURE 13-7 **Basis for the Study of Food, Nutrition, Obesity, Physical Activity, and the Cancer Process.** The genetic message in the DNA code is translated to RNA, and then into protein synthesis, and so determines metabolic processes. Research methods, called "-omics," address these different stages. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

that nutritional factors in many processes are related to cancer development (Figure 13-7).

Research is ongoing to understand the complexity of genomics, epigenomics, transcription factors (transcriptomics), proteomics, and metabolic factors (metabolomics) and the way that modifying any one, or more, influences cancer risk. **Nutrigenomics** is the study of nutrition on the phenotypic variability

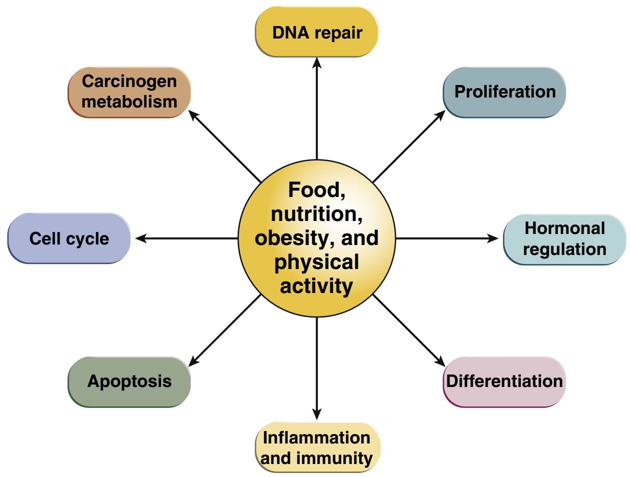

FIGURE 13-8 **Food, Nutrition, Obesity, Physical Activity, and Cellular Processes Linked to Cancer.** Food, nutrition, and physical activity can influence fundamental processes shown here, which may promote or inhibit cancer development and progression. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

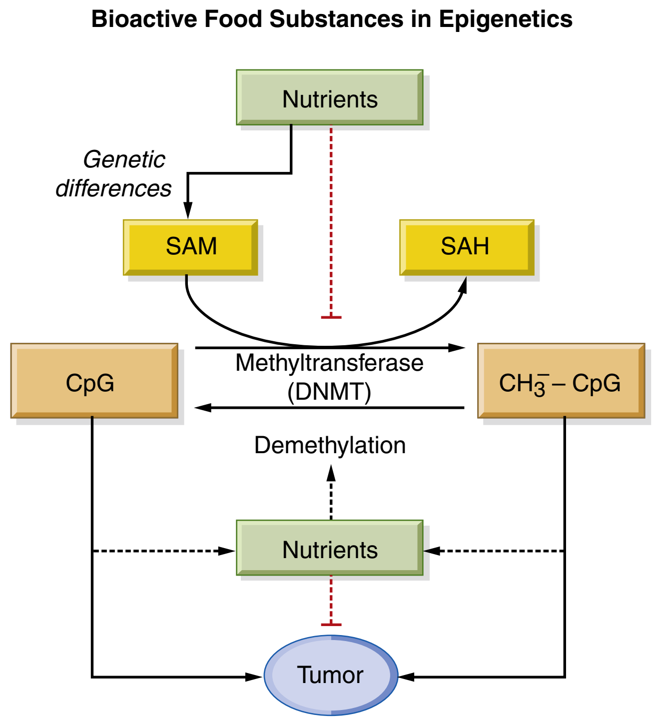

FIGURE 13-9 **Dietary Factors, DNA Methylation, and Cancer.** Certain dietary factors (see Table 13-5) may supply methyl groups (+CH3) that can be donated through *S*-adenosylmethionine (*SAM)* to many acceptors in the cell (DNA, proteins, lipids, and metabolites). Donation and removal (demethylation) are affected by numerous enzymes, including DNA methyltransferase *(DNMT).* Increased DNMT activity occurs in many tumor cells. Hypermethylation can inhibit or silence tumor-suppressor genes (see Chapter 12), and DNA methylation inhibitors as anticancer agents can block DNMT, thus reactivating tumor-suppressor genes. DNA hypomethylation can reactivate and mutate genes, including cancer-causing oncogenes. *SAH, S*-Adenosylhomocysteine.

of individuals based on genomic differences (see Figure 13-7). Investigators are focusing on the sequence and functions of genes, single nucleotide polymorphisms (SNPs), and amplifications and deletions within the DNA sequences as modifiers of the response to foods and drinks and their components.[64]

Nutrition, Obesity, Alcohol Consumption, and Physical Activity: Impacts on Cancer

What we eat, how much we weigh, and how much we move influence our risks of developing cancer. Mounting evidence is clear—everyday *choices* impact our chances of getting or preventing cancer. Ongoing tedious and comprehensive investigative work is linking diet, body weight, and exercise to risk of specific cancers.

Nutrition. Important cellular processes affected by nutrition include the cell cycle; the balance between cell proliferation and cell death (e.g., apoptosis); cell differentiation; genes, including oncogenes and tumor-suppressor genes; cell signaling; gene expression; cellular microenvironment that influences gene expression; epigenetic regulation; hormonal regulation; DNA damage and repair; carcinogen metabolism; and inflammation and immunity (Figure 13-8).

Gene expression is influenced by epigenetic processes like DNA methylation or acetylation (addition of an acetyl group) (see Chapters 6 and 12). Dietary sources of methyl groups including folate, methionine, betaine, serine, and choline are primary potential donors as modulators of DNA methylation[65] (Figure 13-9).

B vitamins, coenzymes in one-carbon metabolism (vitamins B_2, B_6, B_{12}), also are modulators of DNA methylation.[66] To date there are limited human studies of the effects of methyl donor supply on methylation of specific genomic sequences.[65] However, a recent study[67] found that periconceptional maternal supplementation with 400 micrograms (mcg) of folic acid/day was associated with increased methylation in offspring aged 17 months. In the Waterland study, methylation effects were found to be similar in all tissues examined, suggesting that the mechanism may alter markings in stem cells early in embryogenesis before tissue differentiation, and persist into adult life.[45] Choline deficiency in pregnancy results in hypermethylation of genomic DNA and of the *IGF2* gene.[68] Several studies have reported that severe folate deficiency (which increases risk of hepatocellular cancer) induces hypomethylation of the *p53* tumor-suppressor gene.[69] In vitro studies have shown that several bioactive food components, including tea polyphenols and bioflavonoids, inhibit DNA methyltransferase (DNMT-1)-mediated DNA methylation in a dose-dependent manner[70] (see Figure 13-9). Acetylation and deacetylation are mediated by enzyme histones (see Figure 6-1), histone acetyl transferase (HAT), and histone deacetylation (HDAC). Dietary components have been identified that act as regulators of gene expression by epigenetic mechanisms.[71] For example, there is strong evidence for the epigenetic effects of organosulfur compounds from garlic and of isothiocyanates from cruciferous vegetables.[71] Interest in reservatrol is growing because of its demonstrable role in possibly delaying age-related diseases, including cancers.[72] Butyrate produced in the colon by bacterial fermentation of non-starch polysaccharide (fiber), diallyl disulfide from garlic and other allium vegetables, and sulforaphane from

cruciferous vegetables can act as histone deacetylase inhibitors to maintain DNA stability or modify transcription.[64]

MicroRNAs (miRNAs) expression in response to diet may be involved in several cancers.[64] Several dietary factors, including macronutrients (fat, protein, and alcohol) and micronutrients (folate and vitamin E), alter the expression of many miRNAs in animals and humans[65] (see Chapter 12).

Bioactive components have a profound effect on differentiation and a major area of investigation is on the differentiation of cancer stem cells. Cancer stem cells have been isolated and identified in hematopoietic and epithelial cancers, including cancers of the brain, breast, ovary, prostate, colon, and stomach.[64,73] Stem cells are found among most adult tissues, where they maintain and regenerate tissues. Stem cells can remodel organs in response to physiologic triggers—*adaptive resizing*.[74] Cancer stem cells utilize several developmental mechanisms for self-renewal and these mechanisms appear to be fundamental to the initiation and recurrence of tumors. Even if chemotherapy or radiation eliminates cancer cells, it is only when the cancer stem cells are destroyed that a full recovery is achievable.[73] Repopulation with radioresistant or chemoresistant stem cells may significantly contribute to therapy resistance. Evidence from both drug and bioactive food constituents shows modifications in cancer stem cell self-renewal capabilities; for example, retinoic acid may promote differentiation of breast cancer stem cells.[75] Adequate consumption of specific food compounds, including vitamins A and D, genistein, green tea, epigallocatechin gallate (EGCG), sulforaphane, theanine, curcumin, choline, and possibly many others, may suppress cancer stem renewal.[73] Uncontrolled self-renewal process may be initiated by abnormal developmental signals that come from the extracellular microenvironment known as "niches." The loss of regulation in self-renewal signals, including Wnt, Notch, and hedgehog pathways, is a characteristic of cancer stem cells.[73] Various food bioactive components can modulate the signaling pathway.

A variety of food constituents may influence DNA repair[64] (Figure 13-10). Observational studies suggest that malnutrition can reduce DNA repair from damage.[76] In vivo studies have demonstrated that healthy adults consuming kiwi fruits, cooked carrots, or supplemental coenzyme Q_{10} improved their DNA repair.[64] Consumption of lycopene-rich vegetable juice was associated with significantly decreased damage to the DNA of lung epithelial cells in healthy adults.[77]

Humans are constantly exposed to a variety of compounds termed **xenobiotics** (Greek *xenos,* "foreign"; *bios,* "life") that include toxic, mutagenic, and carcinogenic chemicals. Many of these chemicals are found in the human diet. Most xenobiotics are transported in the blood by lipoproteins and penetrate lipid membranes. These chemicals can react with cellular macromolecules, such as proteins and DNA, or can react directly with cell structures to cause cell damage.[78] The body has two main defense systems for counteracting these effects: (1) detoxification enzymes and (2) antioxidant systems (see Chapter 2). Enzymes that activate xenobiotics are called **phase I activation enzymes** and are represented by the multigene cytochrome P-450 family, aldehyde oxidase, xanthine oxidases, and

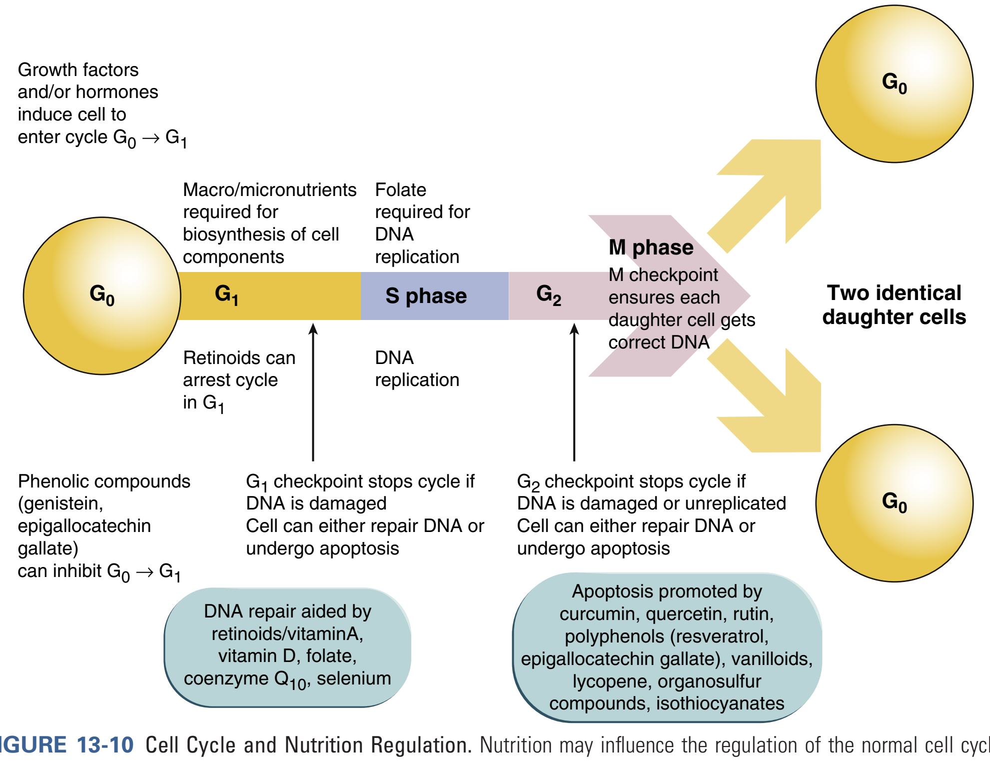

FIGURE 13-10 Cell Cycle and Nutrition Regulation. Nutrition may influence the regulation of the normal cell cycle, which ensures correct DNA replication. G_0 represents the resting phase, G_1 the growth and preparation of the chromosome for replication, S the synthesis of DNA, G_2 the preparation of the cell for division, and M mitosis. (Adapted from World Cancer Research Fund/American Institute for Cancer Research: *Food, nutrition, physical activity, and the prevention of cancer: a global perspective,* Washington, DC, 2007, AICR.)

peroxidases. **Phase II detoxification enzymes** then protect further against a large array of reactive intermediates and nonactivated xenobiotics.[64] These enzymes are located predominantly in the liver and provide clearance of compounds through the portal circulation, thereby preventing the potentially carcinogenic agent(s) from entering the body through the gastrointestinal tract and portal circulation. They also occur in the skin epithelia and can be induced in other extrahepatic tissue, such as the lung. They represent a potential target to influence carcinogen metabolism. Isothiocyanates from cruciferous vegetables induce the expression of phase II detoxification enzymes. Food and nutrition modify carcinogen metabolism and may modify carcinogenesis. Some examples include selenium, allyl sulfur, sulforaphane, and isoflavonoids. The enzyme CYP3A4 is involved in the metabolism of many drugs and is sensitive to foods.[64] Interactions, for example, have been reported for grapefruit juice, red wine, garlic, and drugs.

Glutathione-*S*-transferases (GSTs) are enzyme housekeepers involved in the metabolism of environmental carcinogens and reactive oxygen species. Individuals who lack these enzymes may be at higher risk for cancers because of decreased capacity to dispose of activated carcinogens. For example, the fungi that produce aflatoxins can grow on certain crops like peanuts and certain cereal (grains) are carcinogens activated by phase I enzymes in the liver that can produce DNA adducts. Individuals lacking these enzymes are at higher risk of colon cancer. Diets high in isothiocyanates (from cruciferous vegetables) may decrease this risk.[79] Individuals who consume diets high in red meat and processed meat and who carry certain genetic polymorphisms have an increased risk of developing colorectal cancer.[64,80] Processed meats include those preserved by preservatives or by smoking, curing, or salting. The European Prospective Investigation into Cancer and Nutrition (EPIC) study, which included 478,040 people from 10 countries, reports that the most convincing data are from meats, including sausages, bratwursts, frankfurters, and hot dogs, all of which have nitrites, nitrates, or other preservatives. These *N*-nitroso compounds can increase nitrogenous residues in the colon and cause DNA damage.[64,81] Dietary components either can be activated into potential carcinogens through metabolic processes or can be inactivated and prevent DNA damage.[64] High intake of red meat may result in the synthesis of higher levels of heme iron; iron can activate oxidative stress and inflammation in the colon. A new report suggests meat may have certain thermoresistant oncogenic bovine viruses (e.g., polyoma-papilloma) or possible single-stranded DNA viruses.[82] Certain single nucleotide polymorphisms (SNPs) in the *N*-acetyltransferase gene alter the activity of the enzyme involved in the activation of heterocyclic amines from cooking meat at high temperatures and may increase the risk of colon cancer.[64]

Other foods that alter the metabolism of carcinogens and induce GSTs include cruciferous vegetables, especially brussels sprouts and red cabbage. Red cabbage leads to changes in meat-derived mutagens in urine.[64] Flavonoids found in plants may alter carcinogen metabolism, and dietary indole-3-carbinol inhibited spontaneous occurrence of endometrial adenocarcinomas in rats.[64]

Chronic inflammation and immune function may help explain patterns of cancer around the world. People who are undernourished or live in poverty may have impaired immune status, which can be a factor in cancers caused by infectious agents, for example, cancers of the liver and cervix.[64] Undernutrition can include deficiencies in vitamin A, riboflavin, vitamin B_{12}, folic acid, vitamin C, selenium, and zinc, and these nutrient deficiencies may be related to chronic inflammation and immune alterations.[64] The cytokine interleukin-6 (IL-6) can act as either a proinflammatory or an anti-inflammatory cytokine; consequently, it can enhance both innate and adaptive immunity as well as stimulate or suppress tumor growth.

In summary, epidemiologic and laboratory evidence suggests that diet has important consequences for cancer development and perhaps its rate of progression.[21,83] Diet affects many pathways to cancer including cell cycle control, differentiation, DNA repair, gene silencing, inflammation, apoptosis, and carcinogen metabolism. Many of these processes are likely influenced, if not regulated, by DNA methylation, an epigenetic mechanism that affects gene function. As illustrated in Figure 13-2, it is possible that many environmental factors interact with the genome to produce altered epigenetic markers that change the expression of cancer-causing genes, tumor-suppressor genes, and oncogenes. Future research is needed to define robust biomarkers of cancer risk.

Obesity. Obesity in most developed countries (and in urban areas of many developing countries) has been increasing rapidly over the past 20 years. Obesity in the United States is an epidemic and constitutes a startling setback to major improvements in other areas of health during the past century.[84] Childhood obesity also is increasing. Numerous health conditions are linked to obesity and physical inactivity. The substantial suffering and long-term human and societal costs of obesity underlie the urgency to accelerate progress in obesity prevention.[84] This will require a comprehensive approach including the involvement of knowledgeable healthcare personnel, the provision of appropriate education from schools, the access to healthy food and beverage choices, and the promotion of physical activity.

Studies have significantly improved the understanding of the relationship between overweight/obesity, energy balance and cancer risk, cancer recurrence, and survival (Figure 13-11).[64,85-87] Consensus now exists that obesity is a risk factor for cancers of the endometrium, colorectum, kidney, esophagus, breast (postmenopausal), and pancreas. Evidence is evolving of the association between obesity and cancers of the thyroid, gallbladder, liver, and ovary as well as aggressive types of prostate cancer and non-Hodgkin lymphoma.[64,85,87] Importantly, obesity is recognized as a poor prognostic factor for several cancers.[88-90] Worrisome are the effects of obesity on incidence and the poor outcomes in individuals with cancer because of the rising obesity epidemic.[91]

The only globally accepted criteria for overweightness and obesity are based on body mass index (BMI). Widely accepted standards based on BMI criteria for overweightness and obesity are recommended by the WHO[92] and supported by other panels and federal agencies (WHO classifications are shown in Table 13-4).

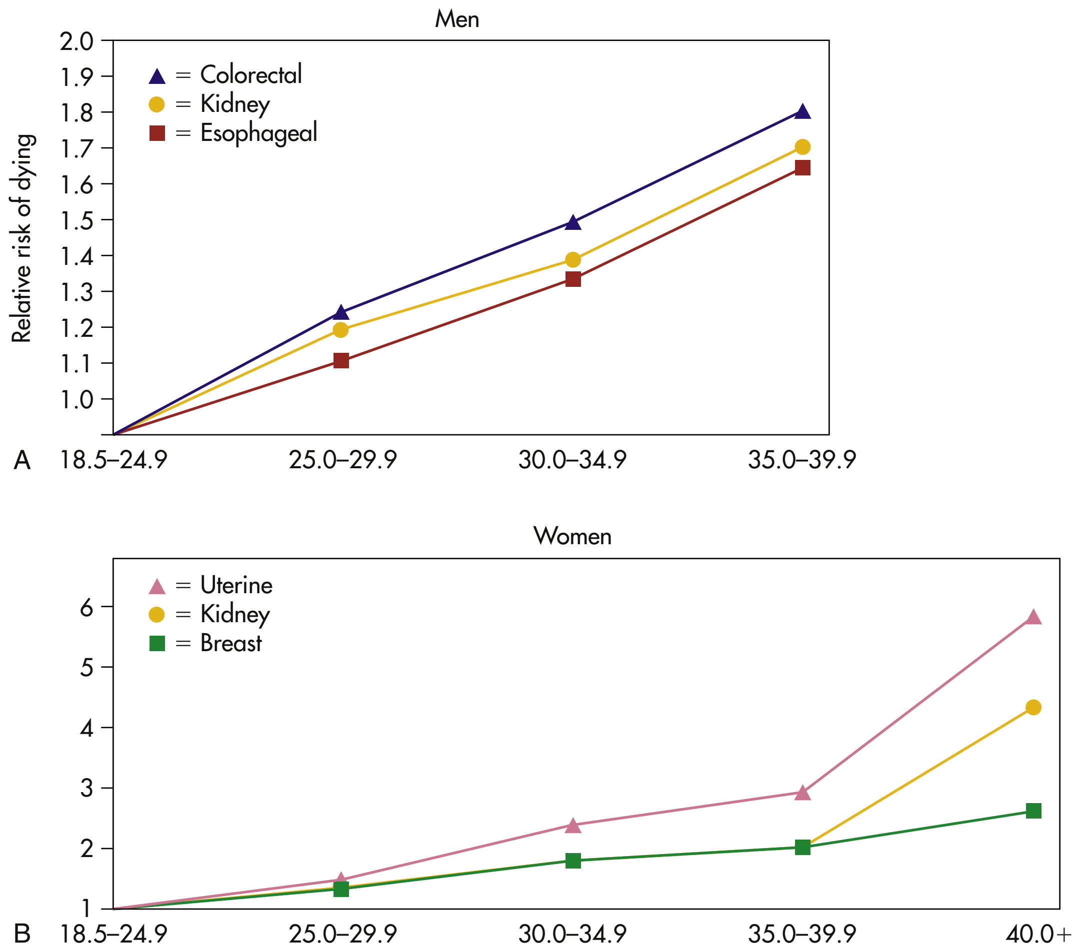

FIGURE 13-11 **Weight and Risk of Dying from Cancer. A,** As a man's body mass index (BMI) rises above the normal range (18.5 to 24.9), his risk of dying of colorectal, esophageal, kidney, and other cancers also rises. For example, the risk of dying from colorectal cancer is 10% higher for men who are overweight (BMI 25 to 29.9) than for men of normal or lower BMI. For the most obese men (BMI 35 or higher) the risk is almost double (84%). **B,** As a woman's BMI rises above the normal range (18.5 to 24.9), her risk of dying of breast, kidney, uterine, and other cancers rises. For example, the risk of dying from breast cancer is 34% higher for women who are overweight. For the most obese women (BMI >40), the risk of dying from breast cancer is double. The risk of kidney disease is almost five times higher, and the risk of uterine cancer is six times higher. (Data from Calle EE et al: *N Engl J Med* 348:1625–1638, 2003.)

TABLE 13-4 WHO* CLASSIFICATION OF BODY MASS INDEX (BMI)

BMI (kg/mM²)*	WHO CLASSIFICATION	OTHER DESCRIPTIONS
<18.5	Underweight	Thin
18.5-24.9	Normal range	"Healthy," "normal," or "acceptable" weight
25-29.9	Grade 1 overweight	Overweight
30-39.9	Grade 2 overweight	Obese
≥40	Grade 3 overweight	Morbidly overweight

*The cutoffs are somewhat arbitrary, although they are derived from epidemiologic studies of BMI and overall mortality. It is important to understand that within each category of BMI there can be substantial individual variation in total and visceral adiposity and in related metabolic factors. These variations are also true for the normal range BMI. *WHO,* World Health Organization.

Worldwide estimates are 1.5 billion adults are overweight (BMI ≥25 to 29.9 kg/m^2) and 500 million are obese (BMI ≥30 kg/m^2).[93] There is considerable concern for children with early onset of obesity.

Mechanisms Associated with Energy Balance and Obesity. The IOM and National Cancer Policy Forum convened to discuss mechanisms of obesity and cancer, cancer recurrence and mortality, research needs, and future directions.[94] A simple model based on energy balance and energy expenditure was utilized. **Energy balance** measures intake-absorbable energy against the energy demands of the body. Energy expenditure is comprised of: (1) the resting metabolic rate (RMR), the energy required for normal body functions, which constitutes the majority of energy needs; (2) the thermic effect of food, or the amount of energy needed to digest and metabolize food; and (3) physical activity, a moderate and modifiable part of energy expenditure. This model does not include body composition (i.e., lean tissue, adipose tissue) or the dynamic state of body

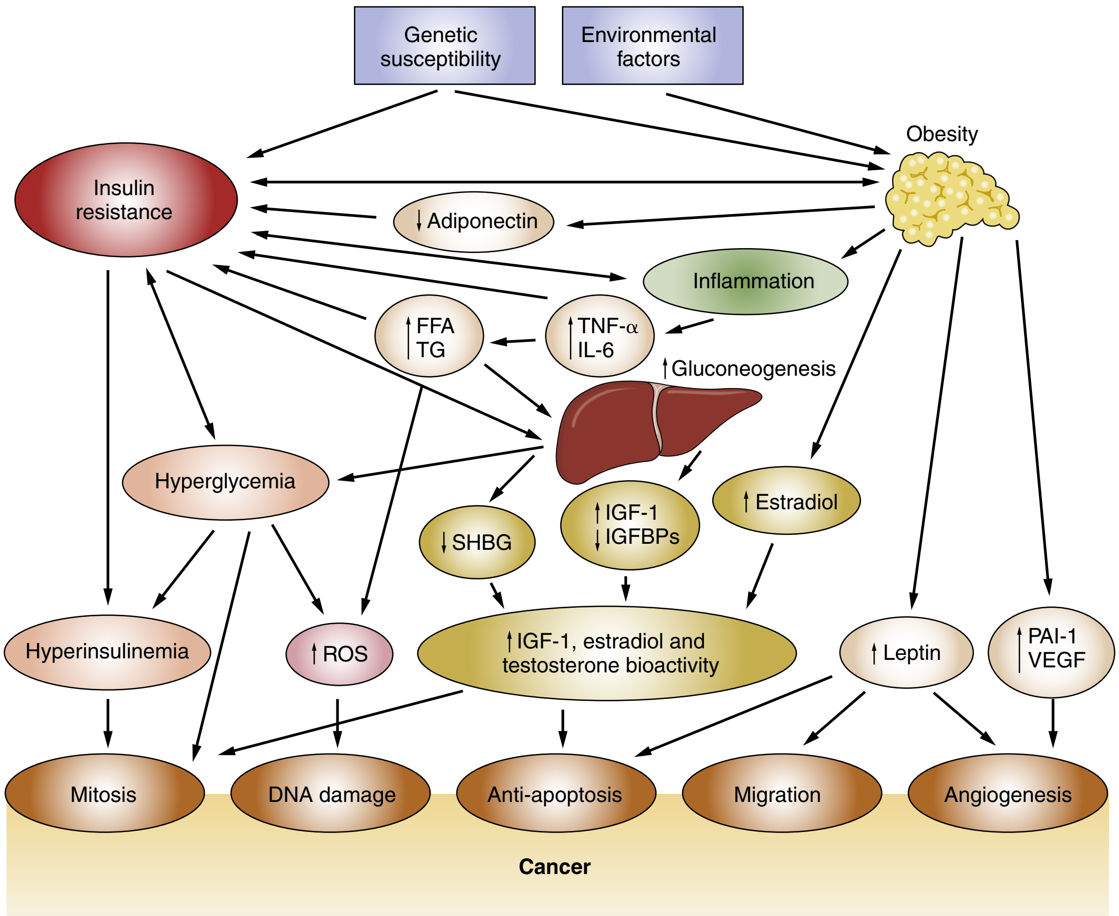

FIGURE 13-12 Obesity, Insulin Resistance, Inflammation, and Cancer. A proposed model of the role of insulin resistance, obesity, genetic susceptibility, and environmental factors and cancer. This model suggests insulin resistance and inflammation as driving forces for cancer development. *FFA,* Free fatty acids; *IGFBPs,* IGF-binding proteins; *IL-6,* interleukin-6; *PAI-1,* plasminogen activator inhibitor 1; *ROS,* reactive oxygen species; *SHBG,* sex hormone–binding globulin; *TG,* triglycerides; *TNF-α,* tumor necrosis factor-alpha; *VEGF,* vascular endothelial growth factor. (Adapted from Arcidacono B et al: *Exp Diabetes Res* 789174, 2012.)

composition. Because lean mass determines resting metabolic rate it is unknown whether obesity itself drives cancer progression or whether components of energy balance (i.e., too much consumed or too little expended) have a greater impact, and therefore it is uncertain which factors hold more promise for cancer control and prevention.[85]

Overall, the putative mechanisms whereby obesity drives the progression of cancer are not completely known and the process is complex. Earlier studies linked levels of circulating free hormones (e.g., estradiol) and hormonally driven cancers as an important mechanism. (Chapters 22 and 24 contain discussions on hormones and cancer risk.) Research now includes other mechanisms whereby energy balance may affect: (1) genomic instability, (2) dysregulated growth signaling and cellular energetics, (3) inhibition of apoptosis and immune surveillance, and (4) angiogenesis. Additionally, numerous signaling pathways and factors are involved in the acceleration of cancer. Data now exist for several factors including energy-driven signaling from insulin, insulin-like growth factor 1 (IGF-1), phosphatidylinositol 3-kinase, and AMP-activated protein kinase and many others.[85] These pathogenic effects of insulin might be mediated by insulin receptors in the preneoplastic or neoplastic target cells, or could be caused by alterations in endogenous hormone metabolism secondary to hyperinsulinemia. Insulin resistance increases with body fatness, particularly with abdominal fatness, and the pancreas compensates by increasing insulin production. Hyperinsulinemia is associated with a risk of cancers of the colon, endometrium, and possibly kidney and pancreas.[64] Like sex steroids, leptin produced by adipose cells also can stimulate premalignant and malignant cell types.[64]

Insulin promotes the synthesis and biologic activity of **insulin-like growth factor 1 (IGF-1),** a peptide hormone that has mitotic and anti-apoptotic effects.[95] Intense investigation is ongoing on the relationship between IGF-1 and the development of certain cancers (Figure 13-12). For example, a pooled reanalysis of world-wide prospective data showed IGF-1 is associated with an increased risk for prostate cancer.[96] Insulin also can promote the synthesis and biologic availability of the male and female sex hormones, including estrogens, progesterone, and androgens[97] (see Figure 13-6).

Parts of the insulin resistance syndrome have been well studied in both breast and colon cancer.[96] As an example, in

individuals with nondiabetic breast cancer, higher levels of fasting insulin were associated with a twofold to threefold increase in risk of mortality.[98,99] One biologic basis for this effect is the overexpression of insulin receptors, especially the fetal insulin receptor (IRα) on breast cancer cells.[100] Similar findings are reported for colon cancer and suggest that adiposity, physical activity, and diet influence insulin and IGF levels that can stimulate growth and inhibit apoptosis of micrometastases—possibly a cause of recurrence.[101] It has recently been reported that postmenopausal diabetic women treated with insulin had a significantly higher risk of lung cancer.[102] This relationship needs much further investigation. Additionally, the Women's Health Initiative (WHI) investigators report that diabetes severity assessed by duration or need of pharmacologic care had stronger links to risk of liver, pancreatic, and rectal cancer.[103] A first review of epidemiologic studies revealed diabetes mellitus as an independent risk factor for colon and rectal cancer.[104] The biologic mechanisms between diabetes mellitus and cancer risk are currently unknown.

The survivorship literature is growing and data suggest that increasing BMI is related to less favorable outcomes for recurrence, survival, and comorbidities (e.g., cardiovascular disease, diabetes, wound healing).[85] A meta-analysis of more than 40 studies of women diagnosed with breast cancer showed a modest but significant increase in all-cause and breast cancer–specific mortality in obese vs. nonobese women.[105] Obesity has been consistently associated with prostate cancer mortality in cohort studies.[85,106] Emerging data on colorectal cancer so far show mixed findings.

Adipose tissue can have greater effects on the physiology of other tissue (see Chapter 41). The metabolic function of adipose tissue is derived in part because it can secrete many proteins, collectively called **adipokines.**[107] Adipose tissue is a source of inflammatory modulators, and increasing evidence indicates that obesity is casually linked to inflammation (Figure 13-13).[108,109]

The adipokine leptin enhances the production of inflammatory factors and tumor necrosis factor-alpha (TNF-α).[85] These inflammatory factors also are modulated by sex hormones (e.g., estradiol and testosterone) and growth factors, especially vascular endothelial growth factor (VEGF). Importantly, increased adiposity is correlated with *lower* levels of adiponectin that normally induces apoptosis, thus increasing cell proliferation.[85] Lower levels of adiponectin also give rise to insulin resistance—a state characterized by the reduced metabolic response of tissues to insulin and to compensatory hyperinsulinemia.

Adipokines have both proinflammatory and anti-inflammatory activities and their balance can contribute to the initiation and progression of obesity-induced metabolic changes that can affect other organs (including the brain, heart, vasculature, liver, and muscle) and increase the risk of cancer, cardiovascular disease, and metabolic disturbances.[107]

Cancers have altered metabolism. Normal tissues use oxidative phosphorylation (OXPHOS) to convert glucose into CO_2 and energy (i.e., ATP). Some cancers use a different approach; they consume large quantities of glucose—*aerobic glycolysis*—to make cellular building blocks **(Warburg effect),** supporting rapid proliferation[110,111] (see Chapter 12). However, this concept has been challenged because some tumors use oxidative phosphorylation.[112] New research reveals that cancer cells can use *oxidative* stress as a "weapon" to extract recycled nutrients from cancer-associated fibroblasts in the stromal tissue. The oxidative stress changes the normal fibroblast cancer-associated fibroblasts (CAFs). This transition seems to cause the aging of the stromal environment, or senescence. Autophagic senescent fibroblasts then produce high-energy nutrients resulting in anabolic tumor growth. This two-compartment tumor metabolism is sometimes called the **Reverse Warburg effect.** It is possible that this simple model of metabolism by the cancer could explain why chronological aging is one of the most important factors for the development of cancer. Emerging data indicate that cellular signaling and metabolism are tightly linked.[111] Several signaling pathways implicated in cell proliferation also regulate metabolic pathways. Signaling pathways activated by hormones and growth factors stimulate the metabolic activity of cells to promote proliferation or differentiation.[111] Metabolism affects key cellular processes by regulating signaling, gene expression, and metabolic processes.[111]

Recent studies reveal a link between glucose availability and protein acetylation, an epigenetic change.[111] Importantly, in the context of constant glucose levels, metabolite levels seem to oscillate in a circadian way within cells and tissues.[111] Food metabolism and circadian cycles are linked and impairment of clock regulation (e.g., disrupted night sleep and light; shift work) results in dysregulated metabolism.[113] **Circadian rhythms** pervade mammalian biology (Figure 13-14). They manifest and permeate temporal organization in behavioral, physiologic, cellular, and neuronal processes.[114] This ancient timekeeper interacts with multiple cell systems, including signaling mechanisms, and the cell cycle, thus impacting disease. Evidence is emerging that circadian mechanisms are linked to cell proliferation and its control at the DNA (epigenetic), RNA, and protein levels. Circadian disruption accelerates malignant growth.[114] In addition to nutrient levels oscillating metabolically, circadian rhythms appear to affect detox cycles.[113,114] Mutations in internal clock genes alter glucose and lipid metabolism and affect the function of the kidney.[115]

Alcohol Consumption. Alcohol is classified by the International Agency for Cancer Research as a human carcinogen. Excessive alcohol plays a contributory role in several common cancers.[65] Overall, there are strong data describing alcohol as a cause of cancers of the mouth, pharynx, larynx, esophagus, liver, colorectum, and breast (Table 13-5).[64,65,116] The evidence does not show any "safe limit" of intake, and the effect is from ethanol regardless of the type of drink.[64]

Animal studies show chronic alcohol intake is associated with reduced genomic DNA methylation in the colon.[117] Alcohol and cancers of the esophagus and liver also involve epigenetic alterations.[118,119] The molecular actions of ethanol are believed to include site-specific changes to histone modifications and alterations of one-carbon metabolism causing methylation changes.[65] MicroRNA expression has recently been linked to alcohol consumption in a case-control study of head and neck cancer (i.e., head and neck squamous cell carcinoma

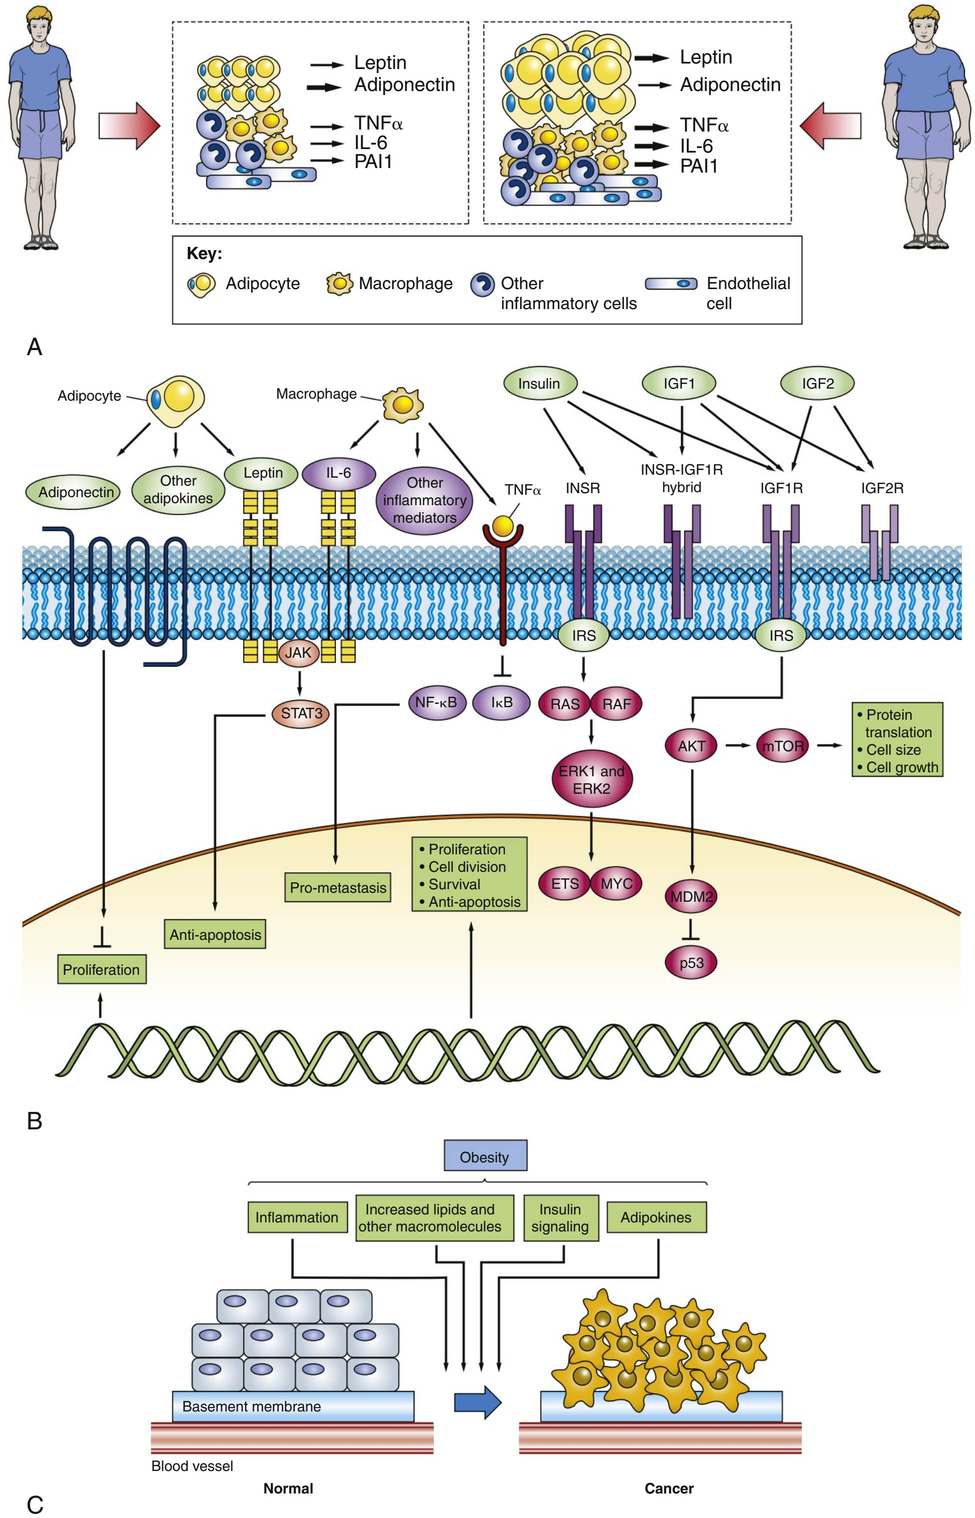

FIGURE 13-13 Adipose Tissue, Obesity, Inflammation, Insulin, and Cancer. **A,** Changes in adipose tissue and obesity. Adipose tissue is composed of adipocytes and stromal-vascular tissue (pre-adipocytes, macrophages, other inflammatory cells, endothelial cells). With obesity there is an increase in the size and number of adipocytes and increases in the inflammatory and vascular compartment (endothelial). **B,** Adipokine and inflammatory signaling in obesity. Overall, adiponectin inhibits proliferation and metastasis. Circulating leptin can bind to the leptin receptor or IL-6 and activate JAK signaling and STAT signaling. STAT3 can function as an oncogenic transcription factor. Inflammatory cells in adipose tissue produce IL-6 and TNFα as well as other cytokines. IL-6 activates JAK-STAT signaling which promotes proliferation and metastasis. TNFα activates NF-κB through the degradation of the inhibitor of κB kinase (IκB). NF-κB is now free to translocate to the nucleus where it inhibits apoptosis and promotes proliferation and metastasis. Obesity increases circulating insulin and possibly IGF-1 and IGF-2. Binding of insulin, IGF-1 and IGF-2 results in phosphorylation of IRS proteins that can activate downstream signaling, such as ERK pathways. The oncogenic pathways MYC (oncogene) and ETS (oncogene) are activated by ERK. Activation of PI3K pathways causes AKT (serine/threonine protein kinase) phosphorylation and mTOR activation promoting protein synthesis and cell growth. AKT also activates MDM2 that degrades p53 preventing cell cycle checkpoints and apoptosis. **C,** A summary of increased inflammation, increased availability of lipids and other macromolecules, insulin, and changes in adipokine signaling may contribute to the conversion of normal epithelial cells to an invasive tumor. *ERK,* extracellular signal-regulated kinase; *IGF,* insulin-like growth factor; *IL-6,* interleukin-6; *IRS,* insulin receptor substrate; *JAK,* Janus tyrosine kinase; *mTOR,* mammalian target of rapamycin; *MDM2,* mouse double minute2 homolog; mammalian target of rapamycin; *NF-κB,* nuclear factor κB; *PAI1,* plasminogen activator inhibitor-1; *PI3K,* phosphoinositide 3-kinase; *STAT,* activator of transcription signaling; *TNFα,* tumor necrosis factor alpha. TABLE 13-5 ALCOHOLIC DRINKS AND RISK OF CANCER*

	DECREASES RISK		INCREASES RISK	
	EXPOSURE	CANCER SITE	EXPOSURE	CANCER SITE
Convincing			Alcoholic drinks	Mouth, pharynx and larynx, esophagus Colorectum (men)† Breast (pre- and postmenopause)
Probable			Alcoholic drinks	Liver‡ Colorectum (women)†
Limited—suggestive				
Substantial effect on risk unlikely	Alcoholic drinks (adverse effect): kidney§			

Adapted from World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR): *Second expert report: food, nutrition, physical activity, and the prevention of cancer: a global perspective,* London, 2007, Author.
*In the judgment of the Panel (WCRF/AICR), the factors listed modify the risk of cancer. Judgments are graded according to the strength of the evidence.
†The judgments for men and women are different because there are fewer data for women. Increased risk is only apparent above a threshold of 30 g/day of ethanol for both genders.
‡Cirrhosis is an essential precursor of liver cancer caused by alcohol. The International Agency for Research on Cancer has graded alcohol as a class 1 carcinogen for liver cancer. Alcohol alone only causes cirrhosis in the presence of other factors.
§The evidence was sufficient to judge that alcoholic drinks are unlikely to have an adverse effect on the risk of kidney cancer; it was inadequate to draw a conclusion regarding the protective effect.

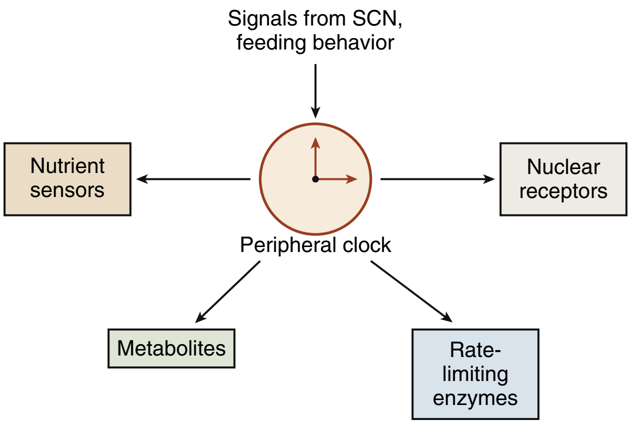

FIGURE 13-14 Regulation of Metabolism by the Circadian Clock. Peripheral clocks, such as that in the liver, are regulated by the master clock present in the suprachiasmatic nucleus *(SCN).* The liver clock can regulate multiple metabolic pathways by various mechanisms. These mechanisms include regulation of rate-limiting steps, control of metabolite levels, interaction of nutrient sensors, and modulation of nuclear sensors. (Adapted from Sahar S, Sassone-Corsi P: *Trends Endocrinol Metab* 23[1]:1–8, 2011.)

TABLE 13-6 PHYSICAL ACTIVITY AND RISK OF CANCER*,†

	DECREASES RISK	INCREASES RISK
Convincing	Colon‡	
Probable	Breast (postmenopausal) Endometrium	
Limited—suggestive	Lung Pancreas Breast (premenopausal)	
Substantial effect on risk unlikely	None identified

*In the judgment of the Panel (WCRF/AICR), physical activity† modifies the risk of the cancers. Judgments are graded according to the strength of the evidence.
†Physical activity of all types: occupational, household, transport, and recreational.
‡Much of the evidence grouped colon cancer and rectal cancer is together categorized as "colorectal cancer." The Panel judges that the evidence is stronger for colon cancer than for rectal cancer.

[HNSCC]).[120] The risk may be modified by alcohol dehydrogenase genes.[121] Alcohol is now an established risk factor for breast cancer in women and has been linked to genome-wide leukocyte DNA hypomethylation.[122] Alcohol interacts with smoke, increasing the risk of malignant tumors, possibly by acting as a solvent for the carcinogenic chemicals in smoke products.

Other mechanisms involved in alcohol-related carcinogenesis include the effect of acetaldehyde, the first metabolite of ethanol oxidation; the induction of cytochrome P-450 2E1 (genetic variant CYP2E1) leading to the generation of reactive oxygen species (ROS); the development of increased procarcinogen activation (e.g., nitrosamines) and the modulation of cellular regeneration (cell cycle); and the manifestation of nutritional deficiencies (e.g., retinol, retinyl esters, folic acid, other vitamins). Nutritional deficiencies may result in altered mucosal integrity, enzyme and metabolic dysfunction, and other structural abnormalities.

Physical Activity. Studies suggest that regular exercise decreases the risk of breast cancer, colon cancer, and endometrial cancer, independent of weight changes. The World Cancer Research Fund summarized the effects as *convincing* for cancers of the colon and *probable* for postmenopausal breast cancer and endometrial cancer[64] (Table 13-6).

The effect of physical activity on the risk of rectal cancer is much less certain,[87,123] and one study shows an inverse

TABLE 13-7 NUMBER OF NEW CANCER CASES* IN 2008 ATTRIBUTABLE TO INFECTION, BY INFECTIOUS AGENT, AND DEVELOPMENT STATUS†

	LESS DEVELOPED REGIONS	MORE DEVELOPED REGIONS	WORLD

*Numbers are rounded to two significant digits.
†Data are number of new cancer cases attributed to a particular infectious agent (proportion of the total number of new cases attributed to infection that is attributable to a specific agent).

relationship.[124] Evidence of a reduction in breast cancer risk in postmenopausal women was associated with higher levels of activity (dose-response effect).[64,125] A recent meta-analysis concluded that physical activity seems to be related to a reduction in the risk of endometrial cancer independent of body weight.[126] Several biologic mechanisms suggest physical activity may protect against cancers of the breast and endometrium, by decreasing insulin and IGF levels, decreasing obesity, altering inflammatory mediators, decreasing levels of circulating sex hormones and metabolic hormones, improving immune function, and enhancing cytochrome P-450 activity, thus modifying carcinogen activation.[64,127-130] For colon cancer, physical activity increases gut motility, which reduces the length of transit time that the bowel lining is exposed to potential mutagens.[129] Other mechanisms of protection may include a reduction in insulin resistance, reduced body fatness, and changes in steroid hormone metabolism.[64] A randomized trial found that after 12 months of moderate-intensity exercise, postmenopausal women had significantly decreased levels of serum estrogens.[131] Physical activity also helps prevent type 2 diabetes, which has been associated with risk of cancer of the colon and pancreas.[129,132] However, evidence that physical activity protects against pancreatic cancer is limited.

Many questions are unanswered regarding frequency, intensity, and duration of exercise. Much of the literature suggests that between 3.5 and 4 hours of vigorous activity per week are necessary to optimize protection for colon cancer.[130] There is likely a dose-response relationship for colon cancer and breast cancer, and 30 to 60 minutes per day of moderate to vigorous intensity is proposed to decrease breast cancer risk.[133] A recent 12-month randomly controlled trial supported the Institute of Medicine and Department of Agriculture guidelines of 60 minutes per day of moderate to vigorous physical activity for decreasing weight, BMI, and amounts of body fat and intra-abdominal fat.[134] Several reports suggest that physical activity after a cancer diagnosis is associated with better cancer-specific sequelae and improved overall survival time with early-stage breast, prostate, and colorectal cancers.[85] Further research is needed on cancer outcomes and physical activity.

Infection, Sexual and Reproductive Behavior, Human Papillomaviruses

Infection is an important contributor to cancer worldwide and the population attributable fraction (PAF) indicated that 16.1% of cancers diagnosed in 2008 were caused by infection, or about 2 million new cases.[135] Infection and cancer rates vary widely by region: with a 7.4% rate for more developed regions and a 22.9% rate for less developed regions.[135] The highest PAF is for sub-Saharan Africa with a rate of 32.7%. Agents classified by the IARC were used in this report because the strength of published evidence is controversial.[135] The four top notable infections and new cancer cases include human papillomavirus (HPV), *Helicobacter pylori (H. pylori)*, hepatitis B virus (HBV), and hepatitis C virus (HCV) (Table 13-7). According to the investigators these results probably are conservative and underestimate the true burden of infection-associated cancers.[135] Most of the following discussion will be about human papillomavirus (HPV); however, hepatitis B and hepatitis C can infect the liver and together account for the large majority of liver cancer cases (see Chapter 41). It has been estimated that *H. pylori* accounts for about 75% of all stomach cancers.[136] Epstein-Barr virus (EBV) is linked to cancers of the nasopharynx, Hodgkin disease, and non-Hodgkin lymphoma. Human herpesvirus type 8 is linked to Kaposi sarcoma and human T-cell lymphotropic virus type 1 is linked to leukemia and lymphoma.

Human papillomavirus (HPV) is the most common sexually transmitted virus in the United States. At least 50% of sexually active people will have genital HPV at some time in their lives.[137] HPVs are a group of more than 150 related viruses. More than 40 of these viruses can easily spread from direct skin contact or through vaginal, rectal, or oral sex.[138] *Low-risk HPVs* do not cause cancer but can cause skin warts, called condylomata acuminata. *High-risk*, or oncogenic, *HPVs* can cause cancer. Even though about a dozen HPVs are identified, HPV types 16 and 18 are responsible for the majority of cancers.[138] However, most high-risk HPV infections may cause cytologic abnormalities or abnormal cell changes that disappear unexpectedly. Persistence of infection with high-risk HPV is a prerequisite for the development of cervical intraepithelial neoplasia (CIN) (see

Figure 24-19), lesions, and invasive cervical cancers.[139] Almost all cervical cancers are caused by HPV infections, with HPV types 16 and 18 responsible for about 70% of all cases.[140,141] HPV can cause anal cancer, with about 85% of all cases caused by HPV-16.[138] HPV types 16 and 18 also have been found to be responsible for almost half of vaginal, vulvar, and penile cancers.[142] Recently, HPV infections have been found to cause cancer of the oropharynx (soft palate, base of the tongue, tonsils).[138] More than half of the oropharyngeal cancers diagnosed in the United States are linked to HPV-16.[143] The incidence of HPV-associated oropharyngeal cancer has increased during the past 20 years, especially among men, and it has been estimated that by 2020 HPV will cause more oropharyngeal cancers than cervical cancers in the United States.[144] Factors that may increase the risk of developing cancer following a high-risk HPV infection include smoking, decreased immunity, having many children (for increased risk of cervical cancer), long-term oral contraceptive use (for increased risk of cervical cancer), poor oral hygiene (for increased risk of oropharyngeal cancer), and chronic inflammation.[141]

HPVs infect epithelial cells that cover the inside and outside surfaces of the body, including the skin, throat, genital tract, and anus. Because HPVs are not thought to enter the bloodstream, having an HPV infection in one part of the body should not cause an infection in another part of the body.[138] Once an HPV virus enters an epithelial cell, the virus begins to make proteins that can interfere with normal functions in the cell, enabling the cell to grow in an uncontrolled manner, and to avoid apoptosis.[138] These infected cells are often recognized by the immune system and eliminated. Sometimes, however, infected cells are not destroyed and a persistent infection results. As the persistently infected cells continue to grow, they may develop mutations that promote even more cell growth, leading to the formation of a high-grade lesion and, ultimately, a tumor.[138] Investigators believe that it can take between 10 and 20 years from the time of an initial HPV infection until tumor formation. However, even high-grade lesions do not always lead to cancer.[138]

Other Viruses and Microorganisms

A discussion of the relationship between viruses, bacteria, and cancer is contained in Chapter 12 and appropriate chapters in Unit II. Other microorganisms involved in carcinogenesis include parasites such as *Opisthorchis viverrini* and *Schistosoma haematobium*. Their specific roles in carcinogenesis are thought to be related to cofactors or carcinogens, or both.

Ionizing Radiation

Much of the knowledge of the effects of ionizing radiation (IR) on human cancer has stemmed from observations of the Hiroshima and Nagasaki atomic bomb (A-bomb) exposures, particularly the Life Span Study. These data provide estimates of human cancer risk over the dose range from 20 to 250 centigray (cGy) for low linear energy transfer (LET) radiation, such as x-rays or γ-rays. Other evidence is derived from groups exposed for medical reasons, underground miners exposed to radon gas, and other occupational exposures (Table 13-8). The atomic

bomb exposures in Japan caused acute leukemias in adults and children and increased frequencies of thyroid and breast carcinomas. Lung, stomach, colon, esophageal, and urinary tract cancers and multiple myeloma have been added to the list. At Nagasaki and Hiroshima, leukemia incidence in individuals 15 years or younger reached its peak 6 to 7 years after the explosions and has steadily declined since 1952. People 45 years and older at the time of exposure had a latent period of 20 years before developing acute leukemia.

Recently, standard models and evaluations of age of exposure to radiation and radiation-induced cancer risks have been questioned.[145-148] Epidemiologic data from Japanese atomic bomb survivors and from children exposed to radiation for medical intervention suggest that excess relative risks (ERRs) for radiation-induced cancers at a given age are exceptionally higher for individuals exposed during childhood than for those exposed at older ages.[149] These data also are published by the International Commission on Radiological Protection (ICRP) and the National Academy of Sciences Committee on the Biological Effects of Ionizing Radiation (BEIR Committee).[150] What is at question is the ERRs of radiation exposure in adulthood and radiation-induced cancer risk. Recent analyses of Japanese bomb survivors suggest that the ERR for cancer induction decreases with increasing age at exposure only until exposure ages of 30 to 40 years; with radiation exposure at older ages, the ERR does not decrease further and for many individual cancer sites (liver, colon, lung, stomach, and bladder) the ERR may actually increase in all solid cancers combined.[146,148,149,151] These new data present a challenge to our conceptual understanding of the mechanisms of cancer induction.[148] Biologic models of cancer development all predict that ERRs should decrease continuously with increasing age of radiation exposure. Recent models, however, of radiation carcinogenesis show IR acts not only as an initiator of premalignant cell clones but also

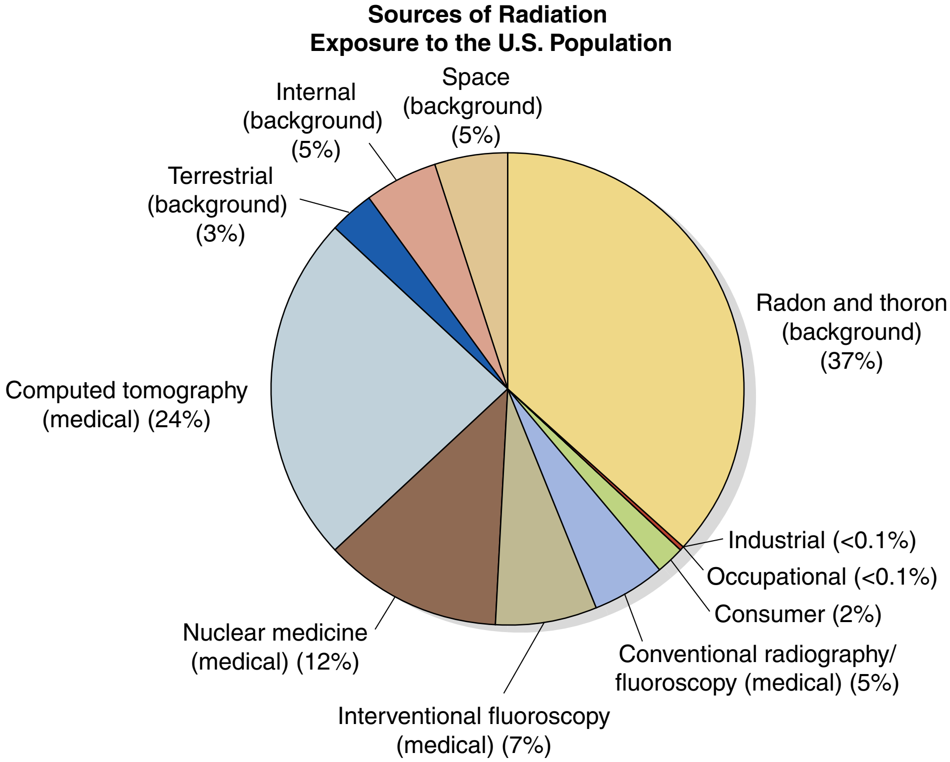

FIGURE 13-15 **Pie Chart Showing Sources of Exposure to Ionizing Radiation.** Percent contribution of various sources of exposure to the total collective effective dose (1,870,000 person-Sv) and the total effective dose per individual in the U.S. population (6.2 mSv) for 2006. Percent values have been rounded to the nearest 1%, except those <1%. *Sv,* Sievert. (From NCRP: *2009 Ionizing radiation exposure of the population of the United States,* NCRP Report No. 160, Bethesda, Md, Author.)

as a promoter of preexisting premalignant cell alterations.[146,148,151] Promotion is used here to mean the process by which an initiated cell clonally expands. Therefore promotional processes from radiation can result in increasing excess lifetime cancer risks with increasing age at exposure. From these new data investigators propose that radiation-induced cancer risks after exposure in middle age may be almost twice as high as previously estimated.[148]

Human exposure to IR includes emissions from x-rays, radioisotopes, and other radioactive sources (Figure 13-15). Health risks involve not only neoplastic diseases but also cardiovascular disease and stroke following high doses in therapeutic medicine and lower doses in A-bomb survivors (BEIR VII).[152,153] Late effects of radiation in A-bomb survivors show persistent elevations in the levels of inflammatory markers, implying immunologic damage may be the cause of later cardiovascular effects.[154] Investigators for the first time using a model of umbilical vein endothelial cells showed that low doses (0.05 Gy) of x-rays induce DNA damage and apoptosis in endothelial cells. These data will need continued research.[154a] Cardiac and blood vessel damage may manifest years after completion of radiation therapy.[155] Other risks include somatic mutations that may contribute to other diseases (e.g., respiratory diseases, birth defects, and eye maladies) and, from animal studies, inherited mutations that may affect the incidence of diseases in future generations. An important summary point in BEIR VII[152] is the concern from medical exposure, for example, computed tomography (CT) (see What's New? CT Scans and Issues). In 2009 the National Council on Radiation Protection and Measurements[156] reported Americans were exposed to more than seven times as much IR from medical procedures compared to the 1980s (Figure 13-16). In Europe, 20 millisieverts (mSv) is the annual allowable occupational exposure of radiation, and in the United States the annual allowable occupational exposure is 50 mSv.[157] The increase in imaging is likely driven by several factors, including improvements in the technology, that have led to increased clinical applications, patient demand, physician demand, defensive medical practices, and medical uncertainty.[158,159]

Evidence, usually epidemiologic, shows cancer associated with exposure to IR (see Table 13-8). Evidence includes animal models and in vitro studies as well as exposed groups including atomic/nuclear survivors, survivors of industrial accidents and the Techa River basin in Siberia, and medical diagnostic/therapeutic data. The studies of exposed groups are large enough to allow epidemiologists to derive detail concerning the dose and quality, age at exposure, and other factors on cancer incidence in a large variety of organs.[160] From data collected over several decades, exposed cohorts reveal that IR is a potent carcinogen.[160] Additionally, reports of occupational exposures may have increased the incidence of certain types of cancer, for example, underground miners and lung cancer.[161] Certain medical conditions, especially those with a genetic basis, predispose individuals to ionizing radiation–induced injury.[160] The most well-known condition is ataxia-telangiectasia (AT), a rare (1 in 300,000 people) condition in which individuals have a strong sensitivity to IR. Additionally, individuals with *BRCA1/BRCA2* pathway mutations have increased radiosensitivity caused by insufficient DNA repair and cell cycle control mechanisms.[162]

WHAT'S NEW?

CT Scans and Issues

Radiation: General Issues

- Many uncertainties exist about low-dose radiation and harmless and harmful effects.
- Currently, almost all of the available epidemiologic data are generated from people exposed to background radiation, such as the Japanese survivors of the atomic bombs.
- Biologic data, especially for low-dose radiation, are insufficient for understanding both harmless and harmful effects.
- The effects of low-dose radiation (LDR) are mainly based on the linear non-threshold (LNT) hypothesis and include the following *overestimated effects*[1]:
  1. No injurious effects are detected at a dose less than 100 mSv for adults and less than 50 mSv for children.
  2. Exposure to LDR has adaptive and hormesis protective effects.
  3. The progression of carcinogenesis is not linear.
  4. Cancer may not develop until there is accumulated genetic damage.
- The LNT hypothesis includes the following *underestimated effects:*
  1. The bystander effect and associated chromosomal effects have not been fully studied.
  2. Amplification of damaged chromosomes could lead to genomic instability.
  3. Some people are hypersensitive to radiation.
- Carcinogenesis is considered the most serious consequence of LDR and it affects other tissues, for example, blood vessels.[2-4]
- The hereditary effect is the variation of damage that could occur in germ cells. Recent epidemiologic studies showed no direct connection between LDR and the hereditary effect.[3] The ICRP estimated the hereditary effect as 0.2%/Sv. Biologic studies are needed.
- Approximately 5% to 10% of individuals are hypersensitive to radiation, for example, those with the ataxia-telangiectasia mutated *(ATM)* gene. *ATM* plays a major role in the response to ionizing radiation.[5]
- The accumulative effects of LDR from repeated CT scans may lead to buildup of radiation doses.[6]
- The proportion of annual CT scans in some developed countries increased from 6.1% (1970-1979) to 48% (1991-1996). In the last 25 years, usage of CT has increased 12 times in the United Kingdom and more than 20 times in the United States.[7]
- Calculations from nuclear industry personnel of 15 different countries are in the range of low-dose radiation and CT. About 0.6% and 1.5% of the cumulative cancer risk could be attributed to diagnostic x-rays in England and Germany, respectively. About 3.2% of new cancer cases in Japan are considered the result of two examinations every year. It is estimated that about 29,000 cancers could be related to CT scans in the United States every year; scans of the abdomen and pelvis are the most common.[8,13] Other estimates indicate that CT scan–induced cancer risk is about 0.7%,[9] CT angiography risk is about 0.13%,[10] and CT colonoscopy cancer risk is 0.15%.[11,12] The carcinogenic risk of low doses and low dose rates of radiation from CT is estimated at 5%/Sv.[1] The mathematical extrapolation of LNT to LDR may not be accurate because of the biology of LDR.
- CT scans can save lives, improve diagnostic accuracy, limit medical procedures, and save healthcare dollars.
- Researchers report that certain CT scans are unnecessary and a survey revealed that about 77% of lumbar spine, 36% of head, 37% of abdomen, 20% of nasal sinuses, and 3% of cervical spine CT scans should have been MRI scans instead.[1]
- It is probable that at least 25% of CT scans are not clinically warranted.

Biology and CT Radiation

- Radiation from CT scans can activate antioxidants, such as superoxide dismutase (SOD), DNA repair mechanisms, and the immune system, to recognize mutated cells.[14]
- Repeated CT scanning can alter the balance between antioxidant and oxidant systems and increase the number of ROS.
- ROS can lead to DNA single- and double-strand breaks, DNA interstrand cross-linking, and eventually the formation of apurinic and apyrimidinic sites.[15]
- A quantitative marker of LDR-induced double-strand breaks is a member of the histone H2A family, H2AX, which becomes phosphorylated within 1 to 3 minutes of DNA damage and forms foci at the break sites.[16,17]
- Continuous DNA damage can lead to chromosomal aberration, chromosomal damage in cell progeny, and elevated levels of γ-H2AX. Such alterations might lead to genomic instability and currently there are reported increases in the number of cases of non-Hodgkin lymphoma and breast cancer.[18-20]
- With the increase in multi-slice CT (MSCT), the radiation dose is gradually increasing. The 64-slice CT to do heart scanning included exposures of other tissues: heart, 32.4 mSv; breast, 39.1 mSv; lung, 33.2 mSv; and spinal cord, 29.8 mSv.[21,22]
- Organ doses relevant to most CT usage are between 5 and 100 mSV; the exposure is a very small but well-established individual cancer risk, particularly for patients without significantly reduced life expectancy.[23-26]
- Epigenetics including DNA methylation and miRNA expression could be especially helpful in understanding the biology of radiation-induced genomic instability (RIGI).

Children

- About 600,000 children under the age of 15 have abdominal and head CT scans in the United States every year, and it is estimated that about 500 children might eventually die from CT-induced cancer.[5]
- Children are more sensitive to radiation and their carcinogenic risks are about 4 times those of an adults' risk (a 1-year-old infant is 10 to 15 times more prone to develop cancer than an adult).[27]
- CT-induced cancer risks were 3% (10 years old) and 2% (15 years old) in children who received abdominal and pelvic CT scans for renal calculi detection.[28]
- German investigators have planned to conduct a historic cohort study to investigate cancer incidence from CT exposure in children younger than age 15.[29]

Confusion for Healthcare Providers and Patients

- Surveys are being done to understand the radiation knowledge of patients and healthcare workers.
- A survey reported more than 70% of patients underestimated the radiation dose from CT scans and had very limited understanding of radiation-induced cancer risks.[30]
- Another survey revealed about 7% of patients were informed about the benefits and risks before having a CT scan and 53% of radiologists and 91% of emergency department physicians believed CT scans would not increase cancer risks.[31]
- About 43% of hospital imaging departments made technologic adjustments for pediatric patients.[32]
- About 33% of CT imaging departments indicated they had adjusted the tube current down to less than 100 milliamperes (mA) when they performed helical CT scans of the chest on 4-year-old children.[33]
- A German study revealed physicians overestimated the radiation exposure from conventional x-rays but underestimated the exposures from CT scans.[34]

FIGURE 13-16 CT Scans in the United States. NCRP estimates that 67 million CT scans (compared to 3 million in 1980), 18 million nuclear medicine procedures, and 17 million interventional fluoroscopy procedures were performed in the United States in 2006. (From NCRP: *2009 Ionizing radiation exposure of the population of the United States,* NCRP Report No. 160, Bethesda, Md, Author.)

Studies conducted jointly by the U.S. Air Force and NASA from 1963 to 1969 studied the relative biologic effectiveness (RBE) of different types of radiation exposures on rhesus monkeys and mice.[160] Long-term follow-up studies of the exposed animals showed an induction of solid tumors and leukemia and the extent of life-shortening depended on dose and not on proton energy level.[163] The general characteristics of radiation carcinogenesis were determined from studies done after World War II, mainly from rats and mice.[160] However, together with epidemiologic studies of humans, these animal studies elucidated radiation carcinogenesis.[164,165] The BEIR VII report that focused on low-level radiation determined that the radiation-induced life shortening observed in mice is reflective in humans of radiation-induced cancer mortality.[166] These studies are important because they show that IR is universally carcinogenic to animals and humans and that there are wide differences in radiation responses according to species, organ, and radiation distribution.[160]

The universal nature of radiation as a carcinogen relates to its ability to penetrate cells and deposit energy in tissues at random. By the 1980s, using in vitro models, the *general* characteristics of IR-induced carcinogenesis were well established.[167] The past two decades have focused on *specific* cellular and molecular mechanisms that relate to the induction of cancer, including dose-response relationships for chromosome aberrations, cell transformation, gene expression (genetic and epigenetic), alternative targets, mutagenesis in somatic cells, and the biologic effects that occur in nonirradiated cells (i.e., **nontargeted effects**) and effects on the microenvironment.[160] Through much of the twentieth century, radiobiology was thought to be a relatively simple science and was dominated by physicists. Now, with biologists entering the field, it has become apparent that radiobiology is not so simple and involves much more understanding beyond a DNA-centric model, including alternative targets, such as membranes, repair, and rescue within a biologic system.[168] Because models and underlying assumptions are incomplete, investigators are working hard to understand induced repair, adaptive responses, hormesis, low-dose hypersensitivity,

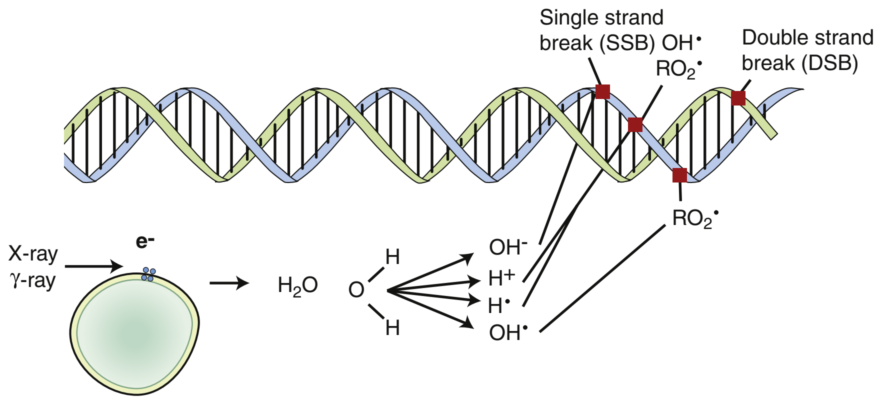

FIGURE 13-17 **Free Radicals.** Free radicals formed by water nearby and around DNA cause indirect effects. These effects have a short life of single free radicals. Oxygen can modify the reaction, enabling longer lifetimes of oxidative free radicals.

nontargeted effects, signaling, exosomes, and long-term persistence of radiation damage and clonal heterogeneity.[168]

Oncogenes and Tumor-Suppressor Genes

Part of the biologic response of radiation-induced cancer is oncogene activation. Although evidence suggests that interindividual differences in radiation responses may be attributed to certain genes, IR can activate oncogenes, resulting in uncontrolled cell growth[160] (see Chapter 12). **Tumor-suppressor genes** also are sensitive to IR. Several tumor-suppressor genes have been identified that are deactivated by IR that promotes carcinogenesis.[160] Recent research has shown that cells can detect and respond epigenetically, altering gene expression after low doses of radiation.[160] Gene expression can change as a function of radiation dose and radiation type.[160]

Chromosomal Aberrations

IR is a mutagen and carcinogen; it can penetrate cells and tissues and deposit energy in tissues at random in the form of ionizations (e.g., removal of an electron from the target atom). Importantly, arising from IR is the localized release of large amounts of energy that can break a chemical bond (electron volts [eV] is the energy per ionizing event). Damage from IR can occur either *directly* from biologic macromolecules (e.g., DNA) or *indirectly,* in the medium from which organelles are suspended in mostly water, and *irreversibly* from ionizations that can attack by water-based free radicals (e.g., H•, OH•) (radiolysis).[169] Electromagnetic radiations, such as x-rays and γ-rays, damage by reactive species produced by ionizations elsewhere in the cell and thus have indirect action. The biologic effects of indirect action include cell killing (days), mutation (generation), and carcinogenesis (years). IR affects many cell processes, including gene expression, mitochondrial function disruption, cell cycle arrest, and cell death. IR is a potent DNA-damaging agent, causing cross-linking, nucleotide base damage, and single (SSBs)- and double-strand breaks (DSBs) (Figure 13-17). Damage to DNA and disrupted cellular regulation processes can lead to carcinogenesis.[170-172] The **double-strand break (DSB)** is considered the important lesion in the induction of both chromosomal abnormalities and gene mutations. Repair of radiation-induced DNA double-strand breaks in human fibroblasts is consistent with a continuous spectrum of repair probability[173-175] (Figure 13-18). The misrepair of DSBs could lead to substantial chromosomal instability.[176] Importantly, DSBs are probably repaired by the nonhomologous end-joining (NHEJ) pathway.[150] Another pathway is by homologous recombination (HR); for example, *BRCA1* and *BRCA2* are tumor-suppressor genes and one of their functions is DNA repair by HR.[177,178] These two mechanisms of DSB repair act at different phases of the cell cycle. Irradiated human cells unable to execute the NHEJ pathway are supersensitive to the introduction of large-scale mutations and chromosomal aberrations.[169]

Cell Transformation

Cell transformation describes the total changes associated with loss of normal homeostatic control.[160] The majority of studies on cell transformation in vitro have been quantitative, using rodent-derived models. Few human-derived assays have been conducted. Overall, the exposure to high-LET radiation results in a higher transformation frequency than exposure to low-LET radiation.[160] There is no tendency, however, for the response per unit dose to decrease at low doses or low dose rates, and a number of studies have shown an enhanced effect.[160]

Nontargeted Effects

A long-held assumption is that cellular alterations—mutations and malignant transformation—occur only in cells directly radiated. There is clear evidence indicating that cells not directly traversed by a radiation particle, but in the vicinity of a cell that has been exposed to or received signals from irradiated cells, can participate in the damage response.[179] The **DNA damage response (DDR)** is a coordinated series of events that allows DNA damage detection, signaling that includes cell cycle checkpoint activation, and repair.[180,181] Emerging and important data indicate that the DDR should be considered not only at the DNA level but also in the chromatin of cell nuclei where DNA envelopes histone proteins.[182] Additionally, the importance of the plasticity of the microenvironment is becoming integrated into the radiation response.

It is now known that cells not directly exposed to radiation, but instead the progeny of cells that were irradiated many cell divisions previously, may express a high level of gene

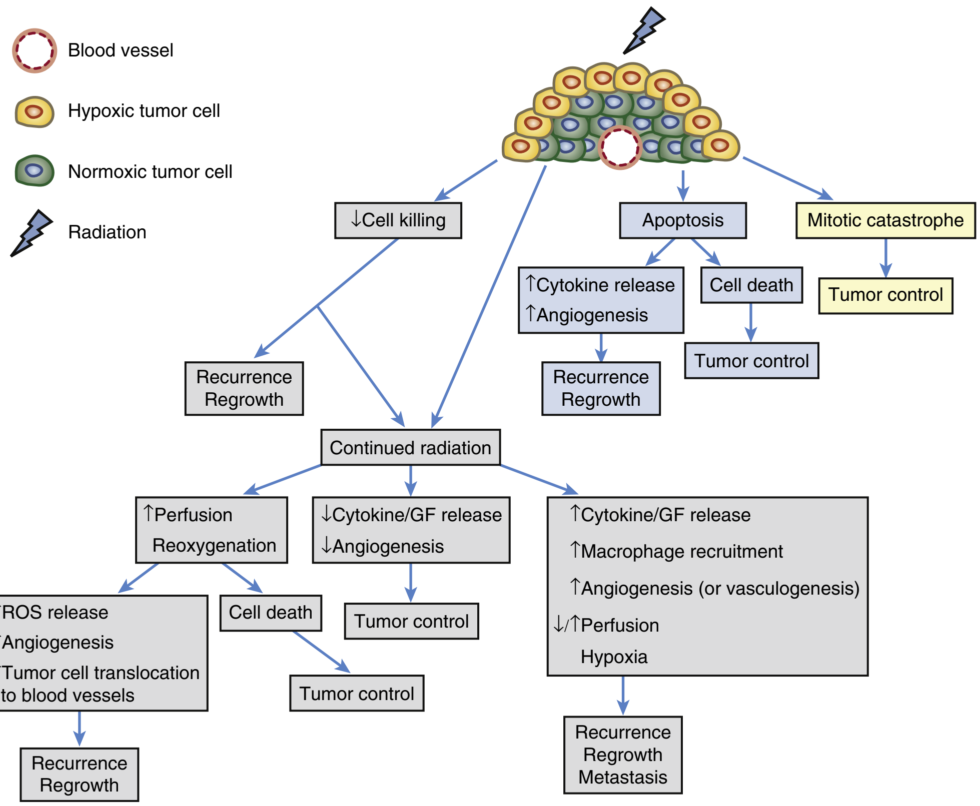

FIGURE 13-18 Simplified Model of the Effects of Radiation on Tumor Microenvironment. Tumor cells that are not hypoxic cells (i.e., called normoxic) are more sensitive to radiation and hence more susceptible to cell death (apoptosis) and mitotic catastrophe or destruction. In some cases, however, pro-apoptotic mechanisms can cause the release of cytokines that promote tumor regrowth and recurrence. Hypoxic cells are resistant to radiation therapy and more likely lead to tumor recurrence. Continuous radiation (especially fractionated) can lead to reoxygenation, which can improve radiation-induced cell killing or promote release of reactive oxygen species (ROS) and angiogenesis and/or induce tumor cell movement to blood vessels; both mechanisms can result in tumor regrowth and recurrence. Decreased cytokine production and destruction of blood vessels from continued administration of high doses of radiation can increase tumor cell killing. In certain situations, however, irradiation is associated with the production of an aggressive phenotype of the remaining cells that survive radiation therapy. This failure is caused by the release of protective cytokines and/or growth factors (GF), recruitment of macrophages, altered perfusion of blood, and hypoxia that increase angiogenesis or blood vessel growth, resulting in tumor regrowth and recurrence and/or metastasis. Importantly, the effects of radiation on tumor microenvironment depend on many factors. (Adapted from Fokas E, McKenna WG, Muschel RJ: The impact of tumor microenvironment on cancer treatment and its modulation by direct and indirect antivascular strategies, *Cancer Metastasis Rev* 31(3-4):823–842, 2012. [Epub ahead of print.])

mutations, cell lethality, and chromosomal aberration. Altogether these effects are called **genomic instability.** Effects in the distant progeny are also called transgeneration inheritance or effects (see p. 410). The directly irradiated cells also can lead to genetic effects in so-called bystander cells or innocent cells (called **bystander effects**) even though they themselves received no direct radiation exposure.[179] The bystander effect has been demonstrated in three-dimensional human tissues[183] and recently in whole animal organisms.[184] Signaling communication is thought to occur from direct physical connection between cells or gap junctions, called gap junctional intercellular communication (GJIC). Other mechanisms, however, may be involved. Numerous intercellular and intracellular signaling pathways are implicated in the bystander response and these effects have been shown to be transmitted to their descendents. The bystander and genomic instability effects also have been termed nontargeted effects.

Acute, Latent, and Microenvironmental Effects

IR causes acute and persistent short- and long-term effects.[185-188] Acute exposure to IR can cause damage to several organ systems, especially those with highly proliferative cells such as the hematopoietic system, the skin, and the gastrointestinal system[189] (see Chapter 2). Investigators have postulated that radiation's carcinogenic potential persists because of nontargeted radiation effects that alter cell and tissue signaling and change the microenvironment.[190,191] Figure 13-18 provides a simplified model of the effects of radiation on tumor microenvironment. With improvement in cancer survival the long-term risks of a second cancer from treatment become more important.[192]

Radiation-induced cancer in humans has latent periods, usually 5 to 10 years but can be decades.[160,193] British investigators reported the following results: for solid cancers, radiation-related excess risk starts to appear about 5 years after exposure in therapeutically irradiated groups, and for leukemia, it starts

to appear within 5 years of exposure.[194] Using U.S. Surveillance Epidemiology and End Results (SEER) data, the estimated excess of second cancers that could be related to radiotherapy is about 8%; data from the United Kingdom, which included diagnostic procedures and excluded therapeutic irradiation, yielded an estimation of 15%.[192,194]

Low Dose and Dose Rate

New studies on low doses of radiation have resulted in three paradigm shifts: (1) bystander effects have been observed in which nonhit cells may respond as well as hit cells; (2) radiation-induced changes in gene expression at very low radiation doses alter response pathways, some of which appear to involve adaptive or protective responses; and (3) early changes in the initiation phase of radiation-induced cancer were thought to be induced by gene mutation and chromosomal aberrations only; however, it is now understood that genomic instability that leads to the loss of genetic control appears to have a major role in the development of cancer.[195] Constant debate involves risk estimates for human exposure at low-dose, low-LET ionizing radiation (0 to 100 mSv or less than 0.1 Gy). Accurate measurements of risks from low doses and low dose rates of radiation are statistically difficult because they require such large populations that theoretic models are used to estimate response curves (Box 13-1).

BOX 13-1 THEORETIC MODELS TO UNDERSTAND LOW-DOSE RADIATION

Several models include the linear no-threshold (LNT) relationship, in which any dose, including very low doses, has the potential to cause mutations (see **A**). Another model, the linear-quadratic relationship, proposes there is a risk mathematical term that is directly proportional to the dose (linear term) and another term proportional to the square of the dose (quadratic term) (see **B**). The threshold model proposes a threshold dose below which radiation may not cause cancer in humans (see **C**). Proponents of this model argue that such thresholds are derived, for example, from the ability to repair damage caused by lower doses of radiation. There is some evidence that low doses may actually produce a higher level of risk per unit of dose, which is called the supralinear hypothesis (see **D**). **E,** Stochastic or random probability is a major model for understanding low-dose radiation. Currently, the shape of the response curve for the low-dose region is really unknown.
